To

RICHARD LIGHTBURN SUTTON

who dedicated the first eight editions of his book and the ninth and tenth editions of our book to his mother Virginia Robertson Sutton

and

LENA IGEL SUTTON

my mother

IN LOVING MEMORY

and to

SERENA NEEL SUTTON

PREFACE TO ELEVENTH EDITION

Diseases of the Skin has been modernized to accord with medical literature through the date of closing the galley proof. It is comprehensive yet condensed. It aims primarily at usefulness. The illustrations, 1,972 in number are an atlas wherein all ordinary and many extraordinary dermatoses may be identified. The book includes features of a dictionary and an encyclopedia. It is a guide to the maze of what may be found, if one knows where to look, in an extensive medical library It is a systematization of what is known about its subject written from the viewpoint of a practicing physician who is inquisitive

The scholar will find the volume comprehensive I wrote in the preface of our *Handbook of Diseases of the Skin* in 1949 for I have held to the policy of at least mentioning almost everything and have included many thousands of bibliographic entries which enable one to find one s way about in the specialistic literature These may be welcome even to the dermatologist certified as learned, whose memory however disciplined, is unlikely to bear the burden of retaining everything at all times. Reviews of previous books of ours have received earnest deliberation and the constructive criticisms have been adopted where they have not conflicted wi h the necessarily limited size of the book, or with each other or with my desires.

The order of presentation here as in the *Handbook* uses causation as the principal guide to classification, in the hope that it will appear logical to nondermatologists who have tended with justification to think of dermatology as having possessed hitherto to some extent, a viewpoint and language set apart from those of other sciences. I persist in wishing to tie descriptions and concepts of disorders of the skin with general medicine and biology as I wrote in 1938 in the preface of the tenth edition.

The utilization of page space has been painstaking I put half of the words onto two-thirds of the page area available and used 8-point type for material of secondary importance as I did in the *Handbook* To print the book in 10 point only would necessitate publishing it in two volumes. A reader may merit sympathy when he peruses material set in small type I know but reading it is easier than writing it, and printing it, more informative than omitting it. The chapter on diseases due to fungi would in itself make a book of 200 pages. That on malformations and neoplasms would make one of 500 pages with 488 illustrations. I have incorporated more material on the psychosomatic aspects of dermatology than is to be found on the psychosomatic aspects of the whole field of psychiatry in a well known, popular and massive volume on that specialty The 6-point bibliographies total over 5 000 lines of type and present thumbnail abstracts of thousands of articles.

Outstanding are the illustrations. Hermann Pinkus, M D supplied for the *Handbook* a magnificent collection of photomicrographs of normal adult and embryonic cutaneous tissues. I am indebted here, too for his normal material Dr Pinkus prepared for this edition a handsome collection of photomicrographs of abnormal tissues, which are used to illustrate the chapter on Pathology Credit for numerous excellent illustrations is due Drs. J Lamar Calloway O G Costa, Clyde L Cummer Robert N Andrade Emanuel Muskatblit John Belisario and F Ronchese The clinical pictures of Drs. Calloway Costa, Cummer Andrade and Ronchese are scattered throughout the book. Those of

Dr Bellisario are in the section on Carcinoma Those of Dr Muskatblit, showing fungi and diseases caused by them, are of unusual excellence as are also those so generously given to me for previous editions by Drs. George M Lewis and Mary Hopper The privilege of taking what I desired from *Oral Pathology* by Kurt Thoma and from *Skin Manifestations of Internal Disorders* by Kurt Wiener deserves especial acknowledgment. To Dr Gustav Riehl I am indebted for many fine illustrations of cutaneous tuberculosis, to Dr S William Becker for a group showing the histology of nevi and melanomas, and to Drs. Duncan Loth and J J Zoon for groups showing keratoacanthoma.

The bibliography as a whole consists of that which is incorporated in the text plus that which is postscripted to the particular section. This latter material contains what I did not fit into the text yet desired to mention. To many such references I have added a word or two identifying them refreshing the memory of one who has read them before or giving some idea of the content to one who has not.

In judging the ideas that are quoted so profusely in the text, one should note the dates of the references I was aware of them.

Documentation can be accomplished in only a few ways. Superscript numbers and corresponding terminal references are not practicable. Footnotes are hopelessly confining when one intends to re-edit a book, for classifications change in fifty years. Finally why insert (Smith, 1951) and oblige the reader to look to the end of the topic for the bibliographic reference when one can insert (Smith Lancet 2 1020 1951) and have done with it? I asked many friends for advice about styles of documentation and learned that two-thirds of them preferred mine and four fifths of them considered mine either preferable or acceptable

Credit within the text, the bibliographies, and the titles of illustrations is everywhere carefully given. For that too which is original, the source is indicated. My opinions are nowhere hard to find. I remember with gratitude a review by a man who approved of my expression of personal opinions that man will like this book. I claim some originality in paragraphs to be found hereinafter on several topics the treatment of contact dermatitis the interpretation and treatment of acne the histologic and clinical understanding of early epidermoid carcinoma the interpretation of autoeczematization and its relation to hypoproteinemia what to do about chronic dermatitis of undetermined etiology especially when it affects the hands a certain hyperkeratotic form of volar dermatitis the treatment of prurigo nodularis and of calcinosis universalis *Microsporum canis* infection of the finger tips; *Gaffkya tetragena* infections of the skin what I have chosen to call Summertime pityriasis of the elbows and knees summer acne of the extremities and apocrine cysts of the scalp which I have not seen described elsewhere.

Dr Charles R Rein wrote the section on Serology of Syphilis, as he did for the tenth edition and the *Handbook*

Dr F Stanley Morest read the section on Peripheral Vascular Disorders. The improvements he recommended attest to his extensive and effectual knowledge of this subject

The galley proof on Leprosy was read by Rolla R Wolcott, M.D., Medical Director U S Public Health Service Hospital, Carville, Louisiana, and the material was conformed with his invaluable criticisms. I am grateful to Hermann Pinkus, M D., further for he graciously pointed to certain corrections desirable in the page proof of the chapter on Anatomy to Walter C. Lobitz, Jr M D., who did this for the chapter on Physiology and the section on Diseases of the Sweat Glands, and to Sloan Wilson, M.D., who did it for the section on Purpura What imperfections remain are not the fault of these kind friends.

Gilbert E Ryder M D for whom I am presently preceptor under the American Board of Dermatology and Syphilology read all of the page proof

with me There is not a "dilatation" in the book other than this one, not a "therapeutic armamentarium" We corrected an occasional misspelling in a *direct quotation in order to avoid an uncharitable* [sic]

The index is pointed out as a source of a variety of information and guidance, especially under such titles as "Disease" "Prescription," "Syndrome" and "Test"

Abbreviations of references are listed on p xix, ff preceding the text

Many have asked me how such a book as this is made One obviously depends on the publications of others, to which one's own observations and opinions are added. Among the requisites are time experience in the practice of medicine (to which I have by now devoted some twenty five years) and a generous measure of stubbornness. Of writing a book Winston Churchill said, "To begin with, it is a toy and an amusement. Then it becomes a mistress, then a master, then it becomes a tyrant. Finally when you are reconciled to your servitude, you kill the monster"

I have worked during morning hours, protected from every kind of interruption by teammates, who have occasionally been obliged to tax their consciences in defending me from people who itch. During 1953 a partnership with Norman D Asel M.D., was established. To our comfortable and satisfying relationship I am indebted for many hours that could have been granted me in no other way I am grateful for the cheerful and efficient cooperation of Miss Margaret Egy my patient secretary skilled not only in orthography and syntax but also in getting along with a moody man and of Mrs. Betty Standke Miss Mildred Young Mrs. Corinne Gallup, Mrs. Margaret Lynch, and Mr Robert Sauvan.

Systematic reading is required. For years I have abstracted onto 3 x 5 file cards everything appertaining to dermatology that crossed my desk. These are cast alphabetically by subject matter In abstracting I record that which appears to add to my own knowledge. Most articles contain, of what I want less than enough to crowd one side of a file card. The content of an exceptional essay may oblige me to use several sentences. One that I could not condense much, for example was that of Bedford Shelmire (J 113 1085 1939) on dermatitis due to plants, of which I quoted whole paragraphs (p 154) Some articles condense to nothing at all.

My descriptions of a disease frequently take the form of a reference to the original recognition of the entity a statement of what may be called its average manifestations, and then several case references suggesting range variability or extremes of its potentialities. The mention of rare odd or curious instances helps, I imagine in formulating a concept of the condition. Also to me these are interesting

In revising a description of a disease I put together the pertinent group of file cards, some of which are cross references, like fragments of a mosaic. Sometimes an article is quoted with respect to only a fraction of its content, particularly if it covers a certain facet of the subject nicely and I cite other articles appropriate to document other facets.

Here and there I quote a statement or hypothesis that is patently absurd although not to its originator I have done this to dispel ennui and to exemplify some of the contemporary "thinking" that is not critical (see Asher BMJ 2 460 1954) Yet to me there is apparent in what I have written some mellowing with maturity as evidenced by a recently acquired lack of conviction that certain opinions of others are wrong or that opinions of mine are right. Credit has evolved into credibility certitude into wonder faith into hope Thus where I have expressed my views, I may have antagonized fewer individuals in this edition than formerly and in places I have actually avoided disputation.

Pertinent is a quotation you will enjoy from an obscure source my father and I happened upon. John Smith, M.D E., Coll. Med. Lond. Cand., published *King Solomon's Portraiture of Old Age Wherein Is Contained a Sacred*

Anatomy Both of Soul and Body in 1666 His Epistle to the Reader ' in contrast with what was then customary, was not devoted to flattery of a patron John Smith whatever might have been his now quaint ideas on sacred anatomy of soul and body was a man one would like to know and his preface, cold from his pen these 290 years, pleases me (I wish I could tell him so) Whosoever thou are into whose hands this Paraphrase may fall know that the Author of it is not near enough any Nobleman to put it into his hands, nor hath he face enough to call at a distance, but could he do both, yet know also he would do neither for he desireth not that anything either of others or of his own should be patronized beyond its own native worth, And is himself willing that all the shame that is due to the ill managing of this good Subject should return upon his own pate "

Those to whom Senior can be only a tradition may wish to become acquainted with the man who initiated this book in 1916 and put it through eight editions single handed by 1931 My father was friendly communicative buoyant desirous of approval. When he became famous he enjoyed it immensely He was the antithesis of colorless, being uninhibited in expressing vivid views. His contemporaries do not forget him he did not bore them. Fishing and hunting were coequal with medicine in his enthusiasm and he covered the earth in his travels. Vast numbers of persons from all walks of life adored him Few have filled the hours of a lifetime so full. Obituaries were written by *Harold N Cole (ADS 66 424 1952) John Belisario (Austral* JDermat 1 263 1953) and myself in the Yearbook (1951 1952) of the Royal Society of Edinburgh.

My father retired in 1940 to devote himself to the hunting and fishing he so dearly loved. His health did not long remain good. While new editions had been his almost biennial habit, the eleventh remained only an ambition for a number of years. The necessity for revising our *Introduction to Dermatology* in 1941 and my entry into military service not long thereafter caused delay By 1949 I had prepared our *Handbook* for publication, after which I again gave thought to tackling the Big Red Book. Senior s death in May of 1952 made the task seem impossible He had the ability to make hard work easy and to revivify when energy flagged. His decisions were instant and generally right, and his capacity for turning out work commanded the respect even the awe of those who knew him.

In the preface of the first edition of *Diseases of the Skin* published in 1916 with 916 pages and 701 illustrations, my father said The present volume is the outgrowth of several years of study along this particular line and is an attempt to present the entire subject of dermatology in a comprehensive and at the same time concise manner A treatise covering so broad a field cannot well be based entirely on the personal knowledge and observations of any single individual For this reason I have not hesitated to draw from the publications of other writers selecting the material which I considered most appropriate Every effort has been made to properly credit the ideas thus secured. The majority of the therapeutic measures recommended are those which I have found useful and practicable in my own practice

The second edition appeared in 1917 containing 1021 pages and 841 illustrations. The preface read, The demand for a second edition at this time has given me opportunity to supply supplemental matter in a few instances, as well as to cover the important literature of the year 1916 and to eliminate a number of typographic and other minor errors. I am deeply grateful to my friends and colleagues for the kind and generous reception accorded the first edition

The third edition with 1084 pages and 921 illustrations, appeared in 1919 While the war has had a deterrent effect upon the study of cutaneous medicine in general it has added to our knowledge of the successful management of a few disorders, notably those due to animal parasites and has

developed a few new affections, such as occupation and traumatic dermatoses due to tetryl dichlorethylsulphide and similar chemical irritants. The gravity of syphilis as a social disease is becoming more evident each year a fact to which attention has been called by the splendid contributions of William Allen Pusey John H. Stokes, Loyd Thompson, H. H. Hazen and other authorities. The important part played by focal infections in the causation of disorders of the skin is at last becoming generally recognized I am indebted to many colleagues for valued suggestions and advice and particularly to my friend, Dr Charles J White of Boston whose encouragement and example have been constant sources of inspiration during my entire dermatological career '

The fourth edition was published in 1921 with 1132 pages and 980 illustrations. The clinical and serological study of syphilis continues to hold the attention of a large and able body of investigators, and the general public is at last beginning to appreciate the widespread prevalence and disastrous consequences of this malady The researches of Ormsby and Mitchell Charles J White Wende and Wilkinson and others, on epidermophyton infection and its etiologic relationship to certain chronic inflammatory disorders of the skin, have served to call attention to an important field which has hitherto been sadly neglected in this country

The fifth edition, in 1923, contained 1214 pages and 1080 illustrations. To one who has had a watchful finger on the pulse of dermatological literature for a decade and a half the output for the past two years is as promising as it has been prolific. I am indebted to my son, Richard L. Sutton, Jr., for many of the photomicrographs.

The sixth edition, in 1926 contained 1303 pages and 1158 illustrations. Additional light is constantly being thrown on a number of cutaneous disorders, and while our therapeutic advances have not kept pace with the information gained along other lines, we at least are in position to combat the various mycotic disorders far more intelligently if not more successfully than we were a decade ago

The seventh edition appeared in 1928 with 1394 pages and 1248 illustrations. Several recently discovered diseases have been introduced, the descriptions of some of the older ones rewritt_n, and the importance of others, such as certain of the occupational dermatoses and those related to allergy emphasized. An attempt has been made to discuss intelligibly the latest developments in cutaneous therapy and to recommend those agents known to be reliable and practicable. In order to economize space a considerable number of valuable references have had to be confined wholly to footnotes otherwise the volume would soon become so bulky and unwieldy as to seriously impair its usefulness.

The eighth edition was published in 1931 with 1352 pages and 1301 illustrations. Modern dermatological literature appears to grow by leaps and bounds. It is essential that each new edition contain an easily accessible and complete record of all the authoritative reports that have appeared in the interval This I have endeavored to do to the best of my ability, but even the most skilled of phraseological artists will experience difficulty in condensing and crystallizing the wisdom of a three thousand word masterpiece into the space of one or two brief sentences and I must acknowledge that I am no literary Cellini. Scanning the completed task, no one realizes better than I how incompletely it fulfills the ideal.'

The ninth edition, the first of Sutton and Sutton coauthorship was published in 193_ with 1433 pages and 1321 illustrations. Twenty years ago when I began collecting material for the first edition of this work, Senior wrote little did I suspect that it would ever grow into the present ponderous volume. Had I done so it is very probable that I should have tried to content myself with labors that demanded far less time and effort. A book of this sort is like a child the author an anxious and doting parent.

The tenth edition, a three-year labor of rewriting appeared in 1939 with 1549 pages and 1473 illustrations. With emendations it was reprinted in 1942 and again in 1943 We imagined that we had systematized the progressively increasing difficulty of reflecting current dermatology in such a fashion that future editions would be relatively easy to prepare I wrote the preface that time In view of the favorable reception accorded the etiologic classification in the 1937 edition of our *Introduction to Dermatology* and the tendency nowadays to inquire What is going on? rather than What name is applicable to this manifestation? the material has been arranged in a fashion radically different from that in the ninth edition. Descriptions of all significant entities, syndromes and concepts, and of many exotic unusual and even exceptional dermatoses have been incorporated. Emphasis is laid, however on the purpose of practical medicine which is to cure the ordinary patient of his ordinary complaints by scientific or by pragmatic means.

Quotations from prefaces of the past indicate that the endeavor to reflect contemporary medical thinking and practice involves a variety of problems. They are problems that become more and more challenging as one measures the capacity of a human being against the quantity of dermatologic science (and fiction) that appears in print

DISEASES

OF THE SKIN

DISEASES OF THE SKIN

ANATOMY

The skin is a soft, flexible membranous covering which completely invests the body and is continuous at the natural orifices with the mucous membranes. It consists of (1) a connective tissue frame incorporating blood vessels, lymph vessels and nerves, collectively comprising the dermis, and (2) an epithelial covering the epidermis. Dermis is that which becomes leather when skin is tanned Epidermis is that which forms the cap of a blister

The skin ranges considerably in thickness and consistency on various parts of the body It is the largest organ of the body weighing three times as much as the liver It serves principally in protection, heat regulation sensation and secretion. It is attached loosely or firmly to underlying structures so as to resemble a closely fitting elastic garment. Its area averages 16,000 to 18,500 cm.[2] and its weight 3 000 to 3,500 gm. (Leider JID 2 187 1949) The weight of the epidermis is approximately 225 gm. The specific gravity of the whole glabrous skin is 1.1, while for hair and nail the figure is about 1 3 (Leider and Buncke ADS 69 563 1954)

Superficially the skin is marked by tiny wrinkles and furrows. Underlying glands communicate with the surface through pores. On the palms and soles occur parallel ridges corresponding to rows of underlying dermal papillae.

Subcutaneous tissue is composed mainly of adipose lobules. It unites a regular surface with the deep fascia covering muscle and bone, and forms a resilient base for the overlying skin. Lobules of adipose tissue are latticed by an areolar fibrous network which supports blood vessels and nerve trunks. Thickness of the adipose layer was investigated by Stuart and Sobel (JPed 28 637 1946) Fat is an important but ill understood special tissue and storehouse (Wells PIMChi 13 26 1940)

Lines of cleavage result from the disposition of collagenous bundles under the influence of tension. In general, they parallel the natural creases and the direction of the hair roots (Cox BJS 29 234, 1941)

Color is determined by the pigment in the upper layers, by the blood of the capillaries in the dermis and by carotene It may be altered by vasoconstriction, vasodilation, cyanosis, methemoglobinemia, sulfhemoglobinemia, acrocyanosis, local asphyxia, dehydration and edema, as well as by pigmentation of external or internal origin, and by the thickness of the epidermal covering

Epidermis.—This ectodermal vestment consists of cornifying stratified squamous epithelium It is apposed to the papillated surface of the underlying specialized mesodermal structure the corium, or dermis. The basal membrane is the adhesive substance conjoining epidermis and dermis and behaves like a collagen gel, for separation of epidermis from dermis is effected by acids and bases at those hydrogen ion concentrations which cause swelling of gelatin (Felsher JInvD 8 35 1947) Agents which swell these hydrophilic colloids, including NaSCN and NaI decrease their cohesiveness, a fact which may explain their influence on dermatitis herpetiformis. Shrinking agents include Na_2SO_4 and Na citrate in 2N concentration. Karyokinetic division furnishes the layers from within outward. Mitoses occur twice as frequently in the night as during the day (Broders and Dublin PSMMC 14 423 1939) and epidermis of glabrous skin renews itself continuously from within outward in about 7 days, corneous scales flaking off inconspicuously under normal conditions

The ultimate derivation of superficial epidermal cells is, of course, from the basal layer and from below outward there may be described (1) the

stratum mucosum (2) the stratum granulosum, (3) the stratum lucidum and (4) the stratum corneum. The alterations in appearance of the cells as they are pushed outward are not evidence that they are intrinsically different. A basal cell its daughter cells in the mucosal layer and the derived cells in the horny layer are all of the same strain and manifest changes due to environ ment rather than to differentiation.

The deep layer consists of palisaded basal cells elongated perpendicularly to the surface The superficial ones become polygonal and flattened. These comprise the prickle-cell layer or stratum mucosum Its cells are soft and mucoid, nucleated and rich in cytoplasm their surfaces are covered with short protoplasmic spines, which give individual cells a cocklebur appearance. The structure of epithelial cells at high magnification was studied by Gray et al (JID 10 449 1952) The intercellular bridges may be in fact cytoplasmic tubes connecting the cytoplasm of adjoining cells in a syncytium (Laden et al. JID 19 211 1952 see Allen The Skin, Mosby 1954 p 5 ff.)

Fig. 1 —Normal skin from trunk (Dr H Pinkus.)

Mitoses are not limited in occurrence to the basal layer (Pillemer et al.: JExperM 70: 387 1939) In fact most mitotic figures are seen i the stratum spinosum, in fresh human scalp material (Thuringer: JID 2: 313, 1939) More mitoses take place during the night than during the day according to Cooper and Schiff (ProcSocExperBiol 39: 323, 1938) In volar epidermis mitoses are seen especially during rest and during and after stimulation (Thuringer) peak reproductive rates being reached independently in the basal nd spi ous l yers, respectively one and two hours after stimul tion. Maximal acti ity in preputial tissue was found at from 9 to 10 P.M. and minimal at from 5 to 10 A.M. by Cooper (JID 2 289 1939) The night rate is about twice the day rate (Broders and Dublin: PSMMC 14 423, 1939) The colchicine method of demonstrating mitoses revealed ac tivity in the entire Malpighian layer, according to Uehlinger et al. (JID 4: 331 1941) Mitos s eq ires about half an hour Hoffman (APath 47 3 , 1949) estimated, calculating that while one basal cell undergoes division some eight cells are being produced in the spinou laye He calculated that a basal cell in scalp tissue may spend about 3100 hours as such a prickle cell spe ds 2900 hours as such, d a granular cell about 1900 hours as such. When epidermis of glabrou kin is removed from patient by means of the actual cautery n w epithelium covers the defect in from 5 to 7 days. Thi is also the time re qu red fo the granula layer sta ned by silve nitrat to be shed and replaced. Unde normal cond tions the loss of corneou scales is entirely inconspicuous. The quantity of ep lermal material which is continuou ly bei g produced is notabl when, fo ample, an ocel lress g l t th normal loss.

The outermost cells of the prickle layer are differentiated, forming the stratum granulosum. They lie flattened parallel with the surface and con tain, in addition to degenerating nuclei coarse basophilic granules of kerato-hyaline which is a precursor of the horny substance of the corneum There is abrupt transformation from the stratum granulosum to a thin transparent

Fig. 2.—Normal skin from digit, showing corneum and eccrine sweat glands. (Dr H. Pinkus.)

Fig. 3.—Skin of digit, showing normal corneum, epidermis and papillary portion of dermis. Sweat duct in epidermis is seen centrally. (Dr H. Pinkus.)

Fig. 4.—Epidermis, showing keratinization, granular layer and corneum. (Dr H. Pinkus.)

layer the stratum lucidum. *Prominent* in volar skin and absent in many regions, *this consists of clear, flat cells containing* droplets of eleidin, but nuclei and cell membranes are inconspicuous in ordinary preparations. Eleidin probably is intermediate chemically between keratohyalin and keratin. The outermost layer the stratum corneum, is composed of flat imbricated keratinized cells of which the superficial ones are horny scales (Ludford QJMicroscSc 66 27 1924) Keratin, the main constituent of the corneum is relatively resistant to acids, but less so to alkalies.

Molecular aspects of cornification were investigated, using electron microscopy, by Meirowsky and Freeman (JID 21: 83 1953) who found reasons to believe that keratin is a growing substance, not inert. Electron microscope studies of epidermal fibers show the intercellular bridges clearly and these appear to terminate at the cell boundaries, reported Adolph et al. (Sci 113: 685, 1951) The precipitated cytoplasm exhibits a fine felt work of fibers which are different in size from the intracellular fibers and seem not related to the intercellular bridges. Electron microscopy of the skin was also studied by Pease (AmJAnat 89: 469 1951) and Laden et al. (AD 1 19 1956)

Bizzozero s nodules are nodular thickenings of the intercellular bridges. Favre et al. (AnndeD 6 537 1947) noted that they are stained by Heidenhain's iron hematoxylin, although the bridges themselves, the cytoplasm and the nucleus remain colorless with this stain. The nodule is not always in the center of the bridge. It may be ovoid or fusiform. Where keratohyalin granules are voluminous the nodules are not seen but can be detected more superficially in the horny layer as a wreathlike arrangement in the outer dense layers. They do not occur in epithelium of mucous membranes unless there is definite keratinization. Favre et al. concluded that the structures are intercellular epidermal corpuscles, autonomous and not representative of fusion points of intercellular spines, possibly related to the chondriomes of the protoplasm for they take the mitochondria stain. Mitochondria were studied by Regaud and Favre (AnndeD 10: 241, 1950), who described them *as long coarse wavy filaments parallel to the cell surfaces of the basal* and prickle cells, characteristically spiral, found in epidermis of volar skin, not in the granular layer They disappear in psoriasis and in various other abnormalities.

Histochemical studies of the intercellular material were made by Dupré (AnndeD 80 490 1953 abs ABD 1954, p. 338) McManus stain showed Bizzozero's nodules rose colored, nodular o fusiform, often with a median bulge. In the stratum granulosum they formed a continuous moniliform line In the corneum they formed an irregular framework for the keratinized cells. They were not found between cells of the basal layer They stained deep black with Sudan black B. It appe red that the intercellular substance a complex lipid-glucoid protein, forms a histochemical unit at the dermo-epidermal junction and more superficially, and that the semiliquid, McManus-positive portion solidifies into nodules in the intercellular bridges.

As Pinkus (JID 16 383, 1951) has emphasized there is only one race of epidermal cells from the basal to the outermost layer The cells of this one race are called by different names depending on their position in the mattress like *three dimensional epidermis, and on their state of differentiation.* The prickle cells are usually larger than the basal cells, both in nucleus and body and stain lighter The nucleus is round or oval with a thick nuclear membrane and with usually one or two large collections of chromatin. The cytoplasm is divided into two zones, a small inner zone called endoplasm by Studnicka containing a relatively small number of chondriosomes and the Golgi net and outside this the main part of the cell body the exoplasm tougher in consistency and containing the tonofibrils. Tonofibrils are protoplasmic differentiations barely visible in routine preparations but capable of being stained by special methods. They are wiry fibrils which traverse the cells and form a basketlike net around the nucleus. They extend from one cell to another through the intercellular bridges.

Pinkus has observed that both basal and prickle cells are capable of movement if a small fragment of skin is isolated under favorable conditions. It is a mass movement comparable with the flow of lava so that the available material covers a larger area. During this migration the cells change their shape and give up their system of tonofibrils and intercellular bridges, so that the cells come to touch each other with broad surfaces. Tonofibrils do not re-form in isolated epidermal cells, but if the culture stops growing and establishes an equilibrium tonofibrils form again. When cells separate from each other the t n fibrils pass through remaining spots of contact but prickles, intercellular bridges and tonofibrils are not identical A differential staining

technic for mitochondria, tonofibrils (including Herxheimer s spirals) and desmosomes in skin sections was given by Pinkus and Steele (JID 22 367 1954)

Keratohyalin occurs in only one or two layers of normal skin, except in those regions with a thick horny layer the palms and soles, where multiple layers of granular cells are to be found.

At follicular orifices the cells are arranged in a circular manner supplying a lining for the ducts Ducts of sweat glands are separate from other epidermal cells, though resembling them. Between the deep cells of the epidermis are branched dendritic pigment-containing cells. Clear cells balloon like and perhaps of neural function also occur among the cells of the basal layer see melanoblasts (p 787)

Separation of the Epidermis.—Epidermis may be lifted off the dermis by blunt dissection after the skin has been soaked for about 30 minutes at 20 C, in isosmotic ammonia, but the deep portions of hair and gland structures remain in the dermis (Baumberger et al: JNatlCaInst 2: 413, 1942) Dilute acetic acid may be used for this purpose, and Blank and Miller (JInvD 15: 9 1950) used a suction technic. When transparent adhesive tape is applied to the skin a single layer of horny cells adheres to it, a d repeated applications show that the forearm corneum is from 10 to 40 cell layers in thickness (Pinkus: JInvD 16: 383, 1951)

The loss of keratin by stripping apparently served as a stimulus of epidermal proliferation stated Pinkus (JID 19: 431 1952) who studied quantitatively the regenerative process. Hypertrophy of the cells and their mitosis were more pronounced in the basal layer than peripherally

Maceration was used to separate the epidermis from the dermis in both normal and abnormal conditions as illustrated by Horstmann (AfDuS 194 104, 1952) Chloropre e dimers, allyl laurate or iodoacetic acid can be used to effect the separations (Flesch et al.: JID 18: 187 1952)

If a thin strip of skin is stretched to its limit and anchored with thumbtack the epidermis can be grasped with forceps and teased off in a continuous sheet (Van Scott: JID 18: 377, 1952) *The adhesiveness of epidermal cells varies inversely with the temperature* (Zeldman: Sc 109 596 1949)

Connective tissue was removed from epidermis by means of 0.1% collagenase or 2% sodium iodide in the preparation of cleared unfixed whole mounts, as described by Hambrick and Blank (JID 23: 437, 1954) Providing comprehensive visualization of the epidermal pattern such preparations demo strated the pilosebaceous apparatus as a whole and confirmed the existence of the epidermal eccrine sweat duct unit. The McManus-positive cuticle of the sweat duct could be traced as a continuous lining of both the straight dermal and the coiled epidermal parts of the duct up to the level of the keratinized portion.

Dermis.—The dermis is the layer of fibrous and elastic tissue which underlies the epidermis. Its thickness, ranging from 0.3 to 3 3 mm., is least on the eyelids and prepuce and greatest on the soles, palms and back. The superficial, papillary portion supports the epidermal basal layer and is intimately attached to it. The line of attachment, or basal membrane is of disputed structure but probably is fibrillar (Szodoray ADS 23 920 1931) Nutrient exchange occurs through the medium of tissue juices, for the epidermis is avascular The basal epidermal cells rest on the dermis, and the conjunction consists of many short pedicles or rootlets which interlace with the felt of reticulum and fine collagenous fibers of the papillary layer

The papillary layer of the dermis consists of finely felted collagenous bundles forming rounded projections upon which the epidermis rests. Within these connective tissue projections, numbering perhaps 100 to each square millimeter of surface (Sappey Traité d Anatomie Descriptiv Paris 1877) are capillary loops, nerve fibers and special nerve endings, as well as a lacy net work of fine elastic tissue fibers.

The deep portion of the dermis, the reticular part, consists of dense interlacing bundles of white fibrous tissue and merges beneath with the subcutaneous tissue. Slender branching strands of yellow elastic tissue are threaded through it, surrounding sebaceous and coil glands, hair follicles and blood vessels. Larger fibers of elastic tissue are in the deeper part of the dermis, and small fibers form a fine network close beneath the epidermis, but the reticular fibers of the dermo-epidermal junction are demonstrably distinct from elastic tissue according to Dick (JAnat 81 201 1947)

Collagen fibers apparently take form in an extracellular medium under the influence of factors elaborated by the fibroblasts (Day JPathBact 43 49 1936) Vascular endothelium may also have an active part in the production of argyrophilic connective tissue substance Chronic lymphatic obstruction may lead to massive fibrosis. Electron microscopy of collagen fibers

shows axial repeating periods of from 500 to 800 A.U., while fibril width ranges from 700 to 1400 A.U (Gross and Schmitt JExpM 88 555 1948) See Randall, edit. (Nature and Structure of Collagen, Academic Press, 1953)

Elastic tissue in branching strands surrounds the bundles of fibrous and muscle tissue glands, follicles and vessels. Lynch (ADS 22 67, 1934) observed their genesis as early as the third fetal month. Their function in hold

Fig. 1.—Skin from chest, showing lanugo hair; elastic tissue is stained black. (Dr H. Pinkus.)

Fig. 2.—Elastic tissue of the papillary portion of the dermis. (Dr H. Pinkus.)

ing the skin together is attested by their absence in epidermolysis bullosa, a disorder in which the epidermis is easily separated from the dermis presumably because of the lack of elastic tissue (Engman and Mook JCutD 24 55 1906) Elastic fibers begin as tiny fibrils which mature in morphology and tinctorial reaction slowly functional demands playing an important role in their development even in embryologic sequences, according to Hass (APath 27 334 583 1939)

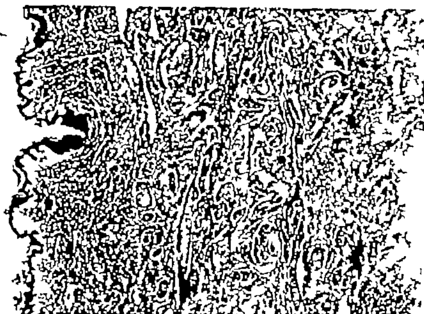

Fig 16.—Skin from the areola of the nipple, showing smooth muscle tissue in the dermis (Dr H. Pinkus.)

Pigment.—The brown hue of the skin is due to an amorphous substance melanin. It is the melanin of the epidermis not that more deeply located, which gives the skin its color (Gates and Zimmermann JID 21 339 1953) Melanin is present as intracytoplasmic granules in the basal cells of the epidermis and in argyrophile dendritic cells capable of ameboid movement. These dendritic cells melanocytes, occur in the epidermis and also in the dermis. Some of them do not contain melanin but contain precursor oxydase granules *that react on treatment with dopa, dihydroxyphenylalanine* changing it to melanin (Bloch AfDuS 124 129 1918) Melanin is a chromoprotein, iron free probably a metabolite of pyrocatechol Pigment production is increased by many forms of irritation and inflammation the increment being conspicuous in persons capable of generous formation of pigment especially in Negroes. Some kinds of inflammation result in depigmentation. Pigment granules are carried to the epidermis, and they may also be carried from it (Becker ADS 16 259 1927, Clin 3 886 1944)

The recommended terminology of pigment cells (Fitzpatrick and Lerner Sci 117 640 1953) is as follows melanocyte means the mature melanin forming cell melanoblast signifies the immature melanin forming cell macrophage or melanophage applies to a *cell containing phagocytized* melanin and melanophore is the contractile cell.

Melanoblasts probably originate from the neural crest of the embryo and wander outward to permanent locations (Becker: Clin 3 886 1944) The neural crest separates from the dorsal pole of the medullary tube and is the matrix of the spinal ganglia, the autonomic nervous system and the chromaffin tissue as well as the melanoblasts. These first appear in the fetal Negro skin in the third month (Zimmermann and Cornbleet: JIn D 11 383 1948) From the first they do not resemble ordinary epithelial cells, and transition between these two cell types have not been observed.

Dendritic melanoblasts progressively pervade the epidermis via the intercellular spaces. In the fifth month numerous secondary processes arise from the main dendrites,

and these progressively surround the epidermal cells, which are dopa negative but receive melanin secondarily by transfer from the dendritic processes of the melanoblasts, which become carriers of melanin during the fifth fetal month.

Melanocytes form a syncytial network, according to Findlay (BJD 65: 437, 1953) in substantiation of the findings of Munch (ZtschrAugenheil 1..: 525 1904). Their cytoplasm contains numerous fibrils lying in the long axis of the cell and in a zigzag or spiral pattern across it. Fine granules of melanin are arranged in an intimate relation with the fibril pattern. Spectrophotometric studies indicate that the color depends on an optical combination of melanin with collagen, the blue color of the iris being attributed to reflection of blue and absorption of violet by collagen, combined with absorption by melanin of much of the light on the red side of blue.

Fig. 11.—Melanin pigment in basal cells of Negro epidermis. (Dr. H. Pinkus.)

M la ocytes are seen in routine sections of normal adult skin usually in the form of clear cells loc ted in the basal layer, where they exhibit smaller darker nuclei and paler cytoplasm than epidermal cells. The afibrillar and shrunken cytoplasm may result in an appearance as of a hole between the palisaded basal cells of the epidermis. Clear cells may be sparse or n merous thei number being not related to the degree of pigme tation. Their long, branching dendrites extend fa in the intercellular spaces while the small body of the melanoblast remains wedged in or just below the basal layer.

Solar pigmentation seems to be related to oxidation (Miescher and Minder: Strahlenthe 66 6, 1939). Tyrosinase in human skin possesses a role in the formation of melanin (Fitzpatrick et al.: Sc 112: 223, 1950). When small areas of black and white skin in guinea pigs were interchanged by full-thickness grafting there occurred depigmentation of previously pigmented skin, while pigment appeared in the host skin at the edge of a pigmented graft (Lewis a d Pecks JInvD 4: 483, 1941).

Inheritance of skin color in human beings apparently takes place by blending (QMN: J 119 1235 1942).

Carotenoid substances give rise to the yellowish hue (Edwards and Duntley AmJAnat 65 1 1939). Blood in the superficial capillaries is the source of the reddish color. Dilation of capillaries increases intensity of redness. Compression, constriction, collapse, and atrophic diminution in the number of capillaries, and anemia result in pallor.

Lymph Vessels form a superficial plexus in the papillary part of the dermis, and in the subdermal layer a deep plexus communicates with the trunks which follow the subcutaneous blood vessels. The superficial plexus is so abundant that injections in the lymphatics are absorbed almost immediately. While particulate matter is not perfused through the walls, slight trauma causes great increase in permeability as do heat, light and chemicals also (Hudack and McMaster JExpM 57 751 1933).

Blood Vessels.—A rich supply of blood is maintained by two parallel horizontal systems of vessels, the subpapillary and subcutaneous plexuses.

Fig. 11.—Vermilion border of the lip blood vessels injected. (Dr H. Pinkus.)

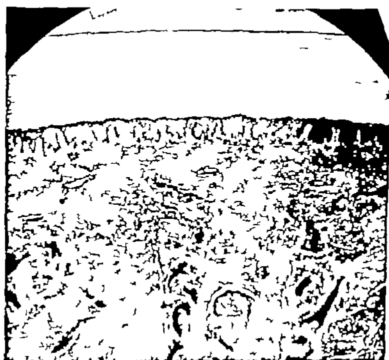

Fig 12.—Transverse section of nail and nail bed, blood vessels injected (Dr F O Harris.)

From the superficial plexus, capillary loops extend into the tips of the papillae Numerous branches of the deep plexus supply the hair follicles sebaceous glands and coil glands. (Clark and Clark Am J Anat 64 [illegible]1 1939)

Myoarterial Glomus.— In the pulp of the fingers and toes, the palms and soles, and elsewhere in the body there are special organs which function as arteriovenous anastomoses. In a glomus the afferent arteriole divides as it approaches the surface part going to the skin and part by way of a thick

walled neuromuscular glomus to a venule. These Suequet Hoyer canals are normal and functional parts of the vascular system serving to control the acral circulation

Nerves of the skin follow in general the course of the blood vessels. There are medullated and nonmedullated fibers. The main trunks run horizontally in the subcutaneous tissues and give off branches which divide and pass into the dermis with the arteries from the subcutaneous plexus. Slender branches pass into the papillary bodies, and some terminate there in special end organs. Nonmedullated fibrils are distributed to the endothelium of the capillaries and also pass through the papillae lose their sheaths, and terminate on the cells of the epidermis. Skin innervation is beautifully illustrated in the article of Weddell (BMBull 3 733 1945) Free sensory endings are often ball or knob-shaped. *Merkel has described tactile cells which are found in the deeper* layers of the epidermis, especially numerous in the epithelium of hair follicles. Nevi seem to be collections of anomalous cells of this type (Ebert ADS 37 1 1938)

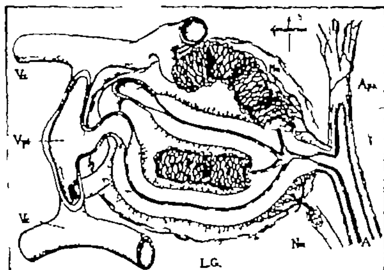

Fig. 14.—Glomus: neuromyoarteriovenous anastomotic organ, schematic. *A*, superficial preterminal artery. *Apa*, terminal branch entering capillaries. Side branch is afferent artery entering the glomus dividing into 4 neuromuscular arterioles. Elastica of afferent arteriole disappears as arteriole enters glomus. Wall of vessel becomes thick due to increase in smooth muscle fibers, which terminate abruptly at beginning of venous segment. Efferent glomic vein leads into a collecting vein (*V. pc.*) which is dilated and thickened at the junction; and it leads into superficial vein, *V.s.* *Nm* is rich perivascular network of nerves, connected with periarterial sympathetic nerves as well as myelinated sensory nerves (*Nm*) to the skin. *L.G.*, connective tissue capsule. (After Masson, Ourbitson and Tennant: Surg. 5 84, 1939.)

Hair follicles receive nerve supply in a manner similar to that of the epidermis the fibers passing into the prickle-cell layer of the follicle.

Several types of encapsulated nerve endings occur the tactile corpuscles, or corpuscles of Meissner the end bulbs of Krause and of Pacini, the genital corpuscles, and the terminal cylinders. The corpuscles of Meissner are small, oval structures from 80 to 150 microns long and about one-half as broad. They are found in sensitive regions the palms, soles, lips nipples penis, and clitoris, and dorsums of the hands and feet They generally occupy the tips of the papillae their long axes perpendicular to the surface. Pacinian corpuscles are not confined to the connective tissue of the skin but are also found in many other parts of the body These bodies are large oval, onionlike structures, which range from 0.5 to 2.0 mm in length They possess a thick capsule composed of from one to three dozen concentric layers of fibrous tissue and a core of granular semisolid material in which the naked axis cylinder is embedded.

Evidence indicates that the end organs of Krause are cold receptors, those of Ruffini are warmth receptors, and those in hair follicles are touch receptors, while free endings mediate painful stimuli. Tactile fibers are myelinated, pain *and thermal fibers nonmyelinated. One nerve fiber carries* only one kind of endings (Woollard JAnat 71 54 1936 Zotterman JPhys 95 1, 1939 Kuntz and Hamilton AnatRec 71 387 1938) The doctrine of specificity of

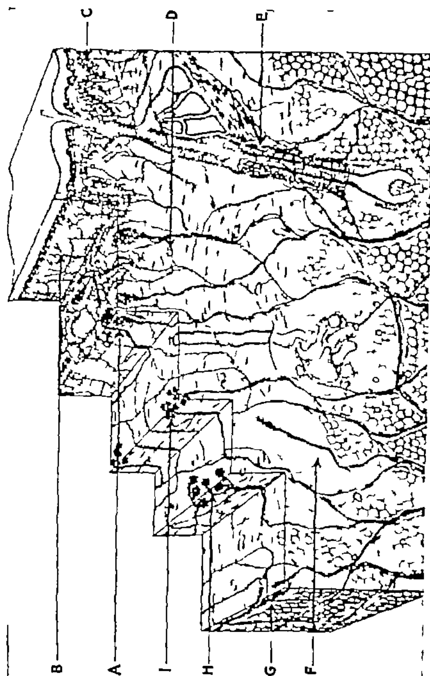

FIG. 16—Cutaneous innervation, schematic. *A* groups of Meissner corpuscles subserving the sensation of touch *B* beaded nerve nets subserving pain (probably fast pain) *C*, Merkel discs subserving touch; *D* beaded nerve fibers derived from nerve nets subserving pain and associated with blood vessels (probably slow pain) *E* nerve terminals around the sheath of a hair subserving touch *F*, a pacinian corpuscle subserving pressure *G* a group of Ruffini endings subserving warmth H and I, groups of Krause's end bulbs subserving cold (these lie at somewhat variable depths beneath the skin surface) *Note*—The organized endings are accompanied in every instance by fine-beaded nerve fibers subserving pain. (Weddell HMBull 3 187 1945)

nerve function is supported clinically physiologically and anatomically (Walshe Brain 65 48 1942) of the 4 primary modes of sensation touch pain, cold and warmth each is a sensory unit with end organs disposed in the skin in area and in depth such that activation of a spot influences the whole unit Pain is the *sense mediated by all on extreme excitation. The anatomy* of cutaneous sensibility was well set forth in Edit. (BMJ 2 342, 1942)

Nocifensor System.—The existence in the skin of an intrinsic neural system, a posterior root system the axones of which arborize freely in the skin, has been postulated. Vascular flares at the sites of injury apparently are due to the vasodilating influence of these nerves, for the flare reflex, normally provoked by pricking the skin through a droplet of histamine solution persists only 5 to 7 days after a cutaneous nerve is cut. The histamine test is useful to test the integrity of cutaneous nerves, as in leprosy Histamine

Fig. 16.—Meissner' corpuscles in dermal papillae of finger (Dr H. Pinkus.)

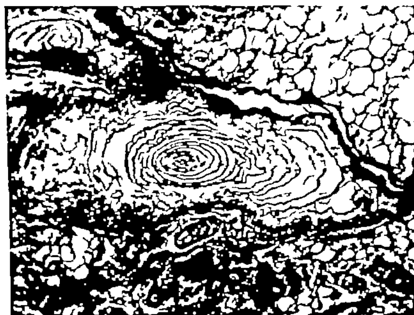

Fig. 17—Vater Pacini corpuscle of finger tip. (Dr H. Pinkus.)

provokes whealing, but not erythema, after degeneration of the nerve (Lewis BMJ 1 431 491 1937; Castello and Tianti ADS 47: 826 1943) No direct evidence of the existence of an independent system of branching axones of posterior nerve root origin could be found by Kuntz and Hamilton (AnatRec 71: 382, 1938)

Muscles of the Skin.—The striated are limited to the superficial voluntary muscles of the face and neck. The nonstriated are abundant, particularly

in the scrotal and perineal regions about the nipples, and in the scalp Ar rector muscles of the hair follicles are bundles of smooth muscle fibers, the contraction of which gives rise to goose flesh

Glands of the Skin.—The glands of the skin are of two types the merocrine and the holocrine In the merocrine glands, eccrine and apocrine secretion takes place without the destruction of cells. Eccrine glands secrete clear fluid and apocrine glands secrete an emulsified milky fluid from the tips of the secretory cells. The secretion from the holocrine glands is the actual dis integration product of the cells themselves. Sweat glands are eccrine or apocrine Fat glands are holocrine

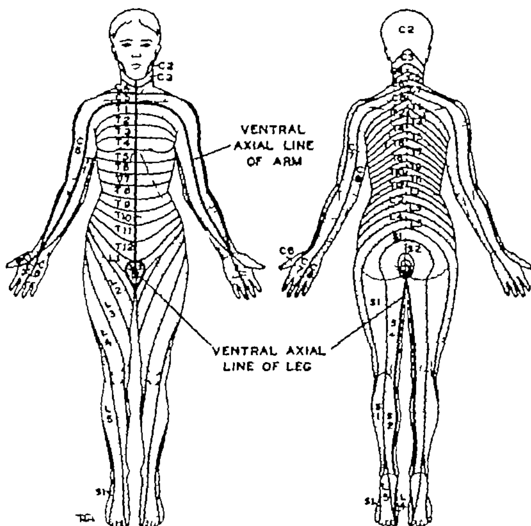

Fig. 18.—Dermatome chart f localization of nerv root lesions (Dr J J Keegan, U i ersity of N braska College of Medicine Anat Rec 102 409, 1948)

Eccrine Sweat Glands, or coil glands, are modified tubular glands which occur on all parts of the body except the margins of the lips the glans, and the inner surface of the prepuce They are most numerous on the palms and soles. Anatomically there are two parts, a body and an excretory duct. The body is globular and consists of windings of an epithelial tube of fairly uni form caliber The secreting or glandular portion of the tubule is composed of a single row of low columnar cells. Their bases rest on a thin layer of myo-epithelial cells the spindle-shaped elements of which are arranged longi

tudinally Surrounding this layer is an external sheath of fibrous and elastic tissue The glandular portion of the sweat coil is supplied with blood from a network which surrounds it

The epidermal sweat duct unit designates a morphologic and biologic entity which includes the intraepidermal portion of the sweat duct a single

layer of lining cells the periductal sheath of epidermal cells concentrically arranged about the cells lining the duct and the eccrine sweat pore (Lobitz et al JID 22 157 23 329 1954) See Epidermis, separation of p 5

Two moderately distinct types of cells line the secretory tubules, designated, on the basis of their affinity for basic dyes, as dark ' and ' clear cells by Montagna et al. (JID 20 415 1953) The smaller dark cells contain numerous granules composed chiefly of ribonucleic acid while the clear cells contain only sparse fine granules. Vacuoles and canaliculi, both inter and intracellular are conspicuous only in the clear cells. Both types of cells contain abundant glycogen and numerous mitochondria. The secretory cells have in their cytoplasm lipid granules, mostly pigmented reactive to Baker s test for phospholipid The lipid and the pigment remain sudanophilic even after embedding in paraffin. The cells of the lower portion of the excretory duct abound in ribonucleic acid, glycogen and mitochondria suggesting that the duct itself may have an active secretory or resorptive function.

Histologic variations in normal sweat glands were depicted by Holyoke and Lobitz (JID 18 147 1952)

The nerves consist of nonmedullated sympathetic fibers, which form a close plexus on the outer surface and give off fibrils to the glandular and muscular cells. The duct is a tubule lined with two layers of pavement epithelium It passes through the dermis in a spiral until it reaches the epidermis, where it loses its connective tissue sheath In the stratum granulosum it assumes a corkscrewlike course and opens on the surface. Sweat duct epithelium is distinct from the epidermis, although encased in it (Pinkus JInvD 2 175 1939 AexperZellforsch 22 47 1938 tissue culture)

Apocrine Sweat Glands—Certain large glands, especially of the pubic circumanal, abdominal mammary and axillary regions, secrete fatty and odorous substances as well as sweat They are twice as numerous in the female as in the male They are more numerous in the Negro than in the Caucasian They atrophy with advance of age more than ordinary sweat glands. The distal portion of the secretory cell is discharged with secretion whereas in sebaceous glands the whole cell disintegrates to form the secretory product and in eccrine glands the secretory cell remains intact (Way and Memmesheimer ADS 34 797 1936 38 373 1938)

Investigations of the myoepithelium of apocrine glands confirmed the contractility previously observed reported Hurley and Shelley (JID 22 143 1954) Myoepithelium exists as a sheath of smooth muscle fibers supplied by adrenergic autonomic nerves, with the function of delivering preformed apocrine sweat to the surface of the skin. The gland is in effect a reservoir of sweat which when once emptied, requires several hours before further sweating can be induced by the mechanical thermal electrical or pharmacologic stimuli which ordinarily initiate contraction of smooth muscle tissue Apocrine tubules in vivo manifest peristaltic waves when stimulated. Apocrine gland function may be divided into 2 phases (1) secretion, a continuous activity under hormonal control and susceptible to the effect of intraluminal pressure and (2) sweating a delivery of preformed sweat to the skin surface as a result of peristaltic waves of myoepithelial contraction in response to stimulation which may be mechanical, adrenergic by way of the innervation or humoral by way of circulating epinephrine

Sebaceous Glands secrete oil These are usually but not necessarily, associated with hair follicles. The Meibomian glands in the eyelids are modified glands of this type as are also the smegma glands of the penis. Sebaceous glands occur on all parts of the body except the palms soles, and terminal phalanges A sebaceous gland consists of a fibrous capsule a membrana propria and a collection of epithelial elements. The capsule and lining membrane are continuous with the corresponding layers of the hair follicle and the epithelium is a direct prolongation from either the outer root sheath of

a follicle or the prickle-cell layer of the epidermis. These organs range from small, simple pouchlike alveoli to large lobular racemose structures. The center of the alveolus is filled with larger cuboidal or polyhedral cells which undergo fatty degeneration. The epithelial débris escapes into the hair follicle *or directly upon the surface of the skin and comprises sebum* Sebaceous glands are responsive to endocrine influence and become larger and more active in response to androgen (Rony and Zakon ADS 48 601 1943) See Seborrhea also histochemical studies of Bunting et al (AnatRec 100 61 1948)

Fig 17 —The scalp, X20. (Dr H. Pinkus.)

Unicellular sebaceous glands have been described by Wolff (BMJ 1 588 1951) who observed large clear cells in the basal epidermal layer with contents that are birefringent in polarized light as in ordinary sebaceous glands. They take the fat stains, and their presence accounts for the oily shine on palms and soles from which ordinary sebaceous glands are absent

Hairs are cylindric horny structures derived from the epidermis, implanted in pouchlike depressions in the dermis. They occur on all parts of the body except *the palms and soles, penis and terminal phalanges. There* are 3 classes of hairs (1) vellus or fine soft hairs (2) long hairs as those on the scalp pubes, bearded region, and axillae and (3) short, stiff hairs, such

Fig 32.—Arrector pili muscle the epidermis lies to the right.

as are found on the eyebrows and eyelids. A hair consists of a shaft and a root, which is embedded in the skin. The cortical substance of the shaft is composed of flat, nucleated, epithelial cells. The medulla of the shaft is filled with cells which contain more or less pigment. Air spaces are present in both cortical substance and medulla. Externally the shaft is covered with a thin, semitransparent, shiny cuticle composed of flat imbricated cells. On transverse section straight hairs are circular and curly and kinky hairs are elliptical.

As the hair grows outward from its papilla the epidermis of the inner root sheath grows outward with it at the same rate (an "effluvial current" of epidermal growth Wilson called it) and the internal root sheath desquamates at the level of the sebaceous gland above which keratinization is like that of the epidermis (Kligman AD 71 313 1955)

SHEDDING OF HAIRS is normal and continues throughout life. Each hair is exchanged at intervals of several months. When a hair is about to be shed, cornification of the root extends down almost to the papilla, the bulb splits into fibrils, the hair separates at the papilla, and the follicle becomes constricted at this point. As the exfoliating hair pushes outward and falls away a new matrix develops by outbudding from the side of the old follicle. See Chase (PhysiolRev 34 113 1954) Montagna and Chase (AnatRec 118: 330 1954)

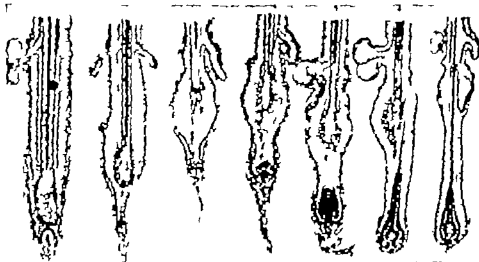

Fig 13.—Regeneration of hair (after Unna) (Pusey Principles and Practice of Dermatology ed 4 D Appleton-Century Company)

GROWTH AND DISTRIBUTION OF HAIR are little understood. Hypertrichosis is found in hypopinealism, hyperpituitarism, hypergenitalism and hyperfunction of the cortex of the suprarenal gland. With endocrine disturbances, there are striking differences between men and women in the growth and distribution of the hair. Hypopituitarism causes the male to assume the female type of distribution of hair but it does not cause the female to assume the male type of distribution. Hyperpituitarism, on the other hand, causes the male to become more masculine in type and the female to become masculine in type. Hyperplasia or tumor of the cortex of the suprarenal gland also causes the male to become more masculine in type of distribution of hair and the female to assume the masculine type of distribution of hair. Vitamin A, thyroid, estrogen and iron metabolism are much concerned with hair texture and its degree of oiliness or fragility.

See Copley (Sci 105 340 1947) physical properties of hair; Marchionini and Dracsche (DWchn 107 91 1938) changes in tensile strength and elasticity in metabolic diseases; Dieke (Endocrinol 40 123, 1947) rhythmic alterations of growth of individual follicles in animals, and investigation of effects of altering adrenal and pituitary glandular balance; Beek (Dermatologica 101 317 1950) distribution of hair in human beings; Odland (JID 21 305, 1953), histochemical studies of keratinization, showing distribution of thiol and disulfid groups and of ribonucleic acid

Nails are flat horny plates which overlie the ends of the dorsal surfaces of the fingers and toes. They are composed of modified epithelial tissue. The nail root is firmly embedded in the nail groove, a pocketlike recess of the dorsal digital skin. The nail plate is composed of flattened corneous cells and together with its underlying epithelium is supported by the dermal nail bed.

The proximal root is largely the productive portion of the appendage and is the zone of distad growth (see Nail growth and manifestations of abnormality) The root from which the nail grows is concave proximally As nail plate grows distad it matures in keratinization only after it has pushed distally several millimeters. The immature nail substance slightly milky shows as the lunula just distal to the proximal nail fold and is concave proximally paralleling the root from which it grew The lunula may be abbreviated, and it may lie entirely beneath the nail fold although this is not common The lunula is more often absent in the Negro than in white persons (Harris ADS 61 115 1950)

The nail bed and plate grow forward together as evidenced by the fact that a subungual clot grows out with the nail, so that the outgrowth cannot be interpreted as a mere gliding of the plate over the bed (Silver and Chicgo JInvD 3 133 1940) Connective tissue fibers in the subungual region are arranged both vertically and horizontally Vertical fibers extend from the periosteum to the undersurface of the nail bed and bind the nail firmly in place.

The rate of nail growth varies. It is said to be most rapid in the young and during the summer months, amounting to about 1 0 mm. per week (Clark and Buxton BJD 50 221 1938) The rate of growth of the thumbnail ranged from 0 112 to 0 172 mm per day without seasonal variation but with gradual slowing over a ten-year period, noted Bean (JID 20 27 1953) regarding his own nail In right handed individuals the rate of nail growth is somewhat faster on the right hand than on the left, according to Wigand (abs ADS 38 961 1938)

The structure and development of the fetal and adult nail were described by Lewis (ADS 70 732, 1954) see Nails, growth and abnormalities of (p 1349)

Epidermis is from an early age an ectodermal vestment of two layers. The epitrichium, a surface layer of flattened horny cells, corresponds to the corneum of the adult even in chemical reactions (Unna). From a single layer of stratum germinativum which rests upon the mesoderm destined to become dermis is derived by mitotic proliferation the multilayered epidermis. During the third month parallel ridges arise from the lower surface of the epidermis first upon the fingers, palms and soles and sweat glands later grow by downward budding from these into the dermis. On parts to be covered by hair comparable ridges develop in a network of star like pattern, and the primordia of the hairs arise in them.

Dermis and Hypodermis during the first six weeks consist of ordinary mesenchyme. In the second month fibrillar interstitial substance begins to be produced elastic fibers appearing later. The mesenchyme becomes apportioned into a superficial compact layer and a deeper loose one which is to be the subcutaneous tissue. The dermis further differentiates into a peripheral papillary layer and a deeper reticular layer in which the collagenous bundles become thick, interlaced and disposed in a direction predominantly parallel to the skin surface.

Hairs are first manifest in the eyebrow chin, and upper lip regions at the end of the second month. Proliferating cells appear in groups in the stratum germinativum. The growth of such a hair germ into the dermis produces a gradually elongating compact epithelial cylinder. Under it the connective tissue is condensed and the hair papilla so formed protrudes from below into the epithelial cylinder. The direction of the latter is not perpendicular to the skin surface. On that side of the cylinder where the angle is obtuse there develop two rounded projections. In the upper of these the central cells undergo fatty transformation and their further development produces the lobed outpouching from the hair follicles which is the sebaceous gland. The lower projection from the cylinder is the place of attachment of the arrector muscle which differentiates in the adjacent mesoderm. Within the bulb of the cylinder which caps the hair papilla a central cone of cornifying cells differentiates. These push upward by the multiplication of the cells on the summit of the papilla and so form the hair shaft.

Nails are earliest evidenced as flat areas on the backs of the terminal phalanges during the third month. These primary nail fields are surrounded by a fold, deeper grooved on the proximal side. Not until the fifth month is the true nail substance produced in the proximal nail groove the deep epidermis being transformed into nail matrix. Its cells become penetrated by fibrils of onychogenic substance and are flat and closely adjoined. As the thin nail plate moves distally within the epidermis, the overlying layers are desquamated until the plate is fully exposed being covered later only by the proximal fold. See Anatomy nails

Sweat Glands are seen earliest on the palms and soles in the fifth month. In their downgrowth the shaft is elongated and the lower portion curls in the form of a ball. A lumen forms in this secretory part in the seventh month and another lumen develops in the excretory portion of the duct to unite with it. The epithelium around the lumen forms two layers which differentiate in the secretory portion into an external layer of flat myoepithelial cells and an internal layer of cuboid glandular cells.

The skin is the dividing line between the individual and his environment It is primarily a barrier It serves in protection sensation heat regulation and chemical exchange with the exterior As an organ of three times the weight of the liver its functions concerned with water nitrogen glycogen and vitamin metabolism and with inflammatory and immunologic activities are significant. See Rothman (Physiology and Biochemistry of the Skin, U of Chicago Press, 1954)

Protection.—The insensitive insoluble fat-covered and relatively inert horny layer with its underlying regenerative epithelium resists abrasion, light, heat and living organisms and the tough resistant dermis on its springy elastic base of fibrous and adipose tissue admirably absorbs extrinsic forces and displacements. Light is reflected or absorbed by pigment Heat is radiated by increased blood flow On a dry healthy skin the number of bacteria and yeasts is reduced by 75% in 10 minutes and 95% in 30 minutes (Cornbleet and Montgomery ADS 23 908 1931)

The pH of the skin surface of children averaged near 4 0 for all age groups on the scalp chest and extensor aspects of the forearms but was higher in the axillae and between the toes (Herrmann et al JID 7 215 1946) The normal range of pH in adults was from 4 0 to 7 0 (Blank JID 2 67 75 231 235 1939) the extensor surfaces of the arms being more alkaline than the flexural, and the antecubital the most acidic region There was more variation between individuals than between males and females. The pH diminishes on hot days and increases following the use of soap (Bernstein and Herrmann: NYSJM 42 436 1942) The pH is relatively alkalinized by bathing but returns to normal after a few hours (Arbenz Dermatologica 105 33 1952)

Alkali neutralization and alkali resistance of the skin may be tested. Wacek (Dermatologica 107: 369 1953) studying these aspects of the cutaneous protective mechanisms in normal and eczematous subjects, used a modification of Burckhardt's method: he placed a drop of fresh N/[illegible] NaOH onto 3 areas of the forearm or arm, and after 10 minutes cleansed the skin and examined it. If no reaction had occurred, he repeated the procedure on 2 of the 3 same areas. Finally he reapplied NaOH on 1 of these 2 areas so that he might compare reactions on areas tested with exposures of 10 20 and 30 minutes respectively Alkali resistance was found decreased in cases of cement dermatitis, housewives eczema, and ichthyosis. Alkali and acid neutralizing powers were found to be parallel. Barriers included sebum, sweat corneum, perhaps the bicarbonate buffer and finally tissue fluid if the epidermis were broken.

Skin Flora.—Microorganisms of many kinds are found on the skin but those which constitute the skin flora have little invasive power Some of them may be able to attack only when mechanical or chemical injury or altered physiologic integrity renders the skin more vulnerable When a pathogen is present, however as in furunculosis or infectious eczematoid dermatitis virulent organisms are available over the whole surface so that a minor abrasion promptly becomes infected. Pathogens may be present transiently the streptococcus being it is thought, always either a pathogen or a transient. The dermatophytes are capable of utilizing keratin, despite the fact that it is chemically inactive this advantage over other fungi forms the basis of their pathogenicity (Benham and Hopkins ADS 28 532, 1933) Hydration or alkalinization increases the flora while dehydration or acidification diminishes it (Arnold JID 5 207 1942) In the presence of pyogenic dermatitis, pathogens may be found widespread on noninvolved skin (Martin BMJ 2 245 1942) See also Pillsbury et al (ADS 45 61 1942) Pillsbury and Nichols (JID 7 365 1946) Rebell (JID 8 13 1947)

There are a few types of bacteria that seem to multiply freely on the skin and particularly in the sebaceous glands these can generally be culti

vated without difficulty The most important of these are the gram positive cocci. Of the numerous types that have been described, much the commonest is the white pigmented variety *Staphylococcus epidermidis albus* Another variety is found very frequently in scurf, and is known as Gordon s scurf staphylococcus. Occasionally yellow pigmented staphylococci are found, and sometimes sarcinae The great majority of cocci found on the skin are com paratively nonpathogenic both to human beings and to rabbits but a few consist of the pathogenic golden variety This variety constitutes 3 to 5% of the total colonies developing on blood agar plates which have been pressed against the normal skin whereas the white staphylococci constitute 90% Amongst the other organisms met with are occasional coliform and Proteus bacilli and diphtheroids. The healthy skin appears to have some natural self-disinfecting mechanism In the skin lining the external auditory meatus, as well as the usual staphylococci diphtheroid bacilli are not uncom mon and sometimes saprophytic acid fast bacilli, derived from the cerumen, are met with This quotation is from Topley and Wilson (Principles of Bacteriology and Immunity Wood 1937 see pp 801 1550)

Cultural studies of normal skins by Evans et al (JID 15 305 1950) revealed anaerobic bacteria outnumbering aerobic by from 10 1 to 100 1 *Micrococcus epidermidis* *Staph albus* and *M candidus* were regularly present while orange strains of *Staph aureus* were rare. *M flavus* was infrequent and *M citreus* was never found. *M saccharolyticus* was present in large numbers and was the predominating organism in some individuals. The sebaceous glands appeared to be the major site of bacterial luxuriation. No bathing for a week did not significantly increase the bacterial population.

DISINFECTION can be accomplished effectively by scrubbing which reduces the flora by 50% each 6 minutes, according to Price (JInfectD 63 301 1938) Hands and arms thoroughly degermed may require a week for com plete re-establishment of the usual flora Beneath rubber gloves the existing flora increases rapidly Drying accounts for much of the mortality of *Str hemolyticus* when it is put onto the skin, and the acidity of the sweat is also important (Burtenshaw JHyg 38 575 1938) Mechanical cleaning defat ting and germicides are all needed for sterilization and Merthiolate is ef fective according to Magath (SCNAm 20 931 1940)

The skin of the newborn sterile at birth is best let alone The baby should be kept away from infection and infection kept away from the baby urged Klein and Aries (IllMJ 77 337 1940)

SELF STERILIZATION of the skin has been studied intensively but is not fully understood Norton and Novy (AmJPH 22 193, 1932) believed that drying is the main factor that accounts for it The acidity of the sweat plays a role and the high concentration of free fatty acids was adjudged significantly related to the germicidal properties of the skin surface by Engman and Kooyman (ADS 29 12 1934) Fungistatic and fungicidal actions of sweat and its chemical fractions were investigated by Peck et al (ADS 39 126 1939) Concentrated sweat they reported fungicidal even if alkaline due to its content of acetic propionic caproic capyrylic lactic and ascorbutic ions Yet Cornbleet and Meyer (NEngJM 230 604 1944) cultivated fungi on sweat and sweat-agar mediums Disinfection can be attributed to at least 5 mech anisms (Burtenshaw BMBull 3 161 1945) drying acidity fatty acids of the sweat light and some other factor which is enhanced by a ketogenic diet According to Ricketts et al. (ClinSci 10 89 1951) drying is the major factor influencing *Ps aeruginosa* and *B coli* unsaturated fatty acids inhibit *Strept pyogenes* and both of these agencies affect *Staph aureus* Drying diminishes resident as well as transient bacteria observed Pillsbury and Rebell (JID 18 17 1952) who found gram negative rods somewhat more resistant than normal skin micrococci to certain fatty acids. Normal skin organisms grow well in the normal pH range of from 5 to 6 excepting the aerobic diphtheroids which do not tolerate much acidity

Sensation.—Sensory end organs are distributed over the skin in a puncti form manner Areas most sensitive to heat and cold are found on the lips, tip of the tongue and eyelids. Pressure points are close to hair follicles and on nonhairy regions probably depend on the tactile or Meissner corpuscles in the papillae They are more numerous and smaller than hot and cold points. Pain sense is disseminated generally and is also punctiform in distribution the free sensory ending is probably its receptive organ Surface pain is ac curately localized Sensory spots on the skin must be distinguished from end organs themselves, for Gilmer and Haythorn (ANeurl 46 621 1942) did not find nerve endings under pressure vibration spots, and Weddell (JAnat 75 346 441 1941) showed that sensory spots overlie more than one ending or group of endings of the same type and that nerve fibers subserving the spot are separate and multiple More than one Krause end bulb may hang on one nerve fiber and a terminal network for pain may spread over a circular area almost 1 cm in diameter

The pricki g pain of momentary stimulation by heat needle prick or pulling of a hair cannot be distingui hed, while burning pain is the identical se sation differing only in its duration, according to Lewis (BMJ 1: 321 1938) Skin pain is only a single quality of sensation with variation in intensity a d duration; it is a sharp pain which quickens reflexes a d, within limits, invigorates The ache-pain of muscle o tendon pain dull reflexes a d sickens. Prick-burn sensation and ache-pain are of completely different qualities of se sory experience Lewis beli ed. No co relation between itching and pain thresholds could be demonstrated by Potel na et al. (JID 1 : 307 1949) They believed that itching and superficial pain must result from different causes nd possess different sensory identities. The adequate stimul for pai is tissue injury (Hardy et al.: Sci 114: 149, 1951; Wertheimer and W rd: Sci 115 499 1953) An algesimeter using f radio stimulation pplied to the ear lobe was so devised by Siker et al. (Sci 1*0: *73, 1954) to give reproducil le results.

Itching and pain are apparently mediated by the same receptors and fibers, argued Rothman (The Nature of Itch ng Williams and Wilkins, 1943) because in pathologic cases of sensory dissociation, the perception of itching disappears and reappears with the per ception of pain. When complete tactile anesthesia is associated with unimpaired pain sense the itching sensitivity is likewise unimpaired. Pain and itching paint has the same density of skin di tribution and they cover each other Tickle becomes itch, and itch becomes burning pain with increase of stimulation. The sensation experienced depends on the frequency of impulses in the slowly cond cting C fibers of Gasser and Erla ger Itching was experimentally produced and studied by Bi hop (JID 11: 143, 1948) It appeared to result from a persistent exitation insufficiently intense to cause pain and too con tinuous to register as prick. It could be induced by the summation of weak electric shocks individually below the prick threshold. Investigating pruritus induced by intra dermal injection of histamine Cormia and Kuyke dall (JID 20: 429 1953) found that the sensation of itch changed to burning and pain if the stimul s was tripled. See Hardy et al. (Pain Sensatio s and Reactions, William and Wilkin 1952) who noted that aspirin in small dosage effectively raises the heat pain threshold.

Nerve impulses induced by discharge of single warm and cold fibers in the tongue of cat and dog were recorded by Zotterman et al. (AnnRevPhysiol 15: 357 1953) See Geldard (The Human Senses, Wiley 1953) containing 3 ch pters on cuta eous sensibilities.

Referred pain from internal disorders is referred to the region of the surface distribution of the same or adjacent somatic neural segments.

Nerve injury which denervates and so diminishes sweating results in in crease of electric resistance of the skin, and the mapping of skin resistance may be used to delineate denervated areas accurately (Richter and Katz J 122 648 1943)

The acetylcholine axone reflex is located in the skin according to Roth man and Coon (JID 3 79 1940) Acetylcholine mediates propagation of impulses across ganglionic synapses in the autonomic nervous system. All preganglionic sympathetic nerve fibers liberate the substance at their end ings. Postganglionic fibers are of two kinds those which liberate acetyl choline and those which liberate sympathin. Cholinergic and adrenergic fibers are not completely parallel in the sympathetic and parasympathetic systems. Cholinergic fibers include (1) all preganglionic fibers of both sympathetic and parasympathetic systems, (2) all postganglionic fibers of the parasympathetic system and (3) postganglionic sympathetics of the eccrine glands. All other sympathetic fibers are adrenergic Epinephrine and

sympathin act on effector cells, whether an organ is denervated or not. Pilomotor fibers are stimulated by sympathin, which can be demonstrated in the circulation after stimulation of the sympathetic chain. Ergotamine blocks the action of sympathin. Atropine inhibits the action of acetylcholine while physostigmine intensifies it. Eccrine sweat secretion is elicited by acetylcholine paralyzed by atropine. An adrenergic component probably exists, capable of being inhibited by ergotamine and other adrenergic blocking agents.

HISTAMINE TEST FOR NERVE FUNCTION.—A simple test for nerve function depends on the kind of reaction which results from the intradermal introduction of 0.01 cc. of 1:1,000 histamine HCl. One punctures the skin at half-inch intervals and applies a drop of the histamine solution. The wheals which result are surrounded by intense flare if the nerves are intact and there is no flare if they have degenerated. The absence of flare in degeneration may precede by several days the electrical reaction of degeneration. A nerve root lesion gives a negative test, a spinal cord lesion gives a positive one. The test is valuable in differentiating hysteria and malingering from neural lesions and in problems of accurate localization.

The flare resulting from intradermal injection of histamine was a good criterion of the integrity of the peripheral sensory axones plus adequate peripheral circulation, Bereston (JID 6 3 1945) concluded in a study correlating skin responses with central nervous system lesions. The pilomotor reaction to intradermal acetylcholine was a criterion of the integrity of the peripheral sympathetic axones. The intensity of reaction was diminished in persons with neurologic defects and this was true of the flare reactions, but not of the papular reactions to tuberculin and trichophytin in these persons. The reaction to ultraviolet light, however, was greater in defective skin, while it was not influenced by atropine, prostigmine or histamine.

NICOTINE 0.1 to 0.2 cc. of 1:100,000 dilution injected intracutaneously stimulates the arrectores pilorum and gives rise to goose flesh in a 3 to 5 cm. circle within 2 minutes, according to Rothman and Coon. The reaction fails if postganglionic sympathetic fibers have degenerated.

Insensitivity to Pain is a curious and rare congenital abnormality. The girl described by McMurray (ANeurP 64 650 1950) never gave indication of experiencing the sensation of itching and was markedly insensitive to painful stimuli. The female patient of Boyd and Nie (ANeurP 61 402, 1949) likewise did not respond to pain although from time to time she was cut, bruised and infected. She occasionally scratched herself as if she itched and in scratching was liable to produce injuries that ought to have been painful. She sometimes scratched lesions which in normal individuals would have been painful. Arthropathy identical with that of Charcot's joints occurred in a woman congenitally lacking appreciation of pain reported Petrie (JBone&JointSurg 35-B 399 1953). In low grade mental defectives with diseases that ought to have been painful (usten (BMJ 1 1128 1954) observed only indifference; he thought this may be explicable on the basis of defective development of the fronto-ophthalmic projection fibers associated with cortical areas 9, 10 and 12, or defect of these cortical areas themselves.

Chemical Exchange.—EXCRETION comprises (1) fat from sebaceous glands, (2) sweat and (3) exfoliation of epithelial cells, which takes place continuously over the entire surface due to epidermal proliferation.

SEBUM, the sebaceous secretion, is an oily, yellowish, semifluid substance mixed at the sebaceous orifices with dirt, bacteria and frequently *Demodex folliculorum*. Accumulating in quantity on the fetus, sebum forms the vernix caseosa. Under the prepuce, mixed with macerated epidermis, it collects as smegma. Denervation does not affect sebaceous secretion, for sebum is a product of growth.

Hyperhidrosis and seborrhea frequently occur in the same individual but their interrelationship is not understood. Interestingly in seborrhea oleosa of the type not allayed by low fat diet or the administration of thyroid, Banthine or Prantal will temporarily inhibit the outpouring of sebum as well as of sweat.

The mechanism of excretion is intimately concerned with pressure and viscosity for with increasing resistance to further secretion pressure alone stops it (Emmanuel Acta DV 19 1 1938) The capacity of the skin to produce sebum graphs as a straight line if the sebum is constantly removed but the curve shows a decreasing rate of production if the fat is allowed to accumulate according to Zehender and Dunner (Dermatologica 93 3?? 1946) Temperature influences the flow greatly through its influence on viscosity Emotional states excited marked increase of sebum secretion as determined by removing fat and applying osmic acid vapor to detect its reappearance reported Robin and Kepecs (JID 20 373 1953)

Removal of sebum from a given area by means of carbon tetrachloride is followed by rapid replacement which is greatest during the first hour and is complete in about 4 hours (Hodgson-Jones et al.: Acta DV 1032, suppl. 29) When samples were removed from normal women daily there appeared a cyclic pattern related to the menstrual cycle with increase of quantity secreted until about the time of ovulation, this level being maintained until menstruation when there occurred a sharp decline This pattern closely followed that of the rectal temperature

The ether-soluble material of the skin surface shows striking quantitative analogy in distribution of lipids as compared to thermogenic sweat mutual emulsification of lipids and sweat might explain this parallelism (Herrmann et al.: JID 1: 397 1933)

Quantitative chemical analyses of sebum were reported by MacKenna et al. (JID 15: 33, 1950) Free fatty acids comprise about 30% combined fatty acids (glycerides, waxes and other esters) about 30% and unsaponifiable fat about 3?% (hydrocarbo cholesterol, alcohols, squalene, and unidentifiable material) The squalene content of hair fat from boys averaged 1.33% as compared with 5.1% from men and 7.0% from women (Nicolaides and Rothman JID 19: 380, 195?) Analyses of hair fat showed it to be increased in amount during adolescence and diminished in older age (Nicolaides and Rothman: JID 1: 9 1933) Ether-soluble substances on the skins of acneic individual quantitatively exceeded what was found in normal controls and were diminished following x ray therapy but not following ultraviolet light (Prose et al.: JID 19: 227 195?) Vitamins A D and E are absent from sebum (Festenstein and Morton: BiochemJ 5?: 168 195?) The biochemistry of sebum and the physiology of its production were interestingly reviewed in Edit. (BMJ 1: 490 1953)

The fatty acids of sebum are somewhat bactericidal, the unsaturated ones of shorter carbon chain length being most active (Miescher et al. Dermatologica 100 65, 1951)

See sebum as carcinogen (p. 1?16); and under alopecia (p. 1339)

CERUMEN contains a number of free amino acids identified by Bauer et al. (JID 21 205 1953) Anatomy and functions of ceruminous glands were investigated and reviewed by Lobitz and Campbell (JID 19 125 1952) Chemical studies were reported by Akobjanoff et al. (JID 23 43 1954)

APOCRINE SWEAT is discharged in small quantities as a milky fluid. Shelley (JID 17 255 1951) noted that it appears only at the hair follicle openings drying like glue to form a light-colored plastic solid which may fluoresce Its pH resembles that of eccrine sweat. Apocrine sweating may be evoked by stress or stimulated by epinephrine but it does not result from thermal stimulation and is not induced by cholinergic drugs (acetylcholine) or inhibited by anticholinergic drugs (atropine)

The function of the glands seems to be under the control of the autonomic nervous system through adrenergic fibers but inhibitory fibers could not be demonstrated by Shelley and Hurley (JID 20 285 1953) The glands respond to sympathomimetic drugs but not to parasympathomimetic agents. Their response to strong pain or fear stimuli is blocked by local anesthesia. Secretion will appear against an external pressure of 225 mm Hg It could not be produced in children and was reduced in quantity in old people Antiperspirants (e g $AlCl_3$) can diminish or abolish the secretion temporarily

Axillary sweat of two types comes from two different glands (Hurley and Shelley BJD 66 43 1954) the viscid, turbid secretion following epinephrine comes from apocrine glands; the clear watery secretion following acetylcholine comes from near by eccrine sweat glands.

SWEAT is a clear fluid of low specific gravity (1 004) faintly acid, containing mainly sodium chloride some 3 to 40 mg of sugar per 100 cc., and 0.5 gm. of organic nitrogen in the 500 to 3,000 cc. secreted daily It also

contains a little urea uric acid, creatinin, ethereal sulfates and other organic bodies. In uremia chlorides and urea may be deposited in crystals on the skin from dried perspiration. See Barney (J Sc 1373 1925) Loss of vitamins by sweating even if profuse is probably negligible excepting perhaps niacin (Mickelson and Keys JBiolChem 149 479 1943)

The chloride content follows the average skin temperature rather than the rate of sweating (Weiner and Van Heyningen abs YBD 1952, p 391) dietary chloride influences sweat chloride independently of other factors. The acidity appeared due chiefly to the lactic acid content which ranged from 247 to 336 mg % in the normal, higher in males, according to Thurmon and Ottenstein (JID 18 333 1952) The sweat gland is normally a sugar barrier capable of concentrating urea and perhaps able to form ammonia as the kidney does profuse sweat differs from intermittent sweat in that the former contains *no measurable uric acid.*

The normal pH varies in different areas and from single glands, was from 5.2 to 6.8 but not related to the urinary pH. There was no significant correlation between the sodium chloride contents of blood, urine or sweat

There is usually little correlation between sweat composition and disease of the skin, according to Levin et al (UCutRev 44 307 1940) However when ACTH or cortisone is given, the normal mean value of sodium and chlorides is greatly diminished, while patients with untreated Addison s disease show concentrations of sodium and chloride in the sweat far in excess of the highest normal values (Conn AIntM 83 416 1949)

Insensible perspiration consists in water loss from the skin when drops of moisture are not formed on the surface Temperature humidity and air movement greatly influence the rate of water loss. The intact corneum is the main barrier to diffusion. Insensible water loss is increased by from 3 to 10 times in areas of scaly dermatitis (Felsher and Rothman JID 6 271, 1945) There is marked regional variation in the rate of insensible water loss, which is rapid from palms, soles, forehead and cheeks, and slower from the trunk, arms and legs (Burch and Sodeman AmJPhysiol 138 603, 1943 JClinInv 23 37 1944) A film of sweat partially intercepts the erythema producing rays of the sun (Crew and Whittle JPhysiol 93 335 1938)

Secretio is timulated by heat, wind, sun, exertion, anx ty pain, fev pilocarpine, m scarin nt p ret cs Ipecac n cotin, alcohol. It is inhibited by cold, ahydremia, stri gents and tropine Sweat comes from the pores in three ways profuse intermittent and combined, observed Lob t and Osterberg (ADS 56 46 , SIP 5 194 5 69 1945 JID 6 63, 1945 th ir report on ingenious work with single-duct orifices.

If pe h dros was produced b faradic stimulat on of the kin in experiments pe formed by W lk et al. (Brain 61 9 , 1938 who interpreted their results as showing the te f l cal axone reflex overlapping medi ted l y postganglional sympathetics

Absorption by the skin occurs to a considerable degree Abrasion greatly increases the absorptive capacity Iodine sprayed on the skin appears in the urine and saliva in 20 minutes. Mercury is effectually administered by inunctions and vaccines and hormones can be given so Fats with substances dissolved in them absorb largely through the follicular openings (Macht J 110 409 1938 Rothman JLabClinM 28 1305 1943 Mackee et al. JID 6 43 1945) The entrance of water through the skin was proved by Szczesniak et al (Sci 113 293, 1951), using radioactive water

Some gases are absorbed, such as CO_2, NH_3 and H_2S but not CO according to Iburgi (Brux méd 16 1451 1936) Lead poisoning has been known to occur when lead subacetat compresses were used on a patient with exfoliative dermatitis. Bichloride of mercury baths may cause mercurialism in patients with widespread exudative dermatitis. Mercurial inunction results in the absorption of mercury probably from that which has entered the sebaceous follicles (Cole et al.: J 77: 2022, 1941) Methyl salicylate in an ointment can be absorbed through the skin so as to yield urinary excretion level comparable with *those found when aspirin is given by mouth* (Beutner et al.: JLCM 29: 1655, 1943) The incorporation of wetting agents greatly enhances penetrability (Duemling: ADS 43: 264, 1941) Hormones are absorbed percutaneously and produce their physiologic effects (Eller and Wolff: J 114 1503, 2002, 1940)

The penetration of stearic acid into the skin of the rat was interestingly studied by the use of radioactive stearic acid by Butcher (JID 1: 43, 1953) While both the epidermis and dermis acted as barriers, yet radioactive material diffused deeply and widely *throughout the dermal connective tissue the amount of absorption depending on both the* quantity applied and the number of applications.

Intradermal Absorption —When physiologic saline is injected intracutaneously its resorption time, quaddel resorptionszeit (Q.R.Z.) may be interpreted as an index of the state of hydration and the degree of edema. This McClure-Aldrich test was studied with special reference to dermatology by Canizares et al. (JID 13: 323 1949) The disappearance time was fast in exfoliative dermatitis, urticaria and disseminated lupus erythematosus. It was usually fast in bullous dermatoses but was slow in pemphigus foliaceus. Disappearance time less than 55 minutes was considered faster than normal by Hoppe and Christopher (MOO 69 637 1939)

Heat Exchange is accomplished by conduction radiation and evaporation of sweat. This is regulated by nervous activation of the sweat glands and by dilation or constriction of the capillary bed. *Heat loss by evaporation depends* upon humidity and air movement loss by radiation, upon the external temperature and garments. Emotion induces acral cooling by vasoconstriction and hyperhidrosis (Mittelmann and Wolff PsychosomM 1 271 1939 5 211, 1943) The mechanism of heat loss and temperature regulation was discussed by DuBois (AnnIntM 12 389 1938) who emphasized the fact that about *15 kg of tissue is located within 1 cm. of the body surface.*

Temperature.—Investigations of cutaneous temperature are not of great practical importance in dermatology but they have significance in the consideration of vascular diseases. Normal temperature, dependent on environmental and body temperature as well as that of structures immediately underlying ranges usually between 33.5 and 36.9° C Obese persons have lower skin temperatures than thin ones. Symmetric areas have about the same temperature differences exceeding 1° C being scarcely normal The extremities show great variation with environmental changes. If an arm is immersed in hot water the skin of the toes and forehead normally becomes warmer The failure of the toes to warm up under this condition (used as a test) indicates vascular obstruction of some sort. If the arm is immersed in cold water instead of hot, the converse takes place, and failure of pedal temperature response means vascular inadequacy The removal of sympathetic vasoconstrictor influence causes elevation of the temperature of the extremities in vasospastic disease, but not in an occlusive vascular disorder Skin temperature is raised by capillary dilation lowered by constriction. Active hyperemia induced by irritants or inflammation results in increased warmth (Bierman J 106 1158 1936)

Skin temperature seems to diminish with increase in age. Muscular exertion produces a brief fall followed by a considerable rise. There is close relationship of basal metabolic rate and skin temperature. Blushing increases the warmth locally The extremities are more responsive to changes in temperature than are other parts of the body The fore-

contains a little urea uric acid, creatinin ethereal sulfates, and other organic bodies. In uremia chlorides and urea may be deposited in crystals on the skin from dried perspiration. See Barney (J 85 1373 1925) Loss of vitamins by sweating even if profuse is probably negligible excepting perhaps niacin (Mickelson and Keys JBiolChem 149 479 1943)

The chloride content follows the average skin temperature rather than the rate of sweating (Weiner and Van Heyningen abs YBD 1952, p 391) dietary chloride influences sweat chloride independently of other factors. The acidity appeared due chiefly to the lactic acid content which ranged from 247 to 336 mg % in the normal higher in males, according to Thurmon and Ottenstein (JID 18 333 1952) The sweat gland is normally a sugar barrier capable of concentrating urea and perhaps able to form ammonia as the kidney does profuse sweat differs from intermittent sweat in that the former contains no measurable uric acid.

The normal pH varies in different areas, and, from single glands, was from 5 2 to 6 8 but not related to the urinary pH There was no significant correlation between the sodium chloride contents of blood urine or sweat.

There is usually little correlation between sweat composition and disease of the skin according to Levin et al (UCutRev 44 307 1940) However when ACTH or cortisone is given the normal mean value of sodium and chlorides is greatly diminished, while patients with untreated Addison's disease show concentrations of sodium and chloride in the sweat far in excess of the highest normal values (Conn AIntM 83 416 1949)

Insensible perspiration consists in water loss from the skin when drops of moisture are not formed on the surface Temperature humidity and air movement greatly influence the rate of water loss. The intact corneum is the main barrier to diffusion. Insensible water loss is increased by from 3 to 10 times in areas of scaly dermatitis (Felsher and Rothman JID 6 271 1945) There is marked regional variation in the rate of insensible water loss, which is rapid from palms, soles, forehead and cheeks and slower from the trunk arms and legs (Burch and Sodeman AmJPhysiol 138 603 1943 JClinInv 23 37 1944) A film of sweat partially intercepts the erythema producing rays of the sun (Crew and Whittle JPhysiol 93 335 1938)

Secretion is stimulated by heat, wind, sun, exertion anxiety pain, fever pilocarpine, muscarine antipyretics, peras, nicotin, alcohol. It is inhibited by cold, anhydremia, astringents and atropine Sweat comes from the pores in three ways, profuse intermittent and combined, observed Lobitz and Osterberg (ADS 56 462, 819 827 1947; 57 69 1948; JID 6 63 1943) their report of ingenious work with single-duct orifices.

Hyperhidrosis was produced by faradic stimulation of the skin in experiments performed by Wilkins et al (Brain 61 290, 1938) who interpreted their results as showing the existence of a local axone reflex overlapping mediated by postganglionic sympathetics.

Sweating induced by heating and that due to mental, emotional or sensory stimuli are entirely under the control of the central nervous system, according to Chalmer and Keel (BJD 64 43 1952) While thermal sweating is controlled by the anterior hypothalamic center for temperature regulation the center controlling mental sweating has not as yet been accurately localized. From the central nervous system descending pathways relay through the connector cells belonging anatomically to the sympathetic system in the lateral horn of gray matter between the first thoracic and second lumbar segment of the spinal cord These cells may function independently after severance of the cord so as to produce profuse sweating The connector cells in the cord give rise to preganglionic fibers which leave the cord via the anterior roots and the sympathetic chain. They relay in the sympathetic ganglia, the nerve cells of which reach the sweat glands by way of postganglionic fibers traveling in mixed or sensory nerves Curiously while sweat glands [illegible] form anatomically part of the sympathetic system the glands respond to drugs as if controlled by the parasympathetic system being excited by acetylcholine and pilocarpine and inhibited by atropine Volar hyperhidrosis appears to be caused by hyperactivity of central pathways [illegible]

Histochemical changes associated with secretory activity were investigated by Shelley and Mescon (JID [illegible] 1952) the only change is the disappearance of a glycogen-like substance This occurs only after intense sweating and reverses during rest. Glycogen depletion following sweating induced by acetylcholine is a metabolic activity of the lumen cells of the sweat duct as well as of the secretory tubules histochemically demonstrated by Lobitz (Trans ADA 1953) That sweat glands secrete not merely filter is evidenced by the fact that although the urea content of blood and sweat are parallel, the sugar content is low in sweat [illegible]

for little It would seem that changes in pressure and motion are particularly important in causing particles to enter lymphatics and to move along them and this may occur rapidly and without trauma to the lymphatics. The entry of solutions into the lymph system after their introduction into the skin is rapid Hudack and McMaster (JExpM 55: 431 1932; 56: 223 239 1932; 57: 751 1933) demonstrated

In a dependent extremity the flow stops, McMaster (JExpM 65: 347 373 1937) found while in the horizontal position the flow is slow if the part is allowed to hang and then is raised the flow is brisk the flow stops during venous obstructions and is brisk in reactive hyperemia.

Tissue fluid is thought to be simply a filtrate The normal gradient of blood vascular permeability depends on integrity of the vessel walls and the gradient is unaffected until walls are so damaged as to produce edema Sabin believed that there is a special system of large tissue spaces arising from small spaces by a definite method and possessing a definite structure

The lymph capillaries act like semipermeable membranes in allowing entrance of tissue fluid By the intradermal injection of vital dyes Hudack and McMaster showed that the lymph capillaries consist of a wide anastomotic bed with active flow and that any injury physical or chemical, greatly increases permeability at that site Any injection into the skin is in fact intralymphatic, and so it is almost at once systemic. Retrograde dissemination of dye occurs to a rather surprising degree In cardiac edema the lymph flow is slow and in nephritic edema it is rapid. Cannon and Burt (JImmun 27 173 1934) injected living bacteria into the skin and excised the site as speedily as from 3 to 10 seconds later yet this did not prevent entry of the bacteria into the circulation.

Chemical Composition of the Skin.—The outer layers of the epidermis are composed of keratin, an albuminoid, which Wilkerson (JBiolChem 107 377 1934) found to contain 59% histidine, 2% lysine and 10% arginine There are many different keratins, evidently in various hair feather and horn substances. Human hair and nails contain some 1 % cystine the substance that accounts for most of the sulfur in the skin. The amount of cystine in scleroproteins increases with keratinization while the amount of methionine diminishes (Wilkerson and Tulane JBiolChem 129: 477 1939) In keratinization sulfhydryl is converted to disulfide, the concentration of which is about the same in the Malpighian layer as in the stratum corneum (Van Scott and Flesch: ADS 70: 141, 1954; Montagna et al.: JID 23: 23 1954)

Keratin owes its resistance to dissolving to its disulfide bonds in their original position If split without hydrolysis, the reduced material is keratei e which can be reoxidized to metakeratin (Goddard and Michaelis JBiolChem 106: 60 1934) Keratein and metakeratin were prepared from wool, feathers and human hair by Pillemer et al. (JExpM 69: 191; 70: 387 1939) His serologic investigations indicated that species specificity exists among the k ratins d seem to depend on the redox state of sulfhydryl group gs in the protein molecules. Cornification is evidently a protective mechanism nduced by recession from nutrient and decrease in cell metabolism. It is seen in tissue cultures when transplant tion is reduced in frequency, according to Sil er and Chiego (JID 3: 133, 1940) who gave chemical analyses of keratins, which owe their sulfur content to methionine not cystine they thought and which undergo dissolution with quaternary ammonium hydroxides Analyses f the water-sol bl constituents that may be washed off the corneum were made by Spier et al (DW h 130: 1153, 1954)

The normal state of keratin in hai i the lpha keratin form which has a molecularly folded structure according to Taylo (SciNewsSuppl 93: 8 1941) Beta keratin is the stretched form, and hair can be 'set while in this form, retaining its permanent wave when it slowly reverts to the alpha configuration.

The cid-sol ble pigment of red hair wa identified by Arnow (BiochemJ 33: 1281 1939) Iron-containing it was amed trichosiderin by Flesch and Rothman (JID 6: 257 1945), and ts e traction did not change the color of the hair although the light brown granules of the cortex were removed.

Arseni is absorbed preferentially by keratin, and the presence of arsenic in hair may have i teresting criminologic significance (Smith: BMJ 2: 675 1934) From the medicolegal standpoint arsen may reach the hair from external sources, and merely finding it the ha does not demonstrate its source (Young and Rice: JLabClinM 29: 439 1944)

The water content of the stratum corneum is importantly concerned with the flexibility and comfort of the kin. F ct rs i fluencing this were studied by Blank (JID 21: 259 1953) who found that, a corneum was successively stripped off by means of adhesive plaster the rate of diffusion of wate i to the skin increased little until the base of the corneous layer was reached, whereupon an abrupt increase of diffusion rate was observed.

The major barrier against water loss from the skin is evidently this thin layer. Solvents which remove lipid and alter the corneum decrease the water retaining capacity of the skin and also interfere with the capacity of the epidermis for absorption of water. The result is dehydration of the stratum corneum which becomes brittle. This type of investigation has an important bearing on dermatitis due to defatting agents (q.v.)

The sulfur content of the skin was studied by Klauder and Brown (ADS 31: 26, 1935) who found that scales contain 2.5 times as much as the rest of the skin. The normal sulfur content in nails is 3.-% and is less in some nail diseases; the administration of hydrolyzed wool improved the nail in congenital dystrophy. Sullivan et al. (JBiolChem 119 *1 1937) made the interesting observation that in arthritis the cystine content of the nails is reduced some 15%. Zunz (Eléme ts de Pharmacodynamie speciale Masson, 1932, p. 915) reported that removal of the suprarenal cortex increases the sulfur content of the skin by from -3 to 100%.

Microincineration and spectroscopic studies of the ash of the skin have resulted in interesting findings reported by Kooyman (ADS 32 394 1935) and Gaul and Staud (ADS 29 90, 1933 30 433, 1934). There are found magnesium and calcium, sodium and chlorine sulfur iron aluminum, traces of silicon, arsenic, and copper. Adams (ADS 36 606 1937) observed that in rats, the fat free matter doubles between the 10th and 30th days of life increasing less rapidly thereafter. The water phospholipid, total lipid and oxygen consumption decline with advance in age to a relatively constant value. Quantitative analyses of the metal content of the skin, nails and hair were made spectroscopically and the figures reported by Goldblum et al. (JID *0 13, 1953). Hardness and brittleness of nails are not related to the calcium or phosphorus content (Klie: ADS 0 5, 1954)

The chloride content of the skin tends to be kept in the cells, and its balance is maintained even under adverse conditions. On a diet containing less than 1.0 gm. per day it fell in only 10 of 4 cases did not change in 11 and actually increased i 3 (Volk and Fantl Dermatologica 79 91 1939). Steffanson, the Arctic explorer, has long insisted that adding salt to food is a mere matter of habit, not of necessity and has himself subsisted on a meat diet without added salt for many months.

The nitrogenous material of the normal skin surface comprises amino acids, urea ammonia creatine and uric acid in order of decreasing concentration and is due to insensible sweating (q.v. Rothman et al. JID 13 31 1949). Among the amino acids, arginine and citrulline and perhaps ornithine were identified, along with others, by Rothman and Sullivan (JID 13 319 1949) who thought that urea may be formed in sweat glands from arginine by arginase. Arginase activity is present particularly in the epidermis and its amount is increased in abnormalities associated with epidermal proliferation such as psoriasis and verruca but not in basal cell carcinomas or seborrheic keratoses (Van Scott JID 17 -1 1951). It is to be found especially in the prickle cells, not the basal cells. The urea content of sweat exceeds that of the blood but no arginase activity was demonstrable in fresh human sweat (Van Scott 1951)

The cholesterol and phospholipid content of human epithelium ranges from 13 to 4% and 90% of the cholesterol is uncombined (Eckstein and Wile: JBiolChem 69: 181, 1926). Phospholipid comprises only some 3% of the total lipid. The saponifiable fraction has the same od ne umbe a subcutaneous fat. (See Xanthoma.)

Th derm co ist of white con ective tissue collagen and yellow fibers of elastin. These protei consist of approximately 50% carbon, % hydrogen, 17% nitrogen, and ** % ge w th small amount of sulfur and phosphorus. Elastin co tains some 25% gl ine an l t leuci e co tent of ?1% is ten times as great as that of collagen. Elastin easil digested by pepsin.

The m upol saccharides of pig skin were separated by enzyme hydrolysis and fract nat w th lcoh l in th presence of barium by Meyer and Chaffee (JBiolChem 138: 491 1941 who ide tified hyal ronic acid o e part a d, in the other part hexosamine, cet l ro a l a l sulfuric acid. Watson and Pearce (BJD 59 327 1947) reviewed the b och m try of th connecti e tissues with especial i terest in mucopol saccharides. The muc p t n re combin t on of ca bohydrate w th protein classified mainly by the h ra t ri t c f the carboh drate part. The slimy material extracted from connecti e t ssu w th weak lkal e ntain them. Hyaluro ic acid a d other mucopolysaccharides ha bee fou l n huma kin. The lscou nat re of the ground substa ce of the cutis d subcut eou t ssues wh ch offers resistance to the injection and diff on of foreign subst es l ted to these. The abil ty of an experimental animal to withstand t berc lou fect aries versely with the area of spread of an intracutaneously injected ol t . The M M nus stain normally hows an ntensely colored band of polysaccha les t the dermoep derm l junction *nd alterati l this appearance were* observed mos lermatoses but not in scl roderma by Sto ghton and W lls (JID 14: 37 1950)

Th le t se ontent f normal kin, e cl ding th subcutaneou f t layer, ranges from 60 t l o mg pe hundred grams, according to Cornbleet (ADS 36 1078, 193 ; 41 193, 1940 V lues f glycogen range from 68.1 to 94 mg Dextrose values found in skins of diff r t al rs but the amou t i alwa related to th amou t i the blood. Value f l lood ls greater than those for skin. Superficial l rs of human kin contain m re dext se and glycog than deep ones. Intravenou i jectio of dextrose causes sh rp rise the d t ose co t t of the k but onl little increase in the glycogen cont t. Th de t se curv f r the skin parallel that f the blood with a lag l it rise a l f ll. Subcut eou jection of epi phri i reases the content of d trose

and glycogen in the skin, but changes in dextrose val es are greater and more rapid. Inject on of insulin decreases the dextrose content of skin and increases glycogen. Intra cutaneous injection of histamine increases the dextrose content at that site and changes the glycogen value little Local heating of the skin increases the quantity of dextrose at that site with little change i glycogen content. Cold ultra iolet radiation i creases dextrose in the irradiated skin without affecting that of n nirradiated parts, and the glycogen content is not changed. Three hundred fifty r of unfiltered x ray does not in fluence the dextrose content of skin d ring the following week. A reducing agent chrysarobin, increases the dextrose of the skin on which it is applied but does not change the glycogen content. Dextrose i freely diffusible in skin as well as in other tissues and organ but is not stored in the skin.

Inflammation does not change the normal dextrose content f the skin of the rabbit according to Pillsbury and Kulchar (ADS 30: 459 1934) but after injection of dextrose the inflamed kin may have a higher content. Infection of irritated kin appeared to occur more commonly in rabbit receiving injection of dextrose

The vitamin A in the kin was studied by Cornbleet and Popper (ADS 46: 59 194?) using fluorescence methods. Fluorescence of the skin and appendages is charact ristic the epidermi being dark blue b rati lighter blue-gray basal laye dark, and collagen fibers a trong blue A fading green color of vitamin A was noted in fresh material but the vitamin was located in the fat not in the epidermis, even when high doses had been given.

The quantities of water-soluble vitamin in the skin were carefully measured by Lee et al. (JID 20: 19 1953) who gave figures for the concentrations of B_{12}, folic acid, riboflavin niacin pantothenic acid, biotin thiamine and ascorbic acid. The B group vitamins in hair were found to occur in about the same ratio a in other tissues varying with the diet reported Novak and Bergeim (JBiolChem 155: 283, 1944)

Cholinesterase i present in large amounts in the nerve fibers and about the secretory cel l of the eccrine sweat glands, but not about their ducts or about the apocrine glands, fat glands or hai follicles, or in the epidermis (Hurley et al.: JID 21: 139 1953; Magnus and Thompson (BJD 66: 163, 1954) Preserving enzyme activity by utilizing frozen sections, Findlay (BJD 67: 83 1955) mad biochemical and histochemical studies of the esterases of normal human kin. Cholinesterase and lipase w re not responsible for the hydrolys of the este substrates Findlay used. The cytoplasm of all skin cells howed some measure of esterase activity The high concentrations were seen only along the borders of the epithelia. The peripheral dendritic processes of many connective tissue cells showed some esterase activity

Protease in considerable amount can be extracted from the epidermis (Wells and Babcock JID 1: 459 1933) It is possible that epidermal damage produces dermal inflammation as a result of release of proteolytic enzyme

The location of alkaline phosphatase in the skin interested Fisher a d Glick (PSExpB 66 14, 1947) who reported demonstration of this activity in the stratum granu losum, hairs, hair follicles sweat glands a d endothelium of capillaries, especially in the nuclei thereof The enzyme was present in proliferative fibroblasts of scar tissue and n the cellular infiltrate of acne and eczema.

Pigment is discussed on p. 8. Melanin is formed readily in the protoplasm of oxydase-containing cells of fresh skin when sections a e placed in a solution of 3 4 di h droxyphenylalanine (dopa) The role of coppe in pigmentation ha been investigated. Gorter (Nature 136: 185, 1935) found that pigmentation of the hair f cats and rabbit can be reduced by reducing the intake of copper and increased by increasing t. Copper seems t catalyze the in vitro oxidation of dopa

Inflammation is a function of living tissues. Various cellular and hu moral responses are physiologic responses to various kinds of insult physical, chemical, or parasitic. Cells have limited capabilities, and the skin can respond in only a limited assortment of ways. Comprehension of inflammation from both gross and microscopic standpoints and a view of it as an activity with a time dimension are fundamental to the understanding of inflammatory disease of the skin as well as of other organs. The student should have gained this from basic science instruction prior to embarking upon dermatology but nowhere else is inflammation more readily observed

Guiding references include Aschoff (Lectures on Pathology Hoeber, 1924), Rich (APath 22 228, 1936) Menkin (JExpM 67 145, 153, 1938 Sci. 101 422, 1945 ib 105 538, 194 Dynamics of Inflam mation, M cmillan, 1940)

The investigations of Sabin and Joyner (JExpM 68 659 837 1938) and many others concerning the histologic responses of the skin to materials injected intracuta eously con stit te the connecting link between discussions of immunity and pathology The inflam m tory reaction inhibits the dissemination of bacteria at that site. Fixation locally is effectual for foreign animal proteins if the body contains specific precipitin for that protein. Fixation is largely dependent on the early outpouring of fibrin, for this precedes the

appearance of cellular inflammatory response; Menkin was [illegible] at the [illegible] localization [illegible] spread of a given bacterium which had been introduced into the skin [illegible] significantly [illegible] inflammation exudation and thrombosis of local lymphatics. An extract from exudate [illegible] serum [illegible] by [illegible] the [illegible] sequences of inflammation by [illegible] the permeability of capillaries causing swelling of the [illegible] the migration [illegible] polymorphonuclear leukocytes. Menkin (II 8) [illegible] that it contains nitrogen [illegible] leukotaxine.

Some inflammatory lesions result [illegible] complete [illegible] or [illegible] fibrosis or atrophy. Pigmentation [illegible] temporarily enhanced or reduced.

Diffusible substances are absorbed from the [illegible] direct entrance into the blood vessels or into the lymphatics [illegible] serum [illegible] subcutaneously appears in the [illegible] duct lymph within 4 minutes but [illegible] the circulating blood for several hours. Inflammation retards the absorption of diffusible substances [illegible] absorption of diffusible [illegible] and dyes, when they have been injected intracutaneously from an inflammatory site than from a normal one.

Immediately after the injection of an irritant [illegible] a rabbit [illegible] a temporary great [illegible] in the resistance of the [illegible] soon followed by a decrease in resistance. When the irritant injected [illegible] turpentine [illegible] streptococci [illegible] the resistance falls to normal with [illegible]. With staphylococci or pneumococci [illegible] normal [illegible] it remains above normal for a week or more with tuberculin. In all [illegible] inflammation, the preliminary period of resistance [illegible] diminished [illegible] appears sooner (Zaders: Jl [illegible] 1[illegible]3).

The Sanarelli-Shwartzman Phenomenon is a hemorrhagic and necrotizing inflammatory response which appears promptly after the intravenous injection of a bacterial filtrate in a site which 24 hours previously was injected intracutaneously with that bacterial filtrate (Shwartzman Phenomenon of Local Tissue Reactivity Hoeber 1937 Sanarelli J 107 18[illegible] 193[illegible] Annin t Pasteur [illegible] 10[illegible] 1939). This type of reaction may perhaps underlie the relationship of focal infection with certain disease processes. ACTH given before *the provocative injection suppressed the phenomenon in 8 of 10 animals* tested (Soffer et al Sci 111 303 1950). Nitrogen mustard also completely suppressed the effect (Race and Reed SouthMJ 4[illegible] 207 1953). A fatality induced by antibiotic therapy was attributed to the Shwartzman reaction by Nelson and Braslow (ADS 68 728 1953). The significance of the phenomenon in the etiology of dermatoses with reference to purpura gangrene leprosy and acute pemphigus, was discussed by Rostenberg (JID [illegible] 789 1953).

Such inflammation was described from the standpoint of histopathology by Stern (APath [illegible] 41 1938) and [illegible] Stetson (JExpM 93: 4[illegible] 1951). Swelling at the site [illegible] to necrosis. There are [illegible] polymorphonuclear cells [illegible] of the [illegible] with serous and fibrinous [illegible] red blood cells [illegible] Small [illegible] capillaries are plugged by leukocytes and platelet thrombi [illegible] found in lymph nodes as well [illegible]. Polymorphonuclear and mononuclear leukocytes encircle the vessels and penetrate the wall. In the [illegible] the cellular infiltrate resembles granuloma. Increased capillary permeability allows the outpouring of fibrinogen, the deposition of fibrin, and *the thrombotic localization [illegible]*.

Immunology.—The skin is an important organ from the standpoint of immunity. The breadth of its function is indicated by the fact that a great variety of antigenic substances inoculated intracutaneously evoke responses which are characteristic and useful for diagnostic purposes. Among such tests are those for tuberculosis, chancroid, Brucella infection, trichophytosis, moniliasis, echinococcosis and venereal lymphogranuloma. Extensive lists with bibliography are given by Sutton and Sutton (Diseases of the Skin, Mosby 1939 p. [illegible]) and by Baer and Yanowitz (ADS 6[illegible] 491 1950). For a careful discussion of the values and dangers of intradermal tests, see Beerman and Ingraham (AmJMSc 220 415 1950). Percutaneous immunization is possible. Intracutaneous immunization requires comparatively little antigen.

Specifically Altered Reactivity (Allergy) of the skin is closely interrelated with immunity. From a broad standpoint an allergic reaction is an ineffectual and distorted immunologic one. Allergic reactions comprise not only specifically acquired hyper-reactivity (hyperergy) but also specifically

acquired hyporeactivity (hypoergy) and specifically acquired immunity (anergy) Excessive reactivity of the skin varies as to degree. In a given skin, reactivity may fluctuate with nervous, emotional or physiologic activity An allergic response depends on reaction of the noxious substance (allergen) with the susceptible skin immediately in the form of solid liquid dust or gas, or mediately by way of the blood (Sulzberger et al J 104 1489 1935 YBD 1943 p 7 1944 p 7 1945 p 7) Newer concepts of allergy to drugs and bacteria were interestingly set forth by Lowell (J 136 665 1948) Allergy seems to explain a great deal but allergy itself is difficult to explain

See Duke (Allergy Asthma, Hay Fever, Urticaria and Allied Manifestations of Reaction, Mosby, 1925); Sulzberger et al (J 104: 1489 1935); Sulzberger and Goodman (Mitre 143 17 1936) Sulzberger (JAllergy 7: 308, 1936); Sulzberger (Dermatologic Allergy Thomas, 1940); Urbach and Gottlieb (Allergy Grune & Stratton, 1944); Sulzberger Baer et al (Office Immunology Including Allergy Year Book Publishers, 194); Raffel (Immunity Hypersensitivity Serology Appleton-Century-Crofts, 1953, p. 631)

Alteration of reactivity does not denote allergy unless the alteration is specific A skin irritated by a caustic, for example, manifests sensitivity to mercuric chloride but not specific hypersensitivity; a skin manifesting contact dermatitis, whatever the cause usually manifests excessive irritability to soap and its erythema is intensified by warmth but these are not allergic reactions

Von Pirquet and Schick (Die Serum Krankheiten Leipzig 1905) found that an animal after responding to a first injection with a foreign serum reacts differently to a second injection of the same protein. There was needed a lapse of time an interval of a week or more for development of the change and this period of some 8 to 13 days corresponds to the incubation period of many infectious disorders. For altered reactivity they suggested the term allergy One dose of horse serum provokes hypersensitivity in the guinea pig but repeated tolerated doses induce immunity reported Weil (JMRes 27 497 1913) and the serum of the immunized animal will induce hypersensitivity in a normal one Weil indicated thus that the same antibodies are present in allergy as in immunity but in the former their location is predominately in the cells, and in the latter in the serum The immunized animal is potentially anaphylactic, his cells possessing anchored immune bodies, but he is protected by immune bodies in his circulation. Allergic reaction apparently is due to reaction between specific antibodies in cells with the introduced antigen. In immunity on the other hand antibodies present in the serum neutralize introduced antigen and so protect body cells

It is believed that as a result of antigen-antibody reaction, stored up vasodilator substances are set free from the fixed tissue cells, and these freed histamine-like substances are the immediate cause of the typical allergic reaction (Dale and Laidlaw: JPhys 52: 355 1919) It may be that histamine is actually the noxa so released for histaminase is said to diminish allergic reactivity and injections of histamine may induce refractoriness to histamine and diminution (but not disappearance) of allergic reactivity (Edit J 115 1023 1940) Benadryl relieves serum sickness (Peterson and Bishop J 133 1277 1947) and antihistamine drugs are effectively palliative in urticaria hay fever and asthma presumably by virtue of their ability to nullify histamine

Anaphylactic shock has long been attributed in the main to products of proteolytic digestion in the blood plasma. When serum is rubbed up with agar starch or kaolin it becomes anaphylotoxic. Dale s experiments, according to an Editorial (BMJ 1 807 1952) indicated that histamine was released and that anaphylactoid phenomena seemed explicable on the basis of production by these agents of tiny emboli composed largely of platelets and leukocytes. If the isolated liver of a sensitized dog is perfused with a fluid containing all the blood cells histamine and heparin are released in large amounts and the release of histamine is accompanied by the formation and disintegration of microthrombi of platelets and leukocytes in the liver capillaries. The amount of histamine released greatly exceeds, however t amount available from the cells that disintegrate. Likewise when seru

cubated with agar is perfused through guinea pig lungs again much histamine is released Rocha e Silva et al (BMJ 1 702 1952) showed that 4% isotonic trisodium citrate in water appeared to protect the platelets from disintegration and to prevent the development of anaphylatoxic properties in the serum so that it had therapeutic value

Allergy to tannic acid a non-nitrogenous simple naturally occurring compound was observed in a patient whose scratch test was of the immediate urticarial type and whose reactivity was passively transferable by Johnston et al (J Allergy 22 494 1951)

Histologic changes are correlated with immuno-allergic processes When local reaction rapidly destroys attenuates or otherwise renders innocuous microorganisms or their products tuberculoid structure usually is found (Jadassohn-Lewandowsky law) Tuberculoid structure is not seen as a response to drug allergy

Configuration of lesions grossly is also frequently correlated with immuno-allergic processes. When a zone of absolute or relative specific resistance develops peripherally the local process may assume a corymbiform shape for satellite lesions are impeded in their growth Central healing results in annular shaping for the healed zone manifests increased immunity (cf Koebner phenomenon) while the spreading margin manifests activity While disease processes are often explained by immuno-allergic theory explanation of the explanation leaves a good deal to be desired Compare these arguments (1) annular shape results from development of immunity in the cen

tral part of the lesion so that the central part heals and (2) the central part has healed so that immunity may be assumed to have developed there Some investigators appear to see from within outward.

THE ARTHUS PHENOMENON is characterized by the provocation of progressive infiltration induration edema and aseptic gangrene in a site by repeated injection of a foreign protein Such anaphylactic gangrene has followed the repetition of injections of antisera into human beings (Tumpeer et al J 96 1772, 1931 Irish and Reynolds: J 100 490 1933)

SENSITIZATION OR CONTACT TYPE, which is without circulating antibodies, is the basis of a large proportion of dermatologic practice Sensitization may be provoked by the most diverse substances see p 118 ff

SKIN TESTS are discussed with Dermatitis venenata (q v) A positive skin reaction to an allergen reveals a person with allergies (positive reactor) who may or may not have active clinical allergic symptoms, wrote Peshkin (J 157 820 1955) all forms of testing are best regarded as furnishing confirmatory rather than final evidence Skin testing with food antigens especially is of restricted value and in children elimination of foods from the diet solely on the basis of skin tests may seriously interfere with nutrition and at the same time not help the allergy (Edit J 157 825 1955)

FOOD TESTING —Mistaken confidence in food tests has resulted in erroneous interpretation of dermatoses which were actually due to malnutrition infection and contactants food allergies are in fact not common I agree with Babalian (Maine MAJ 39 194 1948) Skin tests with foods, regardless of the type of material used and the method of testing yielded results not over 40% accurate in the extended experiences of Rinkel (JMoSMA 40 91 1949) Skin testing with a food extract killed a patient of Swineford (J Allergy 17 24 1946)

Hyposensitization is a state of partial protection which is induced by small repeated doses of an allergen Hardening occurs in perhaps 90% of industrial employees who handle irritating chemicals (such as TNT) an ability to withstand further contact without irritation a fact which Schwartz taught skeptical dermatologists. Abstinence from contact with the sensitizer may be followed in a few months by loss of this immunity The case usually seen by the dermatologist is the one who is unable to develop hardening Schwartz (ADS 42 318 1940) pointed out

The therapeutic establishment of an antianaphylactic state is not often satisfactory in dermatology It is better to discover the offending material if possible and to segregate the patient from it In practice segregation can generally be accomplished without identifying the allergen positively see Dermatitis venenata treatment

Deallergization (Urbach JID 3: 493, 1940) may be attempted in various ways and it may be partial or total and temporary or permanent. Generally it is sought by repeated administration of minute doses of the antigen such that no gross reaction takes place If an overdose induces macroshock, and if the animal survives, it is deallergized for life Urbach coined the word keptophylaxis for the procedure of giving little doses intended to consume the tissue antibodies and he thought it worked best when attempted orally Hyposensitization in the contactant type of allergy is, for all practical purposes, a failure—it does not work. It is difficult to convince the medical public of this fact, for there is great popular faith in, for example, poison ivy shots. Regarding palliation of allergic symptoms by means of drugs, see Treatment Antihistamines, and Cortisone and ACTH.

Classification of Allergic Phenomena.—Sulzberger and Goodman (MRec 143 17 1936) defined allergy as an altered state of reactivity by a first contact and made manifest by subsequent specific contacts. The term allergy must therefore include acquired hypersensitivity hyposensitivity and absence of sensitivity all probably due to closely related mechanisms.

I. **Anaphylaxis**—occurs in laboratory animals is specific is linked with particular phenomenon is associated with antibodies which occur with (and may be identical with) precipitins

the bronchioles, and the vascular apparatus of the superficial cutis. The reactions of the contact form of allergy are located primarily in the epidermis. The skin is frequently implicated in many different forms of allergy but no organ is immune. The commoner forms of allergic response include

Localized Reactions

HEMATOLOGIC SYSTEM: bone marrow lymphatic system, perhaps the blood cells themselves, agranulocytosis; thrombocytopenic purpura, etc., eosinophilia.

EYES: especially iri conjunctiva, lens; iritis; vernal catarrh, etc.; cataract in atopic dermatitis.

NOSE AND SINUSES: rhinitis, acute and chronic sinusitis, polyps

BRONCHI AND LUNGS: asthma; other acute and chronic infectious and noninfectious processes.

SKIN: contact dermatitis urticaria and angioneurotic edema, atopic dermatitis miscellaneous dermatological manifestations, such as generalized r localized erythemas, erythema nodosum and erythema multiforme; drug eruptions (acneiform, furunculoid, fixed purpuric); and infectious exanthemas, such a in syphilis, leprosy and the exanthemas f childhood.

GASTROINTESTINAL TRACT: various types of acute or chronic, spastic, or inflammatory reaction.

LIVER: acute yellow atrophy arsphenamine jaundice, et

GENITOURINARY TRACT: cystitis (?) nephritis (?)

JOINTS: arthritis, intermittent hydrarthrosis.

CENTRAL NERVOUS SYSTEM: migraine epileptiform seizures, asthenia, psychic disturbances (especially in children) neuralgia, transient paralysis and nerve dysfunction (?) and perhaps some organic diseases, such as multiple sclerosis.

CARDIOVASCULAR SYSTEM: hypertension (?) hypotension (the rule) cardiac irregularities tachycardias, extrasystoles bradycardias, precordial pain. Buerger s disease (?) migratory phlebitis (?) periarteritis nodosa (?)

Generalized Reactions

ALLERGIC SHOCK: subnormal temperature, slow pulse lowered blood pressure prolonged coagulation time, increased N P N decreased blood chlorides, decreased blood calcium and phosphorus, decreased sugar tolerance leukopenia.

SYMPTOMATOLOGY AND PATHOLOGY

Dermatologists are not strict rhetoricians in the differentiation of symptom and sign. Dermatoses are brought to them by their patient because of itching more commonly than for any other single complaint. Itching, burning, tension, dryness, cracking, crawling, tingling, soreness, pain, numbness are words used by the sufferer. He may feel a bump or roughness or describe his sores or blisters or complain of unsightliness. He may be heeding the excellent advice nowadays well publicized to attend to a small matter even though asymptomatic because its consequences lie not within his knowledge.

Objectively, external manifestations in cutaneous medicine are composite pictures resulting from the conjoint development of various elementary lesions. These essential primary eruptive elements are relatively few and simple. As a result of the continued action of a pathologic process, secondary infection or trauma, primary lesions may undergo various modifications and so be transformed into consecutive or secondary lesions. The following definitions of gross and microscopic lesions afford a basic vocabulary for description of what is to be seen. But they are not sufficient for the dermatologist is obliged to a l l numerous adjectives concerned generally with color, texture, distribution, temperature and even odor in order to describe with some accuracy and completeness. His finger tips help a dermatologist greatly and his nose not a little.

Gross Lesions.—Each has an underlying histologic basis, and the student must constantly strive to interpret from visible processes their microscopic make-up. The microscope is only an adjunct to the eye. It does not introduce a new world. Any lesion is a manifestation possessing three dimensions in space and a fourth in time and yet another in the psychologic and sociologic relationships of an individual.

PRIMARY GROSS LESIONS

Macules are circumscribed discolorations of the skin which are neither elevated nor depressed.

Papules are small variously shaped circumscribed solid elevations.

Wheals are rounded, elongated or irregularly shaped edematous, transitory elevations of which hives are typical examples.

Nodules are circumscribed solid masses which may lie above, level with or beneath the surface. Tubercles are nodules of bean- to pea-size, firm and deeply seated. Tumors are variously shaped lumps of relatively large size.

Vesicles are circumscribed pinpoint to pea-sized elevations containing free serous fluid. Blebs, or bullae, are vesicles of large size. The burrows of scabies are linear mite-made vesicles, overlying secondary inflammation.

Pustules are circumscribed elevations containing free purulent fluid.

Telangiectases are tiny red linear lesions due to the presence of dilated capillaries.

SECONDARY GROSS LESIONS

Excoriations are superficial traumatic discontinuities of the skin.

Fissures are linear breaches of continuity generally sharply defined with abrupt walls and inflamed bases.

Scales are dry or greasy laminated masses of superabundant epidermis. They range in size from minute furfuraceous fragments to large sheets of horny material.

Crusts are masses of dried exudate

Ulcers are irregularly sized and shaped excavations of the integument due to injury or disease Connective tissue is lost and healing results in scar

Scars, or **Cicatrices**, are connective tissue new formations which replace loss in substance in the fibrous layer of the skin.

Microscopic Lesions are the basic morphologic changes upon which rest the gross evidences of disturbance They may be cellular, intercellular humoral or mixed. Inflammation (q v) is discussed as a physiologic process. Histologic descriptions of diseases are found throughout the text

CHANGES IN THE EPIDERMIS

Hyperkeratosis is hypertrophy of the horny layer as in callusea. Nuclei are not visible in the keratin mass.

Parakeratosis is retention of nuclei in the cells of the horny layer due to defective keratinization.

Acanthosis is thickening of the stratum germinativum due to increased mitosis in the rete cells.

Inclusion bodies are intracellular bodies, such as are seen in Darier s disease highly anaplastic carcinomas, and virus diseases, such as herpes, molluscum contagiosum and variola.

Atrophy consists in general thinning of the epidermis with diminution in the accessory epidermal structures and flattening of the papillae It is usually due to defective nutrition from the corium, or to stretching over an enlarging dermal mass.

Edema, when intercellular spongiosis, is shown by widening of inter cellular spaces. If the severity is such as to rupture the intercellular bridges, the result is an intraepidermal vesicle Intracellular edema takes several forms. In reticulierende collaquation, vacuoles develop in the protoplasm of several cells, the nuclei degenerate, the cells swell to bursting and multilocular vesicles are formed. In ballonierte degeneration, ' young epithelial cells balloon up and become loosened one from another so forming a vesicle In alteration cavitaire, the protoplasm becomes homogeneous and stainless, and perinuclear edema appears, which may increase till the cell ruptures, a third method of intraepidermal vesicle formation

Neoplastic proliferation occurs from the epidermis (basal-cell and squamous-cell carcinoma) and from the epithelium of accessory structures (epithelioma adenoides cysticum) Malignancy is indicated by profusion of mitoses, metaplasia of the cells, invasion beyond a basal membrane and abnormal position of active epithelium.

Pseudoepitheliomatous hyperplasia exists when the normal epidermis is notably hyperabundant, as it may be in response to granulomatous inflammation of dermal papillae or at the edges of chronic ulcers.

CHANGES IN THE DERMIS

Fibrous tissue may be hypertrophic (keloid elephantiasis) or atrophic (old irradiation scars, senility) It may undergo colloid change as in hyalinization of old scars, or mucoid change as in x ray dermatitis. Amyloid deposits may occur about the capillary loops. Lipids of various kinds may be deposited intracellularly or intercellularly or both. In rare instances calcification is found. Degenerate collagenous tissue which stains like normal elastic tissue is called collastin Burns, caustics, powerfully toxic substances, and vascular occlusion are causes of necrosis.

Elastic tissue may be overabundant, as in cutis hyperelastica, or defective, as in epidermolysis bullosa. Elastic fibers that become thick, swollen, broken up and abnormal in staining properties, form what is called collacin.

Infiltrations with various cell types may be localized, perivascular and perifollicular or massive They consist of various proportions of polymorphonu-

clear leukocytes, lymphocytes, mast cells, plasma cells, and cells of reticulo-endothelial origin including giant cells. Histiocytes are cells capable of ingesting foreign substances. The infiltration may be circumscribed or limited to relationship with certain structures or it may form a massive cell infiltrate without reference to vessels or glands. With inflammatory infiltration are associated fibroblastic and endothelial proliferation. Acute processes are characterized by numbers of polymorphonuclear leukocytes; more chronic ones have higher proportions of lymphocytes, eosinophils, and plasma cells. Neoplastic cell infiltrations occur.

Vascular changes consist of vasodilation as in mild sunburn, edema wherein fibers are further separated than is normal and may take a foggy stain, hemorrhage by rupture as in trauma, or by diapedesis as in purpura, inflammation, and thrombosis or occlusion, partial or complete, as in peripheral vascular disease with gangrene (q v). Necrosis occurs in new growths which outrun their vascular supply, as in gummas or caseating tubercles.

Fig. 14—Necrobiosis of dermis with palisade arrangement of histiocytes, in granuloma annulare. (Dr H. Pinkus.)

Pigment occurs in chronic inflammatory conditions as an oversupply of melanin. It occurs abnormally as hemosiderin after hemorrhage into the skin. It is produced abnormally in large quantity as melanin in both benign and malignant neoplasms. Pigment of extrinsic origin occurs in tattoo.

Neoplastic changes in the dermis may affect any structural element there present. Hemangioma, lymphangioma, fibroma, neuroma, myoma, even osteoma, are found, along with sarcomas of various kinds, primary or metastatic.

ETIOLOGY

Etiology is derived from the Greek for "discourse upon causes" and is defined as "the sum of knowledge concerning causes." One must be very wise to know much about causes, for things which might be called simple turn out not to be when scrutinized. As a physician's age and experience increase and his comprehension of the individual problems he meets in his daily work becomes more detailed, his sense of insecurity becomes greater regarding the ultimate knowledge of the nature of causation and its relation to time, for sequence is an inherent part of cause and effect, and to happenstance, for a phenomenon has its unique four dimensions of space and instant. So we can talk longer about a given phenomenon but seem to ourselves to be less on the point and rather to be merely in its vicinity. The cut finger of the housewife whose paring knife slipped becomes not merely a proposition of sharp steel, yielding flesh and physical dynamics but takes on in addition the contributing relationships of whether the woman felt well, slept well, hastened because of social commitments, was angry with her husband or preoccupied with thoughts of the illness of her child. Were her hands slippery with detergent, or her fingers cold and clumsy because the furnace failed to operate correctly—and if it didn't, why didn't it? Was the tool ill designed for its intended use? Why did she not plan something for that meal other than something that had to be pared? The restless mind pursuing the endless ramifications of the "simple" trauma finds itself flustered and dissatisfied even though its sum of knowledge regarding causes is richer than a superficial and naive estimate of the event.

Etiology and diagnosis are inseparably interrelated. To diagnose, or "see through," one must comprehend the intricacies of the background. On the other hand, if one possessed full comprehension of the etiologic background, one would certainly "see through" in the diagnostic sense. An old dermatologist, if he were not too old, could lecture for an hour without preparation or reference to notes on any one of the succeeding sentences of this brief chapter.

In the skin the changes that take place as a result of disease follow the same laws that apply to changes in other parts of the body. Damage may be sustained directly or indirectly. Indirect damage may be mediated by the *blood vascular, lymph vascular or nervous system. Many disorders of the skin are secondary to some derangement of the internal economy.* Others originate in the skin itself and confine their action to this organ alone. The skin is exposed to injurious agencies as other organs are not. *Combinations* of factors are frequently at work in any given patient, so that a dermatologist must daily unravel problems which necessitate a multiplicity of simultaneous diagnoses, a multiplicity astonishing to monodiagnostic purists. For example an age-sex-occupation predisposition in combination with a trauma-medicinal-parasite excitation may explain a secondarily infected, medicinally irritated hangnail on the finger of a stenographer whose digits would not have been rough if she did not scrub off carbon, and who developed sensitivity to the phenol-sulfonamide component of nail lacquer when she scratched her pruritic disease and who got a generalized severe eruption when the infection was treated with a sulfonamide by mouth.

Predisposing Causes.—*Age.*—Some diseases of the skin usually develop only at certain periods of life, while others may appear at any time. Ichthyosis, angioma, epidermolysis bullosa and congenital syphilis appear in infancy. *Children are particularly susceptible to the parasitic diseases*, such as impetigo, tinea capitis, and favus. Acne vulgaris and psoriasis usually start in early adult life. Pruritus and carcinoma are diseases usually of an older age.

See Lynch (ADS 6 957 193) dermatoses of fetus; Dixon (CanadMAJ 39: 261, 1938) childhood dermatoses; Hill and Montgomery (JID 3 31 1940) histology of aging changes; Mintzer (ADS 4 4 3, 1940) dermatoses in girls; Brunsting (TexasSJM 37: 32, 1941) childhood dermatoses; Mackee and Cipollaro (Skin Diseases in Children, Hoeber 1946, 440 pp. 220 ill. s., bibliography); Ormsby (J 138 431, 1947) dermatologic geriatrics; Strobel (AfDuS 186 676, 1948) disease hazards during aging; Lane and Rockwood (NEnglJM 241: 772, 1949) geriatric dermatoses; Kennedy et al. (SouthMJ 43: 128, 1950) skin dermatoses.

Sex is a factor in the etiology of many cutaneous disorders, not only hormones but also habits being concerned.

See Severinghaus (ADS 43 63, 1941) endocrine dermatoses; Lynch (Min M 23: 629 1940) endocrine (Lller and Kest NYSJM 40 182, 1940) endocrine Dunlop (BJD 63 43, 1951) hormones and dermatoses; Wy and Andrews (ADS 61 578, 1950) hormone therapy.

Race and Nationality.—The proclivity of the Negro to keloid, for example is well known (Lewis: PIM(Chi 1 : 11, 1919). Skin cancer is unusual in the Negro as are also neuroses, melanoma, pediculosis xanthoma and extragenital chancre while one often sees acne cheloidalis dermatosis papulosa nigra, pustular syphilids and granuloma inguinale (Hazen ADS 31: 310, 1933).

See Loewenthal (JTropM 41 187 1941 4 20, 36, 52, 99, 1942) African Negro diseases; H n (SouthMJ 32 276, 1939) ; Lab and Pool (AmJMSc 196 25, 1938), Negro; Clark (JTropM 61 49 1951) climate and race; Arnold (ADS 53 6, 1946) Hawaiians.

Heredity.—Familial incidence is a feature of some dermatoses as in ectodermal dysplasia keratosis palmaris et plantaris and epithelioma adenoides cysticum. Most persons who develop squamous cancer of the exposed skin have inherited their susceptible type of sun-sensitive skins. Syphilitic infection may be acquired by the fetus from its mother during gestation. An hereditary bent toward sensitization of the urticaria-eczema-asthma type is recognized. See Cockayne (Inherited Abnormalities of the Skin Oxford Univ Press, 1933); Lller (JCutRev 43: 657 1941).

Seasons.—Prickly heat pruritus aestivalis and the superficial staphylococcic infections are usually diseases of the summer months. Ichthyosis and psoriasis are generally more troublesome in winter. Diseases of plant or animal origin, such as ivy poisoning, ragweed dermatitis, harvest mite and spider bites manifest seasonal frequency of occurrence for obvious reasons. Climatology especially as it relates to atopic dermatitis and Texas weather was interestingly discussed by Smith and Harrett (ADS 68: 79 1953) who pointed out that moving to a new location not only affects humidity temperature and circulation of air but also influences nervous tension and chemical contacts. Heat and humidity *combine to increase liability to prickly heat*, bullous impetigo and *hidradenitis* especially when the minimum temperature remains high (Horne: JID 18: 10 105) See Physiology keratin; Dermatitis due to defatting; Anhidrosis.

Occupation.—Numerous irritants are used in both household work and trades, and so frequently do these various substances give rise to dermatitis that occupational dermatoses (q.v.) comprise an important class of dermatoses of medicolegal importance.

Coexisting Organic and Constitutional Diseases.—Sometimes the development of a cutaneous disorder largely depends on the coexistence of an organic or constitutional disease. Tuberculosis, scrofuloderma and the tuberculids are frequently closely associated as might be expected. The *relationship of diabetes mellitus to xanthoma diabeticorum*, and *to moniliasis*, pruritus and staphylococcic parasitism is a matter of common observation. The relation of impaired liver function and macrocytic anemia to chronic eczematoid dermatitis has received the attention especially of Ayres et al. (ADS 62 851 1950). Cutaneous manifestations occur in the majority of systemic diseases. See Wiener (Skin Manifestations of Internal Disorders, Mosby 1947); Montgomery (MinnM 22 451 1939).

Deaths from dermatoses were reported on by LeVan and Sternberg (ADS 59 101 1949) the majority they found, having been caused by pemphigus, exfoliative dermatitis and neoplasms, but a toll was also taken by other kinds of dermatitis, stasis ulcers, herpes zoster syphilis *disseminated lupus erythematosus* erythema multiforme and a miscellany of statistically minor causes.

Focal Infections.—A persistent nest of pathogenic microorganisms may reside in dead or diseased teeth pyorrheic gums, tonsil or tonsil tube, paranasal sinuses, vagina, pelvic organs, prostate bladder or rarely appendix or gall bladder. Occasionally escaping from a focus, parasites may provoke ... or complicate cutaneous disease. A skin which has been chemically irritated may be vulnerable to bacteria of the oral flora which were previously unable to invade the skin. In focal infection in the mouth (q.v.) streptococci are the usual agents. Monilia, too, occur in focal infections particularly of the vagina or nails, and cause trouble when opportunity avails.

A focus of infection is defined as a commonly occurring host parasite relationship wherein pathogenic organisms are located in the host in a circumscribed lesion from which they can be eliminated only by mechanical means, such as extraction, excision or plastic repair (Sutton and Andrews ADS 68 774, 1953).

See Editorial (J 133 111 1947) fact, not theory; Edit (J 134 698, 1947), tonsil stumps; Ayres and Anderson (ADS 34 431 1936) ; Van Stoddiford (SouthMJ 36 225 1943), intestinal worms as foci; Elliott (ProcRoySocM 32 747, 1939) bacteremia and oral sepsis; Epstein and Macaulay (ADS 57 736 1948), bullous eruption not cured until infected teeth were removed; Reisman and H ens (J 114 1 1940) conservative; Curtis (JAmDentA 42 88, 1951) against the whole idea; Chobot (J 150 1420, 1952) significance in allergy; Coleman (J 151 330, 1953) "an accepted principle"; Harding and Knopf (NJerseyMSJ 50 153 1953), generalized bullous dermatosis cured by removing infected teeth; Stevens (BGO 63 348, 1954) foci causing recurrent streptococcic infections of the skin, subcutaneous tissues and lymphatics, cases.

PSYCHIATRIC AND PSYCHIATRIC fact r are significant an l are receiving increa ing recognition Because of personality make-up, some people wa h too much scratch too mu h sweat too mu h mistint rpr t or ov remp h ize al ormalities, or perf rm unwholesome act A de mat logi t hould develop hi amateur psychiat ic, ilit y One mu t possess l nol litres regardi g and wide knowledge of how people think, feel, respond, live a l do things if one woul l interpret skin d seases under tan l them and sometimes cure them.

DIAGNOSIS

Confronted by an individual with a skin disease one has a problem to solve A routine of complete examination is indispensable Accuracy and patience are essential Dermatologic diagnosis is eminently based on objective evidence and in general it is wise to look first and ask questions later Gentleness and tact should be exercised especially in dealing with women. Dispensary patients receive the same consideration as private patients. Particularly in cases of puzzling nature the entirety of the patient must be examined. Diagnostic error is more likely to result from incompleteness and carelessness than from ignorance I recommend to the reader who can—and I refer especially to the medical student—that he drop everything at this point and study an article by Waring (AnnIntM 28 1, 1948)

At first glance one notes the apparent age sex and general condition as regards nutrition, hygiene and malaise One looks at all of the eruption removing and replacing clothes if need be and notes specifically the distribution *of the lesions and evidences of grouping then the primary and secondary* gross lesions. Evidence of pruritus is visible as linear scarification and absence of tops of lesions and in chronic cases the nails are worn and polished The type of exudate is seen to be serous, glairy serosanguineous, or purulent. Crusts may need to be removed (benzine is useful) in order to see the bases of ulcers. Scales may be lifted to determine their adhesiveness, noting the presence or absence of uncovered bleeding points. The lesions are palpated, and the sensations of resistance edema induration infiltration or cystic structure are felt. *Important is examination of the lesion pressed under a watch* crystal diascopy which discloses the color unmasked by the presence of capillary blood Apple butter nodules of tuberculous disease are rendered evident; redness of extravasated blood in purpura does not vanish under pressure while that due to simple hyperemia does. The oral mucosa is examined and the condition of teeth gums and tonsils noted. The general and regional lymphatics should be palpated.

At this stage the observer has sufficient data to form a fair idea of the kind of trouble at hand. He has been asking himself whether the complaint is internal or external in origin and whether it is chemical, parasitic or neoplastic in cause But after examination he should know whether the lesion is hyperemic, inflammatory or hemorrhagic whether it primarily affects the skin or skin appendages, whether it is an irritation, infection symptom or general disease or new growth and he should be able to make a canny surmise as to its duration and symptoms. Cutaneous manifestations of systemic disease must be recognized

He may now add to his data pertinent subjective information as to occupation and habits, the duration and sequence of the eruption and the complaints of itching pain or unsightliness. Further questioning of the patient may be desirable or necessary regarding the functions of the various bodily systems, including the endocrine, and the feelings of the patient and his interrelationships, emotional, sociologic and economic, with other people. These facts are important in formulating treatment, for one must treat the patient, not simply his disease

Scrapings from the lesions digested in 10% potassium hydroxide are examined microscopically if fungus infection is suspected Exudate may be examined for sulfur granules of ray fungus, acid-fast bacilli, streptococci spirochetes. Cultural methods are needed for accurate identification of the mycoses. Biopsy furnishes the histopathologic picture (Rhoden ADS 47 580 1943 Ellis JID 13 26, 1949) Various stains may be applied.

If indicated, a general medical examination must be performed and while few dermatologists excel with the stethoscope they should know how to palpate a spleen The blood picture cell counts, hemoglobin and sedimentation rate while requisite to thoroughness in a hospital are not routinely done in private practice but leukemia or agranulocytic angina is hard to diagnose by guesswork The value of the Kolmer Wassermann and related tests is evident Chemical examination of the blood has its place The blood serum total protein is a significant test of increasing popularity X ray examinations of teeth and sinuses are required in running down focal infections roentgenograms are indicated of tumors attached to bone and of vertebrae long bones and skull in search of metastases. Spinal fluid must be examined in syphilitic patients. The basal metabolic rate may be informative (Leszczynski AnnderD 10 177 1939)

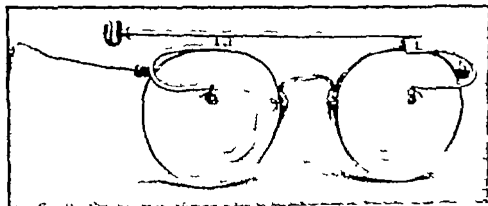

Fig 47 —Magnifying spectacles Accessory lenses, 5 00 spheres with 15-degree prisms, bases in, are mounted in tori strap and pieces connected to hinges on eye wires with L shaped rods allowing unobstructed vision through the distance lenses of the bifocals. Correct collimation and little chromatic aberration, and the glasses may be worn throughout the working day with 2 X magnification immediately available a great aid in both diagnosis and minor surgery (Sutton J 155 1156 1934)

Dermatoscopy by slit lamp or corneal microscope reveals the horny layer and epidermal portions of sweat gland ducts and hair follicles, the pigment and the most superficial blood vessels. Suitable apparatus is expensive and seldom used (Michael ADS 8 603 1923) Surface microscopy using dissection and metallurgic instruments may yield useful information (Goldman and Younker JID 9 11 1947) Photographs may be taken which actually magnify the skin surface (Siebentritt JID 13 281 1949) Capillary microscopy was described and its practical value overestimated by Gilje et al (ADS 68 136 1953)

Diagnosis aims at determining etiology as well as classification. Patch tests and intracutaneous sensitivity tests are further methods of attack. The inquisitiveness and ingenuity of a Sherlock Holmes are required in the elucidation of many problems (Klauder ADS 68 363 1953) Despite the greatest diligence in the attack and the use of the most modern apparatus a physician who is honest with himself is with disconcerting frequency confronted by his own ignorance

Wood s Light has considerable diagnostic utility especially in the treatment of tinea capitis (q v) Fluorescence diagnosis was discussed by Costello and Luttenberger (NYSJM 44 1778 1944) and Ronchese (RhodeIslMJ 28 347 1946)

The val bility and Wood light variou colors wh h m reflect ch ges the amo nt t ovarian hormo es in the blood (Edit: BMJ 1 341 1935) I h ldhood the vulva ot fluorescent but w th puberty appears a brow green backgrou d fluorescence which thereaft r contin es, even fter ca trat on or menopause though during reproductive years a purplish hue of variable intensity is seen which becomes m ch darker during pregnancy fading rapidly after parturition (Morto AmJObGyn 68: 334

1954) The dark purple fluorescence appears in menopausal women within 48 hours after the administration of estrogens and fades after their withdrawal. Precise correlation with estrogenic levels of the menstrual cycle was not found by Benson (BGO 92: 14 1951) who attributed most of the reddish fluorescence to porphyrins resulting from red blood cell decomposition.

Fluorescein given intravenously and followed by Wood's light illumination may reveal interesting findings (Lange and Boyd AIntM 74: 175 1944 Herrmann JID 7: 210 1946 8 421 1947) In general inflammatory lesions imbibe fluorescein and so manifest intense fluorescence while dead tissues do not stain. The method can be used to distinguish vasospasm from embolism or thrombosis and the prognosis of an ulcer associated with varicosity can be estimated, along with the judgment regarding the wisdom of grafting A syphilitic ulcer shows bright fluorescence of the base and poor fluorescence of the margin Wheals and vesicles without blood stasis show rapidly appearing and disappearing hyperfluorescence Inhibition of fluid exchange between the vascular system and vesicular lesions of herpes results in delay in the appearance of fluorescence and persistence of it after it has appeared. Lesions of passive congestion and venous stasis remain dark as in varicosity telangiectasis and rosacea The papules of psoriasis are dark but are surrounded by a bright halo Dark lesions with spotty hyperfluorescence are seen in lichen planus and discoid lupus erythematosus. Clinically as a rule brightly fluorescent lesions will heal while dull lesions respond poorly so that such study has prognostic value

REGIONAL DISTRIBUTION OF COMMON DERMATOSES

Anal Region.—Pruritus, condyloma hemorrhoids, tinea, intertrigo contact dermatitis (soap and medicines) folliculitis o yriasis, phthiriasis, lichen simplex.

Bearded Region.—Impetigo, dermatitis venenata, sycosis tinea barbae, alopecia areata, sinus tract of dental origin keratoses, carcinoma.

Breasts.—Dermatitis venenata, infectious eczematoid dermatitis, carcinoma, Paget's disease, scabies intertrigo.

Chest and Shoulders.—Seborrhea, acne syphilids, tinea versicolor seborrheic keratoses, scabies, psoriasis, pediculosis, drug eruptions, the acute exanthems.

Crural and Axillary Regions.—Tinea, seborrheic dermatitis, intertrigo, dermatitis venenata, streptococcic dermatitis, scabies, furunculosis hidradenitis, infectious eczematoid dermatitis.

Ears.—Seborrheic, bacterial, or chronic lichenoid dermatitis, keratosis, carcinoma frostbite painful nodule.

Eyelids.—Dermatitis venenata, xanthoma palpebrarum, molluscum contagiosum, keratoses, stye, chalazion atopic dermatitis, seborrheic dermatitis. (Hazen ADS 49 253, 1944; Ormsby: AmJOphth 26 850 1943.)

Face.—Freckles, chloasma, vitiligo, seborrheic dermatitis, dermatitis venenata, impetigo erysipelas, acne, rosacea, milium, rhinophyma, syphilids, lupus erythematosus, erythema multiforme lupus vulgaris nevus, angioma, seborrheic keratosis, carcinoma, herpes simplex, molluscum contagiosum. (Thorek The Face in Health and Disease Davis, 1946.)

Forearms and Legs.—Infectious eczematoid dermatitis, dermatitis venenata, ecthyma, urticaria, lichen planus, psoriasis, erythema multiforme, erythema nodosum, purpura, ichthyosis, keratosis pilaris, syphilids, atopic dermatitis (flexures) lichen simplex, stasis dermatitis, bites purpura.

Genital Region.—Pruritus, scabies, pediculosis, seborrheic dermatitis, herpes simplex, chancre, chancroid, lymphogranuloma venereum, syphilids, lichen planus, carcinoma, dermatitis venenata kraurosis, lichen sclerosus, lichen chronicus simplex, tinea.

Hands and Feet.—Vitiligo, tinea, dermatophytid, dermatitis venenata, streptococcic dermatitis, scabies, hyperidrosis pompholyx, palmar and plantar keratoses, infectious eczematoid dermatitis, erythema multiforme, syphilis, dermatitis repens, verruca, carcinoma (hands) x ray dermatitis. (Madden, Nomland, Caro, Montgomery Kulchar: J 124 743 ff 1944, feet; Lane JMichSMS 39: 649 1940, hands; Sutton and Ayres: ADS 68: 226 1953, hands.) Examination of the hands yields valuable clinical information (Silverman: J 155: 902, 1954); when the palmar creases have lost their reddish color the hemoglobin is likely to measure less than 7 Gm./100 cc. (Wintrobe Clinical Hematology Lea & Febiger 1951)

Lips.—Herpes simplex, leukoplakia carcinoma, chancre, mucous patches, cheilitis exfoliativa, cheilitis glandularis apostematosa, Fordyce's disease urticaria, retention cysts, contact stomatitis, lupus erythematosus, fissure.

Neck.—Lichen simplex sebo rheic dermatiti lermatiti venenata (wool fur cos metic) cutaneou tags.

Scalp.—Seborrh i dermatiti dermatiti enenata psoria i tinea (children gen rally) lupu rythematosus, pediculosi apiti i fection ec ematoi l l rmatiti pre mature al pecia, al pecia areata s phili s zruta seborrheic v t n s furun les ne necrotica.

Tongue.—Leukoplakia, carcin ma, transit v benign pl p es bornlag t gu lingual ton illitis yphili avitaminosis, m roesti ab mia, korda i mpani s ndrome

Trunk.—Dermatiti venenata infection eczematoid l rmatitis, purpura seborrh i d rmatiti pit ria is rosea, urticaria h rpes zost r syphilis, psoria is, seborrh i keratosis, scabies pediculosi xanthemata.

See Sabouraud (Regional Topographical Dermatology M rshall Translation, Rebman, 1986)

TREATMENT

Treatment to be successful must accomplish aims which themselves depend on a rational plan and the plan depends on correct interpretation of the disease and the personality Empirical dermatologic therapy is obsolescent. Only the minority of patients nowadays receive treatment which has been prescribed solely because such treatment has helped other patients with similar troubles.

The cleverest plan of treatment is a failure if the patient is not adequately instructed in carrying it out or if the patient cannot be so controlled by his physician that he does what he is asked to do It is unfair and incorrect to ask of a patient what is, for him impossible In possibly half the cases the dermatologist sees cure requires keeping something off the patient rather than putting something onto him or into him. In ordering medication one should not omit the stop order for persistent, unnecessary use of medicines is objectionable and often harmful

A patient is likely to cooperate if he is told why he is asked to do or take something in a certain way Intelligence in the patient may be hoped for but cannot be expected While this fact adds to the physician s difficulties, it also adds to his responsibilities. There is no doubt that rapport, confidence and encouragement play an important part in delivering that for which the physician s services are engaged This aspect of what goes on between physician and patient would by some be called psychotherapy In diminishing the suffering of the sick the laying on of hands has a reputable and ancient history The physician who lacks ability to inspire confidence assuage fears and shoulder burdens for his patient works under a great handicap. In fact lacking the ability to learn to do these things, he should be in another business.

It is not correct to presuppose that the patient is too obtuse to comprehend the nature of his illness and the plan for his betterment. I believe in telling him in language I think he can understand just what is going on, in sofar as I know I willingly confess ignorance when that is the case and thereby justify such diligence, investigation and consultations as are indicated. I label prescriptions so that the contents are identified. This policy differs from that popular several years ago when a doctor might have been taken on faith alone for seldom nowadays is he so taken. It is a conceited man who supposes that the laity are ignorant the truth is that only some of them are A doctor must impose his will on his patient and this can be done best with graciousness, diplomacy and reason.

The handling of patients is a challenging art, in which a physician may throughout his life hope to improve himself. Medicine is a ministerial profession, wherein the desire to be helpful is the basic necessity A good doctor lives by this. He is intuitively sensitive to emotional as well as to bodily needs. He must be an honest man who thinks clearly who possesses stability who can give to others sympathy courage and confidence. He is able to make his good influence felt. He knows that illness and fear go hand in hand, and his gentleness, tact truthfulness, strength and warmth relieve fear which is harder to endure than pain and give comfort. Where cure cannot be obtained palliation may be achieved with resourcefulness A patient can be helped to bear that part of his suffering which cannot be escaped. When death comes, still the doctor serves well if he is kind of heart and understanding and sees to it that all is done that can be done for the patient and the family (Alvarez J 150 86 1952)

Neck.—Lichen simplex, seborrheic dermatitis, dermatitis venenata (wool, fur, cosmetic), cutaneous tags.

Scalp.—Seborrheic dermatitis, dermatitis venenata, psoriasis, tinea (children generally), lupus erythematosus, pediculosis capitis, infectious eczematoid dermatitis, premature alopecia, alopecia areata, syphilis, wen (sebaceous cysts), nevi, furuncles, acne necrotica.

Tongue.—Leukoplakia, epithelioma, transitory benign plaques, burning tongue, lingual tonsillitis, syphilis, avitaminosis, macrocytic anemia, chorda tympani syndrome.

Trunk.—Dermatitis venenata, infectious eczematoid dermatitis, purpura, seborrheic dermatitis, pityriasis rosea, urticaria, herpes zoster, syphilis, psoriasis, seborrheic keratosis, scabies, pediculosis, exanthemata.

See H. Gougerot (Regional Topographical Dermatology, Marshall Translation, Robinson, 1936).

CHEMICAL AGENTS

Adrenocorticotropic Hormone (ACTH) and Cortisone.—ACTH was developed by Armour Laboratories as an outgrowth of the researches of many investigators on Addison's disease, adrenalectomized animals and the relationship of the pituitary gland to the adrenal. After a pituitary extract was found which prevented the atrophy of the adrenal glands which results from removal of the pituitary gland in animals there was achieved a quantitative bioassay method which enabled more precise chemical fractionation of pituitary extracts, and accurate study of the effect of ACTH became possible. Eventually the hormone was produced in adequate amount and satisfactory purity for use in human beings, so that Thorn et al. (NEngJM 41: 829 1940) were able to report that the adrenal gland, though seemingly in a state of exhaustion, was capable of responding to stimulation.

Injection of ACTH is known to cause a marked drop in the number of circulating eosinophile leukocytes, an increase of the uric acid-creatinine ratio in the urine, an increase in the urinary excretion of 17-ketosteroids and 11-oxysteroids, the retention of sodium chloride and the increased excretion of potassium and nitrogen in the urine of normal human beings. The effect of ACTH on the collagen group of diseases, which dermatologically includes lupus erythematosus, acrosclerosis and dermatomyositis, became known. The contraindications including peptic ulcer, diabetes mellitus and liability to development of Cushing's syndrome were recognized. Notable improvement in 4 cases of systemic lupus erythematosus were reported on by Elkinton et al. (J 141: 1272, 1949) and the literature since has been replete with studies of dermatologic import regarding ACTH.

Cortisone has an interesting history beginning with the isolation of numerous crystalline compounds from the adrenal cortex by Kendall and co-workers. Of these compounds only 4 showed significant physiologic activity and were designated as compounds A, B, E, and F. *All were derivatives of delta4 pregnene and differed chemically from one another* only by the number and position of hydroxyl and ketone groups attached to positions C-11 and C-17. Hench observed that rheumatoid arthritis is ameliorated by jaundice and by pregnancy and it was on this basis that he was anxious to use compound E (cortisone) experimentally for this condition. A small supply became available from Merck and Co., who by 1948 had been able to achieve production sufficient for limited purposes. The amazing value of the chemical was at once apparent, and subsequent improvements of production methods have made it available in large quantities at a relatively low price.

Differing from ACTH, administration of cortisone is supplemental adrenal therapy rather than adrenal stimulation therapy. While the indications and contraindications of the two substances, as well as their effects on disease processes, are to a considerable degree similar, yet the differences are significant. Cortisone is, in general, more effectual and less likely to result in harm, for ACTH stimulates more than the adrenal while it stimulates that gland to produce more than cortisone, and the ill effects, when they occur, are of wider variety and more lasting duration.

Both drugs have the capacity to depress mesodermal allergic reactivity (Green: BMJ 1: 1165, 1950). While they have been recommended for use in contact dermatitis, I have not witnessed great virtue in this regard. Their value in pemphigus, systemic lupus erythematosus, atopic dermatitis, lichen chronicus simplex and autoeczematization, exfoliative dermatitis, psoriasis, drug eruptions, scleroderma, erythema multiforme, purpura, syphilitic iritis, interstitial keratitis, Addison's disease and the lymphoblastomas is discussed under those headings.

I have not observed that relapses after withdrawal of cortisone, when its administration has been effectively palliative, are worse than they would have been had the chemical been withheld. Cortisone and ACTH may light up and exacerbate quiescent peptic ulcer, the presence of which denies their use in a given case (Gray et al. J 147: 1529, 1951). They may activate tuberculous infection (Edit. J 145: 907; 147: 260, 1951) and caution is requisite. The patient with systemic lupus erythematosus given cortisone by Harris-Jones and Pein (Lancet 2: 115, 1953) developed miliary tuberculosis. It is dubious that they interfere with wound healing, although this has been reported (Billingham et al. BMJ 1: 1157, 1951). The tendency to promote infections by a mechanism as yet unexplained was reviewed by Thomas (AnnNYAcadSci 56: 799, 1953); perhaps there is some suppression of antibody formation. Judging by the effects on experimental inoculations of mice with streptococci, Lötzsch and Eichoben (DWehn 1?3: 653, 1953) could find no evidence that cortisone favors the spread of infection. The minimal effective dose of antibiotics is slightly increased when cortisone is given (Jawetz and Merrill: Sci 118: 549, 1953).

Other contraindications are hypertension, impaired renal function, personality disorders, Cushing's syndrome, impaired cardiac reserve, polycythemia, osteoporosis and diabetes mellitus (Callaway et al. SouthMJ 45: 63, 1952). The prolonged administration of cortisone is thought to depress the activity of the adrenal gland, which will on this account eventually undergo atrophy (Kendall: AnnIntM 33: 787, 1950) though this is reversible. This is the argument long attached to the use of thyroid and not as yet dead, though moribund. No harm comes, I believe, of proper dosage for cortisone, like thyroid, is replacement therapy supplementing the body's own chemical substances; the right dose is good, the wrong dose is not, for underdosage accomplishes nothing and overdosage does harm. There is no reason why the patient may not take the right dose throughout a lifetime. A patient with Addison's disease must. Osteoporosis resulting in multiple pathologic fractures of the spine was caused in 4 men who received prolonged cortisone and ACTH treatment, observed by Curtis et al. (J 156: 467, 1954).

The drugs are antagonistic to the *anticoagulant activity of ethyl biscoumacetate* and this may account for the thrombo-embolic phenomena that sometimes complicate their administration (Cosgriff: AmJMed 9 5 1950; Chatterjea and Salom: BMJ 1 790 1951). This antagonism may account too, for their palliative effect in urticaria pigmentosa.

When cortisone therapy was abruptly discontinued in asthmatic patients there developed within 1 hour headache and aches in the muscles and joints reported Henn man et al. (J 1 8: 351 19 3). The symptoms while sometimes alarming lasted for only a few days, subsided spontaneously and were not associated with significant changes in vital signs or laboratory tests. A death in status asthmaticus was described in a boy with Besnier's prurigo following the cessation of cortisone and ACTH medication (BMJ 2: 1307 1951).

The influence on skin tests and passive transfer phenomena have been studied and Zeller et al. (AnnAllergy 8: 163, 1950) as well as Feinberg et al. (JAllergy 22: 195 1951) found no effect on immediate wheal reactions or skin reactions to antigens or to histamine while ragweed dermatitis was unresponsive to the administration of ACTH or cortisone. Yet cortisone does appear to depress the reactivity of the connective tissues (Plotz et al.: AIM 61: 919 1950) and in a patient hypersensitive to antipyrine the rash would not develop while the patient took cortisone (Goldman and Hockwald: AIM 61 911 1951).

Compound F (17 hydroxycorticosterone-21-acetate) has physiologic effects similar to those of cortisone acetate and was said by Goldman et al. (JID 18: 89 1952) to inhibit the development of a diagnostic patch test when cortisone did not. Local intracutaneous injection of compound F marvelously palliative in some cases of arthritis when put into the joint have proved helpful in lichenoid dermatitis and a variety of dermatoses, inhibiting cutaneous reactivity (Goldman and Preston: ADS 67: 163, 1953).

Topically cortisone has one notably valuable application in the treatment of syphilitic iritis (q.v.) but despite the report of Spies and Stone (SouthMJ 43: 871 1950) it may safely be said that cortisone ointment has little or no value in any other dermatologic condition (see Goldman et al.: ADS 65: 11 195-). Hydrocortisone acetate ointment has attained great popularity (Sulzberger and Witten: JID 19 101 195-; Sulzberger et al.: J 151: 468 1953; Sulzberger: ADS 68: 451 1953; Baer: ADS 68: 4- 1953; Sidi et al. PresseMéd 61 997 1953). Its effect may be gratifying in atopic dermatitis, lichen chronicus simplex, especially when that of anogenital location, pruritus ani, and chronic eczematous dermatitis of the eyelids, ears or hands. During 1953 we saw it used without advantage in many a case responsive to less recent advances in modern therapeutics. Hydrocortisone, the free alcohol, was said by Sulzberger et al. (J 15- 1450 1953) to possess all the virtues of the acetate when used topically. The incorporation of an antibiotic in hydrocortisone ointment preparations has become popular. It is effective clinically for the dermatoses for which hydrocortisone is indicated and which are complicated with pathogenic bacteria. One of the good combinations is Terramycin with hydrocortisone as attested by Strauss and Frank (AD 71 736, 1955). Quantities of hydrocortisone have been applied unnecessarily but clinicians as well as patients are interested in results, strict science being, from the practical standpoint, somewhat tedious.

See Sulzberger et al. (JID 16 373, 1951; ADS 64 573, 1951); Lever (NEngJM 46 189, 1951); Stollerman et al. (ProcSocExperBiol 76 41, 1951): cortisone does not interfere with passive transfer when given either to the donor or the recipient; Baldridge and Kligman (JID 1 287 1951): cortisone without influence on elicitation of experimental contact dermatitis; Nilzen (JID 18 7, 1952): cortisone delayed reactions in experimental eczema; Kierland et al. (J 148 23 1952); Fisher and Walton (CMAJ 74 5- 1952): benefit in topic dermatitis, drug eruptions, pemphigus; Fischel et al. (ProcSocExperBiol 81 344, 1951): cortisone interfered with antibody formation induced by booster doses of antigen given to rabbits; Sulzberger and Baer (YBD 1952, p. 7): extensive essay on ACTH, cortisone and compound F; O'Leary and Erickson (J 18 1498, 1952): temporary benefits, not cures; Med. Research Council (BMJ 2 1400 1953): hematologic applications; Robinson and Robinson (J 155 1212, 1954): hydrocortisone acetate topically less than 1% ineffective; addition of antibiotics advantageous; Heilesen et al. (ADS 70 300 1954): use in lichenified eczema, especially anal; Sulzberger and Witten (J 155 934 1954): long term study showing no addiction or tissue resistance; dose generally can be reduced; Fuhrman and Downs (JIowaMS 55 322, 1954): hydrocortisone-neomycin ointment harmless; Med. Research Council Rpt. (BMJ 2 1307 1954): ACTH and cortisone in dermatology; McCorriston (CanadMAJ 70 59, 1954): topical in atopic infants, no contraindications; Church (BMJ 1 517 1955): topical for eczema, palliative but sometimes spreading infection; Witten et al. (JID 24 1 1955): topical fluorohydrocortisone acetate effectual, seldom irritating; Robinson (J 157 1300 1955): fludrocortisone acetate ointment 0.1% effective; Lubow (AD 72 164, 1955): 9-alpha fluorohydrocortisone ointment rarely irritant, usefulness analogous to that of hydrocortisone topically; Wright et al. (AD 72 69 1955): 9-alpha F no better than hydrocortisone.

Aerosporin.—See Antibiotics, polymyxin.

Androgenic and Estrogenic Chemicals.—Since testosterone has value in managing menopausal disorders it has some applicability to dermatoses like keratoderma climactericum (Wells et al. JID 15: 391 1950) and to postclimacteric dermatoses in the aging male (Hollander and Vogel: ADS 45 356 1942). The ability of testosterone to provoke acneiform eruptions is well known, and the acne it causes is hy... Its influence on sebaceous glands is pronounced. A dose of 3 mg daily will probably not induce virilism.

The naturally occurring estrogenic hormone was identified and obtained in crystalline form by Doisy et al. (AmJPhys 90: 329 1929; JBiolChem 87 357 1930). Like any other hormone, estrogen is indicated when there are evidences of its insufficiency. A simple clinical criterion involves only a clear history in the acneic girl of menses which last for 6 days or more, with tenderness of breasts at the start and perhaps cramps. The occipital headache, nuchal tension and hot flashes classically symptomatic of deficiency of menopause are often found in young women, who may be greatly relieved by the oral administration of a suitable dose, such as Premarin, 0.3 mg., sometimes 0.625 mg daily

Many cases of acne (q v) both in males and in females respond well to estrogen a fact stressed by Goeckerman and Wilhelm (ADS 66: 40* 105.) Psoriasiform eruptions, scattered lichen old dermatitis and seborrheic dermatitis of the palms may respond well according to Drant (PaMJ 5.: 966 1949) Senile atrophy may respond especially if it involves the genitalia of elderly women. Lamb et al. (ADS 57: 785 1935) reported on the use of these substances in lupus erythematosus and polymorphous photosensitive eruptions. Lichen simple in a flare l often made worse.

Topically estrogenic substances ar absorbed through the skin from an ointment vehicle and produce systemic effects while the ski itself shows epithelial proliferation in postmenopausal females with thin dry i teguments (Eller and Eller ADS 59: 449 1949) Overdosage and severe menorrhagia d veloped in a woman treated with an estrogenic ointment and reported by Goldberg and Harris (J 150: 00, 105) Such ill effects are reversible on withdrawing the hormone (Shapiro: JClinEndocrl 1 : 51 1052) While no ill effects resulted from adding estrogenic ubstances to emollient creams for use on dry ski s, no extra benefits accrued s observed by Behrman (J 155: 119 1954)

Marisone is a steroid complex ol tai ed as a by product in separating estrone from the urine of pregnant mares. According to Duemling and Millman (ADS 65: 327 195.) it has beneficial effects in various skin diseases including pemphigus contact dermatitis and keratoderma climactericum. It is useful in atopic dermatitis a d chronic urticaria and is well tolerated (Spielman and Blau: ADS 66: 488 1952)

Anthralin.—See Reducing substances.

Antibiotics.—These chemical substances, produced by some living organisms and antagonistic to certain ther living organism posses a wide range of values in the treatment of many kind of parasitic dermatoses. New ones are continually being discovered, and their evaluation continues to evoke a massive literature, while the capabilities of those longer known are becoming better and better tandardized (Flory: J 135: 104 , 1947; Baron: Handbook of Antibiotics, New York Penick & Co., 1950, pharmacology of 141 anti biotic drugs) An excellent reference book is that of Welch and Lewis (Antibiotic Therapy Medical Encyclopedia Inc., 1953) which includes biographic sketches of the discoverers, as well as the chemistry toxicity and utility of the substances themselves. See also Wel h (The Manual of Antib otics Medical Encyclopedia, New York, 1954, 87 pp.) Thus it is known that penicillin cures syphilis, and so is the standard agency for treatment of this disease. Methods of choosing antibiotics have attai ed a solid basis. It is now a commonplace laboratory procedure to isolate presumably causative organisms, to test their sensi tivities to various antibiotic medicines and to use that chemical which best antagonizes the particular species and types of infections present (Spaulding and Anderson: J 147: 1336, 1951 practical technic) The a tiparasitic spectrum of each antibiotic has been carefully tested and is becoming common knowledge with respect to particular organisms. Thus one expects to find som strains of staphylococci not responsive to penicillin but responsi e perhaps, to Aureomycin o to find in an ear canal *Pseud monas aeruginosa* which may pe haps be eradicated by neomycin but would not be responsive to Aureomycin, which fact the physician would nowadays know in advance

Correct use of antibiotics requires competent laboratory guidance and a good knowledge of what the drugs are able to do both fo the welfare and to the detriment of the patient. All of them have potentialities for harm, a feature which they share with every other substance with which a physician may wish to treat a patient.

Some antibiotics work together to the advantage of a patient, and others antagonize one anothe (Edit. BMJ 2: 1160, 1950) It seems, fo example, that chloramphenicol negates the effect veness of penicillin. Combination of chemotherapeutic drugs may o may not be wise, depending on factors not as yet fully understood (Edit.: J 147: 512, 1951) Thus while para-aminosalicylic acid and dihydrostreptomycin may together constitute a strong attack on tuberculosis, Aureomycin-penicillin combinations may or may not affect staphylococcic infections favorably depending in part on the concentrations employed. Antibiotic preparations for topical use commo ly contain more than one agent. Terramycin ointment was put up with polymyxin B standardly 1953, for xample, and many othe combinations could be listed designed to improve the antiparasitic spectrum of the product.

Topical Application of many antibiotics is of great practical value in dermatology although penicill may ot be so used because it irritates or sensitizes many individuals. Studies of th injurious effects of arious concentration of various antibiotes were made by Cruickshank and Lowbury (BMJ 2 1070 1952) and are of fundamental importance in adjusti g the concentrations to be employed. These n estigat rs and also Hu t al. (JID 20 357 1953) observed that human tissue cult es suffered toxic effect if the following concentrations were exceeded

Aureomycin	0.2 mg./cc.
Terramycin	0.2 mg./cc.
Chloromycetin	0.01 mg./cc.
Polymyxin B	0.2 mg./cc
Penicillin G	0.6 mg./cc.
Neomycin	1.0 mg./cc.
Gramicidin	0.001 mg./cc.
Bacitracin	0.01 mg./cc.

The inhibitory concentrations and the effects on the skins of patients are not completely parallel, for neomycin and bacitracin are not u ually toxic when applied topically while penicill n often i

THE EFFECT ON THE NORMAL FLORA of antibiotic medications I of int rest (Edit.: J 149: 6., 1181 19.) New infection with organism n t sen itive to the medicine being given may dev l p so to complicate th original disease The suppressi n of one organism may allow anoth r to luxu iat Monilia is (q.v., etiology of) is thought commonly to supers n when Aureomyc penicillin or chl ramphenicol has been given for a con iderable period of time Th re I a question a to wh ther the virulen e of the fungus i actually enhan ed. Sore mouth black hairy tongue (q.v) thru h and diarrhea with monilia abundant in th stool have been observed d ri g antibioti therapy (McGo ern et al.: NEngJM 45: 39 1953) possibly a a res lt of elimination of competition between the sen itive orga m an I the insensitive on Chro ic pulmonary monilia i and even fatal ill es have been known to volve a complicati ns (Brown et al.: J 152: 206 1953) Prot us an I P udomonas i sen itiv to many antibiotics, ha e been known to multiply so as to become path ge ic. As a rul discontin nce of the antibiotic has been followed by restoration after a time of the norm l balance of the fl ra.

ACHROMYCIN —By removing the chlorine at ms from Aureomycin, a new antibiotic tetracycline more soluble and more stable ha been d veloped (Put am et al.: Antibiot& Chemother 3 1153 1953) The spectrum is almost identical with chlort tracycline and oxytetracycline (Fi land et al.: J 1 4: 561 1954) Apparentl prod cing less gastroent ric irritation than the others Achromycin quickly ha become a favorite antibiotic of great excellence in m experience Th ointment i al I le a d nonirr tating See Council Rpt. (J 15 13 1954) t tracycl n A bromy in (Lede le) Tetra n (Pfiz); Robinson et al. (SouthMJ 45: 516 19..) no positiv pat h test t tetra li among 023 patient treated with the 3% oi tment.

AEROSPORIN.—See P lymyxin.

ANTIFUNGAL ANTIBIOTICS.—A strai of B. subtilis wa nh bitory to T. schoenleini gypseum reported Lewi et al. (ADS 54: 300 1946) Clavacin in vitro effectively inhibited M albicans T gypseum T purpureum and especially M and n according to Loewenthal and Tolmach (JID 8 33 194 0 41 194) Fungicidin the name given an alcohol extractable sub tance obtained from the growth of a soil cti om cete by Hazen and Brown (Sci 11 : 423 1950) and it was ffective i itro aga nst C lbica Cryptococcus coformans, H capsulatum B dermatitidis Coccidioides imm i s, T rubrum and T gypseum Mice injected with a lethal mixture of Aureomycin and Candida albica were saved by a preliminary injection of fungicidin (Brown et al.: Sci 11 609 1953) One fraction of neomycin as it was prepared by Swart et al. (P&ExpBiol 3 376, 1950) is f ngicidal (see Edit. J 144: 630 1950) Th olutin, an antibiotic isolated from several strains of Actinomyces was tried b Fra k (JID 19 209 195.) in the treatment of h man tinea capitis w th encouraging although not spectacular result Mycostatin, ol ta ned from Streptomyces ruber rapidl inact ted u less stored in a vacuum, a d high in t se t pro ed act e n vitro against C m ts H capsulat m, B dermatitid S schenck and M audou i, reported Burke et al. (JID .3 163, 1954) N statin, a more h peful preparation, being nont xic is discu sed under Mon lia is treatment (q)

The subject, f great interest but with as yet l ttle practical applicat on, was reviewed by Wooldridge (SouthMJ 45: 351 195.) who noted that actid on u fortunately toxic ah b ts Cryptococcus neoformans, and prodigiosl appears to ffect coccidioidal infect on significa tl See Lechevali r (I resseM 61 1327 1953) 4 nt f gal nt b ot cs from actinomyces candicine of dubiou cl nical value; Kl gman and Lewis (P&ExpB ol 8. 200 1953) c a licine strongly a tif ngal n vitro aga nst major h man pathogens, excepting Coccidioides imm tis and ringworm parasites.

AUREOMYCIN (CHLORTETRACYCLINE) derived from stra of Strept rcofac a ellow crystalline hydrochloride salt sol ble in wat d unstal le in alkaline solution (Brosch rd et al. Sci 109 119 1949) It is ct e aga t um rous gram posit e and gram negat e bact ria ncluding st eptococci staph lococci Kl bsell pneumoniae Hemophilus ducreyi Brucella suis and Br abortus. Pseud monas ruginosa and strains of Proteu were not inhibited by a concentration of 70 µg/ml. (Bry et al. J 138 117, 1948) It i rap dly excreted in the urine eachi g highest concentration within from 4 to 16 hours so that t hould be given at nt rvals of from 8 to 8 hours (Finland t al.: J 138 946, 1948 It is ti e against many rickett oses, especially Rocky Mount in spotted feve (Ha rel et l. SouthMJ 4. 4, 1949) and is useful ma y infection in which penicillin is mpotent (Finland et al AnnIntM 31 39 1949) It probably s curat e in the treatme t of syph lis (q v) Its utility in h rpes ost d dermat ti herpetiformis is in my opi ion, highly d bious. The large doses gi in th earl days f it introduction into medical therapy were often ill tolerated, with diarrhea om ti g d rritation of the anal d oral mucosae, a w ll as those of the gut, but wh n gi en with m lk d in moderate dosage t is a highly effective remedy f those infect on for which it is indicated. It is the best agent in lymphogran loma venereum, accord g to Robinson (AmJSyph 34 273, 1950)

Topically 3% Aureomycin in petrolatum is indeed welcome dermatologic medicament. It irritates seldom, if ever, and serves well in impetigo i fectious eczematoid dermatitis and secondarily infected contact d rmat t s. It is a good prescription for

herpes simplex. On a leg ulcer overlaid by a boot such as Medicopaste, it performs well as a bland, bacteriocidal unguent. Patch tests by Siegel and Schantz and by Hollander and Hardy (abs ABD 1950 p. 68) were negative. See also Robinson and Robinson (South MJ 44: 1116 1951)

BACITRACIN is used only topically A product of a bacterium of the *Bacillus subtilis* group it is a neutral, water-soluble relatively heat-stable substance with activity parallel to that of penicillin It is, however far less likely to irritate or sensitize than penicillin is when used topically It is valuable in superficial infection with bacteria (Miller et al. JID 10 179 1948, ADS 60: 106 1949; Meleney and Johnson: J 133: 675, 1947; Derzavis et al.: J 141: 191 1949; Flanerty: NEngJM 15: 14 1951) In Polysporin it is mixed with aerosporin and polymyxin, and the antibiotic spectra of the ingredients complement one another

CARBOMYCIN (MAGNAMYCIN) obtained from *Streptomyces halstedii* is active against gram positive bacteria, but some strains of *Micrococcus aureus* develop resistance readily and there is a high correlation with the effect of erythromycin (Hewitt and Wood: NEngJM 49 761 1953) Good results have been obtained in pneumococcic and streptococcic diseases with doses of 500 mg by mouth at 6 hour intervals. It appeared effective in granuloma inguinale (Whitaker et al.: AmJSyph 37: 400 1953) See Edit. (BMJ 1 14 1, 1953)

CHLOROMYCETIN (CHLORAMPHENICOL) was originally obtained from a new strain, *Streptomyces venezuelae* by Burkholder (Ehrlich et al.: Sci 106 417 1947) It is a bitter crystalline compound of known chemical composition showing marked chemotherapeutic effectiveness against several rickettsial and virus diseases as well as a wide range of gram negative and gram positive bacterial infections (Edit.: J 138 432, 1948) Unfortunately its internal administration has resulted in occasional but tragic ill effects on hematopoiesis. It was trusted for several years before this fact became generally known from a series of articles in J.A.M.A as well as elsewhere and several victims of fatal aplastic anemia were children of physicians (J 149: 231 01, 1203, 1301 193; see also Dermatitis medicamentosa) Yet its effectiveness in typhoid fever (Woodward and Smadel: AnnIntM 29: 731 1948) typhus (Woodward: AnnIntM 31: 53, 1949) and other rickettsial diseases as well as brucellosis (Smadel: J 142: 315 1950) keeps it from being discarded from internal medicine while topically it is harmless in appropriate concentration possessing great utility against *B proteus* and *Ps. aeruginosa*. Newman and Feldman (ADS 64 1951) observed neither irritation nor sensitivity in 51 cases of pyogenic dermatitis treated with a 1% concentration in a vanishing cream. Trice and Shafer (J 140: 1460, 1952) and Pauletta (GlobitalD 93 07 1952) likewise reported favorable experience. I have used Chloromycetin topically incorporating 7 milligrams per gram in Vioform Cream, on thousands of patients with superficial infections, without ill effect attributable to the antibiotic and with great satisfaction. See Marleonda and Montilli (Dermatologica 4: 13, 1953)

CLAVICIN —See Antifungal antibiotics.

ERYTHROMYCIN (ILOTYCIN) is produced by a strain of *Streptomyces erythreus* and possesses high effectiveness against pneumococci and group A hemolytic streptococci (Haight and Finland: NEngJM 47 227 1952) Other streptococci, staphylococci and Neisseria organisms were somewhat less sensitive as were also the strains of Hemophilus and of diphtheria bacilli. Coliform bacilli, Proteus, and Pseudomonas organisms were all quite resistant. On a weight basis, erythromycin was essentially similar in its activity to penicillin; it was more active than the broad spectrum antibiotics against the gram positive organisms, less active against the gram-negative coliform bacilli, and about equally active against strains of Hemophilus The antibiotic is often active against penicillin resistant staphylococci, though not in all cases, and does not seem to be as effective as penicillin in gonorrhea. Several cases of staphylococcic septicemia were cured with this drug by Herrell et al. (J 152 1601, 1953), who reported no serious toxic reaction I have seen erythrodermas it caused. Topically applied in 1% concentration it proved effective in pyodermas treated by Robinson and Zeligman (JID 20 405, 1953) and by Freeman and Scott (JPediat 4 669 1953) without inducing sensitivity It was combined with neomycin by Livingood et al. (J 153 1266 1953) whose report was not extremely enthusiastic. Strains of *M pyogenes* resistant to erythromycin are being seen frequently (Martin et al. PSMMC 29: 379 1954) See Kirby et al. (AIntM 92: 464, 1953); Robinson et al. (ADS 0 825 1954)

GRAMICIDIN —See Tyrothricin.

ILOTYCIN —See Erythromycin.

MAGNAMYCIN.—See Carbomycin.

NEOMYCIN isolated by Waksman and Lechevalier (Sc 109 305 1949) from a soil organism, *Streptomyces fradiae* is a water-soluble, thermostable basic compound active against various gram positive gram-negative and acid fast organisms and Actinomyces. Kile et al. (ADS 65: 511 1950) were enthusiastic about its topical application in a concentration of 5 mg per gram of water miscible base in the treatment of pyogenic dermatoses. While especially active against hemolytic staphylococci, it possesses some potency against *Pseudomonas* and hemolytic streptococci (Forbes: SouthMJ 45 235 1952; ADS 65: 631 1952) Livingood et al. (J 148 334 1952) judged it superior with respect to infections with *Pseudomonas*, *Proteus* and hemolytic *Staph aureus*, especially in ear canal infections, although for *Pseudomonas* infections, polymyxin B may be better (Id.: ADS

(Gi 4a, 10, 4) No sen tization or primary irritation wa observed in thei cases but several in tances of localized monili i d el ped in th m, di appearing after the ces a ti n of the drug Neomycin combined with hydrocortison ointment has earned great popularit

PENICILLIN discovery of which i credited to Fleming (BJExpP 10 226 1929) and early tried in human disease by Abraham et al. (Lancet 2: 177 1941) ha changed the practice of d rmatology The penicilli s all have the empiric formula $C_9H_{11}O_4SN$ R, R being variabl (Sc 102: 627 1945) All are strong m noba ic a id rea ily deteriorated by heat a id an l oxidation. Polymyxin.—Sterile filtrates of cultures of *Bacillus polymyxa* were found inhibitory to certain gram-negative organisms by Benedict and Langlykke (JBact 54: 4, 1947) and independently by Stansly et al. (BullJHH 81: 43, 1947). Whether aerosporin obtained by Ainsworth et al. (Nature 160: 263, 1947) from cultures of *Bacillus aerosporus* Greer, is identical with polymyxin has been argued (Brownlee and Bushby: Lancet 1: 127, 1948) but the activities are similar. According to the Council on Pharmacy and Chemistry (J 150: 1219, 1952) Polymyxin is the generic term employed to designate a series of related antibiotics derived from various strains of the spore-forming soil bacterium, *Bacillus polymyxa* (*B. aerosporus* Greer). The various polymyxins which have been isolated are differentiated by affixing letters of the alphabet which do not necessarily signify the order of isolation: polymyxin A, polymyxin B, etc. Polymyxin B is the least toxic of those adequately studied. Chemically, the polymyxins are basic polypeptides. Polymyxin B contains leucine, threonine, phenylalanine, α,γ-diaminobutyric acid and a fatty acid of empirical formula, $C_9H_{18}O_2$, and has a molecular weight of about 1,000. It is stable as the acid salt polymyxin B sulfate in the dry state; in solution it is stable for extended periods if buffers are added. Alkaline solutions are less stable. The antibiotic is highly effective in vitro against many gram-negative micro-organisms.

Polymyxin is useful in dermatology in inhibiting *Ps. aeruginosa* (Kagan et al.: JLab ClinM 37: 402, 1951) but when given by injection has been known to cause urticarial and maculopapular rashes and itching especially about the mouth. An ointment containing polymyxin and bacitracin is an effective, seldom irritating combination, according to Gastineau and Florestano (ADS 66: 70, 1952). Kile et al. (ADS 68: 296, 1953, and Pass and Rattner (J 155: 1153, 1954)

Streptomycin was isolated by Waksman in 1941 from a soil streptothrix *Actinomyces lavendulae* (Edit.: J 126: 103, 1944). Its utility in tuberculosis has proved such that the Nobel prize in physiology and medicine was granted its discoverer in 1952. Regarding the chemistry of streptomycin and its variants, including dihydrostreptomycin, see Bogen (J 140: 469, 1949), Tuberculosis, treatment, and the monograph on the drug edited by Waksman (Streptomycin: Nature and Practical Applications, Williams and Wilkins, Baltimore, 1949). Dermatologically its useful use is conspicuous in tularemia (Committee Rpt.: J 132: 4, 70, 1946), chancroid and all forms of cutaneous tuberculosis (O'Leary et al.: ADS 55: 222, 1947). It antagonizes *B. proteus* and *Ps. aeruginosa* and it is the antibiotic of choice in granuloma inguinale (Combes et al.: NYSJM 48: 2024, 1948). Topically while it has proved effective, it frequently provokes sensitization, which may be severe (Goldman and Feldman: J 138: 640, 1948) and its ability to incite eczematous dermatitis as well as to damage the eighth nerve makes it somewhat unsatisfactory. Furthermore resistance is likely to develop in the organism under attack. Thus dihydrostreptomycin ointment, 5 mg. per gram, while extremely helpful in many a superficial infection according to Miller et al. (ADS 61: 648, 1950) is especially useful only during brief periods of time. See Waksman (Sc 118: 259, 1953; The Literature on Streptomycin 1944-1952, Rutgers Univ. Press, 1953)

Terramycin (Oxytetracycline) obtained from *Streptomyces rimosus* by Finlay et al. (Sc 111: 85, 1950) is effective against hemolytic staphylococci, streptococci and pneumococci, with a spectrum resembling that of Aureomycin (Bliss et al.: BullJHH 87: 171, 1950). It is given orally or applied topically or both in the management of dermatoses of various kinds, and appears to be quite safe. I have often used it in furunculosis as a bland yet potently antibacterial covering for crusted lesions. Superficial ecramatoid infections are well managed by the ointment which was highly recommended also by Wright and Tschan (AIDS 67: 1-5 1953); also Robinson et al. (SouthMJ 40: 772, 1953). Pfizer stand[illegible] preparations, 1953 [illegible] polymyxin B.

Orally the drug may induce diarrhea and gastroenteritis, accompanied by marked changes in the intestinal flora (Herrold et al.: PSEBMC 23: 183, 1950); see Moniliasis, etiology; and Council Rpt. (J 146: 254, 1951). Aureomycin (chlorotetracycline) and Terramycin (oxytetracycline) are chemically quite similar (J 151: 46, 1953). The chemical structure, uses and dosage were given by N.N.R. (J 151: 1291, 1953)

Terramycin may be applied topically and given by mouth at the same time safely which is not the case with sulfonamides or penicillin (Tachan and Wright ADS 69: 621 1954) So may Achromycin.

TETRACYCLINE.—See Achromycin. See also Aureomycin and Terramycin.

THIOLUTIN.—See Antifungal antibiotics

TYROTHRICIN is the crude extract from which gramicidin and tyrocidine were subsequently purified. Dubos (JExpM 70: 1; 711 1939) obtained it from a spore bearing soil organism later identified as Bacillus brevis. Toxic when given parenterally causing hemolysis, tyrothricin has considerable usefulness when applied topically in the treatment of infections with gram positive bacteria (Anderson; AD&S 53; 90 1946). Wet dressings rather than ointment vehicles were preferred by Anderson but Fisher and Lee (AD&S 53; 201 1946) pointed out that ointment bases do not lose their effect but rather interfere with diffusion of the drug. MacKee et al. (JID 7 1 5 1946) tested an intra-cerebral solution of tyrothricin in various dermatoses and found it nonirritating soothing and helpful in many cases such as eczema, impetigo and infectious eczematoid dermatitis. It is also used for chronic ulcers where it seems to stimulate tissue growth (Robinson AmJSurg 63 201 1944) Spectrocin combines neomycin and gramicidin in an ointment of considerable value. Tyrothricin containing tyrocidine gramicidin and lanolin was thought by Miller et al. (AD&S 69 303, 1953) to be no great improvement upon an ointment containing any one of the antibiotics singly.

Antihistamine Agents.—Benadryl, Pyribenzamine, Chlor-Trimeton and others have been introduced in the past few years and are notably effective in palliating urticaria, asthma and hay fever. See Council Report (J 132 702, 1946) Epstein (WiscMJ 45 459 1946) O'Leary and Farber (J 134; 1010 1947) Osborne et al. (AD&S 55 309 1947) Acute urticaria is particularly well relieved, and most cases of chronic urticaria are helped. Physical allergy, drug eruption and serum sickness with urticarial manifestation are relieved. Other itchy dermatoses, contact dermatitis, dermatitis herpetiformis, lichen planus and the like are sometimes palliated. Intolerance phenomena occur. See Dermatitis medicamentosa.

Benadryl, β dimethylaminoethyl benzhydryl ether hydrochloride is a white crystalline water-soluble synthetic antispasmodic (Shaffer et al.; AD&S 5 13 1945 Curtis and Owen AD&S 5 39 1945) The chemical composition of several such medicines was given by Waldbott (J 135; 207 1947) The history of their development was clearly outlined by Waldbott et al. (AD&S 61; 201 1950). After Dale and Laidlaw (JPhys 41; 318 1910) showed that symptoms of anaphylaxis resembled the pharmacologic effects of histamine Lewis propounded the theory that allergen unites with antibody in the shock organ and results in the liberation of a histamine-like substance. Bovet and Staub (Compt rend Soc biol 124 547 1937) searched for and found compounds which were antagonistic to histamine. What they first obtained was too toxic for human therapy but researches by Bovet, Halpern, Loew, Mayer and others yielded a succession of practical results (Loew et al. JPh&ExpT 83 120 1945, Benadryl; Mayer et al. Sci 102 93, 1945 Pyribenzamine) In addition to being histamine antagonists, the compounds were shown to have procaine-like effects by Leavitt and Code (PhExpT 85 33, 1947) and much work followed on the topical application of antihistamine drugs in the relief of pruritus. See also Dale (BMJ 2 281 1948)

The antihistamine effectiveness of a chemical compound may be tested by iontophoresis of histamine (Perry et al.; JID 11 461 1948) Iontophoresis of the antihistaminic was tried as a method of treatment of pruritic dermatoses by Aaron et al. (JID 10 85, 1948) See also Sternberg et al. (J 14 960 1950)

Antihistamine drugs are generally given by mouth. Chlor-Trimeton may be one of the best, being effective, adequately enduring in its effect for six to eight hours, and provoking a minimum of side effects as a rule. Benadryl is frequently sedative and this is an advantage in some patients, especially for the evening dose of medication, and for hyperpyrexia. Intravenous injection of antihistamines is admissible but seldom desirable.

Topical therapy with antihistamines yields, in dogmatic generality, more harm than good. They are often irritants. They spread undiagnosed bacterial dermatitis. They seldom accomplish what cannot be done better by other modes of topical treatment. Yet Perazil Cream has its virtues in chronic lichenoid dermatitis when this is dry and stabilized. I advise strongly against the topical use of antihistamine drugs on moist dermatoses and poison ivy.

See Feinberg and Bernstein (J 13 3 4 1947) Pyribenzamine ointment, Sulzberger et al. (JID 10 41 1948) Pyribenzamine cream; Shelmire (PostgradM 4 442, 1948) Thephorin ointment; Ellis and Hu dick (JID 11 25 1948) Thephorin often irritated or sensitized; Epstein and Macaulay (JID 12 145 1949) Histadyl cream; Inman and Cow (BMJ 1 1944, 1952), potent sensitizers; Overton (BMJ 1 874, 1948) Antistine; Lea et al. (JPh&ExpT 90 22, 1947) Histadyl; Pillsbury et al. (JID 11 435, 1948) Hydrillin; Spielman (NYSJM 48 2297 1948); Perazil; Kierland and Potter (PSMMC 23 48 1948) Thenylene; Keeton and Sheard (JID 9 65, 1947) Thephorin. Council on Pharmacy and Chemistry (J 143 144 1953), omission of dermatologic preparations of antihistamines from N.N.R. Warin (BMJ 1 1946, 1954) drugs available in England, usefulness mainly limited to urticaria, ill effects.

Antimony.—Various compounds containing antimony have proved efficient in treating granuloma inguinale, leishmaniasis and creeping eruption (q.v.). Fuadin is a valuable preparation of trivalent antimony. It is said to help in mycosis fungoides (q.v.)

Antipruritics.—Phenol is the most reliable antipruritic, in a strength of from 0.5 to 2%. Menthol evokes a sensation of coldness. Some synthetic topical anesthetics, such as Orthoform and Cycloform, prove serviceable at times. Ethyl aminobenzoate (Anesthesin) in 2 to 3% strength is helpful in combating intolerable itching. The control of itching receives detailed consideration in the chapter devoted to pruritus (q.v.). Among the things worth doing in brief are elimination of the stimulating effect of caffeine, administration of sedatives like aspirin, chloral hydrate or phenobarbital, rarely opiates; and protection of denuded, raw nerve ends by means of cool, bland poultices, which raise the local humidity to 100%, constrict the dilated vessels and cool the inflamed skin. The topical use of antihistamine chemicals is rarely to be advised (see Antihistamine agents). Benadryl has useful sedative as well as antipruritic effects.

Antiseptics.—A wide assortment of chemicals designed to destroy pathogenic organisms is available (see Livingood and Mullins: PostgradM 12: 16 1952). Phenol, the classic one, is used by dermatologists mainly for its antipruritic properties. Several antiseptics receive in this chapter paragraphs of their own, such as gentian violet, iodine, sulfur and Vioform. Numerous antibiotics (q.v.) serve so well when applied topically that other types of antiparasitic agents are considerably less popular than in former days. The phenyl mercuric compounds, potent against fungus infections in vitro, are strongly irritating even in low concentration and a practitioner is not likely to use them, although they have their advocates (Byrne: BMJ 1: 90 1947). Mercuric bichloride 1:10,000 aqueous solution, is good for soaks or poultices if tolerated. Ammoniated mercury (the U.S. Pharmacopoeia preparation being 5%) is an old friend, still a good remedy for impetigo, more often used in the treatment of psoriasis. The combination of ammoniated mercury with salicylic acid, which enhances the potentiality for irritation, was studied by Siemens and Schreiber (abs YBD 1946, p. 190); an ointment containing 5% each may cure a stubborn case of rosacea like folliculitis after other efforts have failed, as Staley showed us. Merthiolate and Mercresin are serviceable liquid antiseptics, although they are frequently irritating when applied in an ointment vehicle (see J 137: 780, 1948). Oxidizing antiseptics include potassium permanganate, which, in a concentration of 3 grains or somewhat less to the gallon of water, is invaluable in treating chronic lichenoid dermatitis of the legs, stasis dermatitis, poison ivy, various vulvovaginal infections and irritations, and infectious eczematoid dermatitis. Hydrogen peroxide and sodium perborate are of value as mouth washes, but are capable of irritation. Meleney's zinc peroxide has been highly recommended in the management of anaerobic streptococcic ulcers. Urea peroxide was deemed valuable by Tharman and Brown (JID 8: 11 1947; ADS 55: 801 1947). Sharlit (NYSJM 46: 147 1946) reported on a study of ozonides, which are organic peroxides made from ozone and unsaturated fatty acids, releasing nascent oxygen. Quaternary ammonium germicides, surface active agents comprising a class of amines in which the nitrogen has a covalence of 5, include such antiseptics as Zephiran, Phemerol and Ceepryn. They have practical surgical and industrial disinfecting uses. Being wetting agents, they abet débridement and are especially suitable for soaks and moist compresses; see Blank and Coolidge (JID 15: 249 1950). The nitrofurans have been popular (Downing et al.: J 133: 299 1947), notably with plastic surgeons, but Furacin often sensitizes (Downing and Brecker: NEngJM 239: 862 1948). The flavine antiseptics to which Strept. pyogenes is susceptible and Ps. pyocyaneus is not are effective even in the presence of blood serum (Edit.: BMJ 1: 837 1933). The aminoacridine compounds have won popularity in managing wounds, but can retard healing if too concentrated (Brown et al.: BMJ 1: 241 1953). Fatty acid antiseptics have their use in treating mycotic infection (Theodore: J 143: 226 1950); see Tinea, treatment.

See Reddish (Antiseptics, Disinfectants, Fungicides and Chemical and Physical Sterilization, Lea and Febiger 1954).

Dyes.—Gentian violet, a pararosaniline dye (pyoktanin blue is an old proprietary name for this) and the closely related methyl violet and crystal violet are deeply staining, nonirritant, nontoxic substances which evince especial affinity for gram-positive parasites. Available inexpensively in crystalline form, gentian violet is soluble in water, alcohol and chloroform but insoluble in petroleum fractions. It is an excellent parasiticidal local application (Sutton: J 110: 1733 1938). Acriflavine, brilliant green, carbol fuchsin and scarlet red are also valuable antiseptic dyes.

Arsenic, when prescribed in the form of liquor potassii arsenitis, sodium cacodylate, or arsenious acid, is largely excreted by exfoliation, for it becomes attached to epithelial tissue. When given over long periods of time even in small doses, arsenic may cause pigmentation and arsenical keratoses. See Dermatitis medicamentosa.

SODIUM CACODYLATE (sodium dimethylarsenate) is worthless as a spirocheticide but is useful in dermatitis herpetiformis.

ARSPHENAMINES.—Many possess specific treponemicidal properties. Chief among these are arsphenamine, neoarsphenamine, sulfarsphenamine, Bismarsen, acetarsone and Mapharsen. The object in compounding the agent is to secure a preparation of maximum injurious effect on the invading organism and minimum ill effect on the host. These are tonic in many disorders as well as efficient in the treatment of syphilis (q.v.). Toxicology is discussed under Dermatitis medicamentosa (q.v.).

Atabrine.—See Lupus erythematosus, discoid, treatment.

Aureomycin.—See Antibiotics.

Autogenous Serum.—For autohemotherapy some 10 cc of blood from the cubital vein is reinjected at once intramuscularly. Or serum after centrifugation may be used in place of the whole blood. From 3 to 10 injections are given at intervals of from 3 to 5 days. Various dermatoses may be treated in this way though the *value of the method is doubtful.* Autohemotherapy is followed by a fall in the number of circulating eosinophils, an effect like that of ACTH of seeming to stimulate the adrenocortical tissue (Sauer: JID 16: 1 1951); but no such effect was found by Franksen and Rasmussen-Jensen (Acta allergol 8: 6 1955). *I am hard up for something to do when I use autohemotherapy.*

Bacitracin.—See Antibiotics.

Bacteriophage.—Interest in this phenomenon from the therapeutic standpoint has *practically disappeared, for phage may be judged to have failed* (Edit.: BMJ 826 1951). Combes (NYStJM 4 : 1143 194) reported on the use of various filtrates on various skin infections. See Krueger and Scribner (J 116: 2160 2209 1941).

BAL, British Anti Lewisite, *2,3 dimercaptopropanol, is a dithiol which reactivates an* arsenic-inhibited pyruvate oxidase system and so detoxifies trivalent arsenical poisoning as well as poisonings with other heavy metals. Its administration is followed by marked increase of arsenic excretion in the urine. The 10% oil solution is injected intramuscularly *each 4 hours for 4 doses of 0.5 cc./50 pound body weight.* Toxic reaction may occur but are preferable to arsenical encephalitis or dermatitis, which BAL may cure. See Peters (Nature Nov. 3 1945); Waters and Stock (Sc 102: 601 1945); WJTDM 101 104 (Oct. 1944); Sulzberger and Baer (J 133: 293, 1947). *BAL is often effective in mercury* and gold intoxication as well as in arsenical dermatitis, *encephalitis and optic atrophy* while it appears to increase rather than diminish the toxic effect of lead (Longcope and Luetscher: AnnIntM 31 545 1949). It has been tried in chrome dermatitis (q.v.).

Baths.—See Cleansing.

Benadryl.—See Antihistamine Agents.

Bismuth causes the rapid disappearance of the spirochetes from primary and secondary syphilitic lesions. *It is generally* inferior in its *therapeutic properties to mercury. It* cannot be relied on as the sole antisyphilitic drug (Walsh and Becke: J 116: 494 1941). Bismuth is also used in the treatment of lichen planus, lupus erythematosus and warts (q.v.). While the subsalicylate in oil suspension is the usual preparation Thiobismol and Bismarsen (Beerman et al.: J 170 333, 194) have also been popular.

Bismuth compounds which differ in solubility differ in rapidity of absorption and excretion and in duration of action. If continued action is desirable too rapid absorption *would necessitate frequent injections, and slow absorption might delay the effect and tend* to produce cumulative toxicity. Oil-suspended bismuth subsalicylate shows slow but continued absorption. Most of the clinical toxic symptoms, including stomatitis, dermatoses and nephrosis, occurred with this preparation (Cole et al.: AmJS 23: 143, 1939).

The usefulness of a bismuth preparation involves the concentration of active bismuth in the tissues and the height, course, rise, duration and decline of this concentration. The more prompt absorption of the watery solution tends to remove them from the site of injection and to empty the absorption deposit so that the concentration of bismuth is not maintained with weekly administration. Oil solutions are easier than similar to watery solution in their absorption but the difference in practice because they are injected in higher doses, so that weekly injections suffice to produce high and lasting absorption. It is therefore not necessary to inject them more often than weekly. Additional advantages of the fact that they usually produce less local irritation than watery solutions. For its use in syphilis see Syphilis, treatment.

Toxicity and tolerance depend on the content of element bismuth and its rate of reaching the blood, so that intravenous administration is dangerous (Clausen: JPhExpT 6 338 194).

Sobisminol mass and its trimate for oral administration are also used in therapeutically active concentration. *Lacking the dangers of injections, they have great utility* (Kay and Fricke: CalWM 50 349 1939; Howles: SouthMJ 41 1032, 1948; Miller and Delane: ADS 60 106, 1949).

Boric Acid is useful because its saturated solution, 3% or so, is isotonic and bland. Its antiseptic power is probably slight but it is seldom harmful. If through error boric acid solution is fed to a baby the result is catastrophe, for it is poisonous (Young et al.: CanadMAJ 61 447 1949). A teaspoon in a pint of water makes a solution to be poured *on a towel, which is laid on a dermatitis such as sunburn or wrapped about the fingers in* dermatitis of the hands, supplying coolness, high humidity and comfort. Boric acid ointment has caused fatal poisoning from percutaneous absorption (Watson: J 129 332, 1945). See Dermatitis medicamentosa.

Calcium.—Coagulability of the blood is perhaps diminished in a number of cutaneous disorders, particularly urticaria, pernio, pruritus and purpura (Tobias: JID 10 229 1948) and calcium salts may be given to overcome this deficiency. Seldom indeed have *I seen benefit resulting from their use either by mouth or intravenously* although intravenous calcium seems really helpful in the cases of penicillin allergy characterized by a rash resembling erythema nodosum.

Carbomycin.—See Antibiotics.

Cathartics.—*Saline laxatives are usually to be preferred. Magnesium sulfate is less* palatable than magnesium citrate. Milk of magnesia (N.F. II) is effective. Aromatic fluid extract of cascara sagrada practically never causes a rash. Mineral oil and the more elegant

proprietaries are usef l. Calom l (gr 1 ll) is drastic but effective. Bad bowel habits, fatigue and hypothyroidism ar among the common causes of constipation. Many patients may ad antageously increase th rati of fruit and vegetables in their diets. One may give the advice t go to bed earlier get p earlier an l allow a q arter hour of leisure in the morni g for evolution of an urge t stool; also, missing a day l rarely f tal.

Chloramphenicol.—See Antibiotics, Chl romycetl

Chloromycetin.—See Antibiotics.

Chlorophyll solution and ointment had a vogue. The preparations were nonirritating and were alleged to possess healing properties (Boehringer: Praxi 32: 703, 1943). Water soluble chlorophyll relieved symptom and alle iated a umber of recalcit nt dermatoses in patients of Langley and Morgan (PaMJ 51: 44 1947). Zeligman (JID 13 111 1949) reviewed the literature and commended the effect of the oi tment in treati g sta i der matitis. It seems to be deodorant (Council Report: J 140: 1330 1949).

Chloroquine.—See Lupu erythematosu discoi l, treatment.

Chlor Trimeton.—See A tihi tamine Agents.

Chrysarobin.—See Reducing Substances.

Clavicin.—See Antibiotics, antifungal.

Cleansing.—The tepid water bath with a mild soap is excellent. Soap baths accomplish débridement, and in dermatology are prescribed with det iled instruction as other medi ci es are. They are necessary in scabies to enable para iticidal agents to get at the mites, and the average case of tinea of the feet ca be cured by lev ti n aeration and the proper use of soap for the removal of excess corneum. Soap m st be rinsed off thoroughly. The typical hospital bath i flicted upon bed patients with wa hrag and a small basi of water causes much irritation.

Saturated fatty acids of low molecular weight more often gi e positive patch test than those of higher molecular weight. Reaction to castor oil is rare. Irritation by soaps i not directly related either to the lkalinity or the fatty acid component alo e. Some fatty acids at pH 7 are more irritant than others at pH 5. A detergent composed of 25% sulfonated oil, 25% liquid petrolatum and 50% water at pH 6.5 proved cellent in replacing soap, and relapse of dermatitis occurred when th use of soap wa resumed, as reported by Blank (ADS 39: 811 1939); see also Lane an l Blank (J 118: 804 1942).

Cationic soap is the t rm applied to germicidal and c eansing detergents i about 1% aqueous conce tration (J L 4 09 1944). They leave an imperceptible yet strongly germicidal film on the skin, and may be of some use (Miller et al.: PSExpB 54 1 4 1943).

All soaps are alkaline. Si ce alkali tends to c use dissol tion of epidermal cells, soaps are contraindicated in acute dermatitis, especially eczematou (Pa khurst: ADS 43 89, 1941). Highly alkaline soap, such as sapo viridis, may be desired f r it keratolytic effect in psoriasis, seborrheic dermatitis or acne. Medicated soaps possess little added germicidal value and are frequently i ritating (J 1 4 1193 1944).

Scales and crusts may be removed b means of mineral l, st rch poultices, or benzine, which is effecti e for cleansing oily greasy surfaces and removing adhesive plaster.

Baths in plain water may dilute and rinse away contactant irritants. They are sel dom harmful, though patients must be cautioned not to rub their skins while immersed. The temperature is important and should generally be t pid or cool as judged by the pa tient when a soothing, antipruritic effect is sought. Baths can spread pathogenic orga isms over the skin, but the shower bath seems rather to get rid of bacteria than to spread them.

The med cated bath is the means for getting a medicine all over a patient when t is easier to put the pat ent i to the medicine than to put the medicine on th patient because of the extent of his dermatosis. Aluminum acetate, a tablespoon to the tub is a common prescription of mine in po son ivy extensive and itchy pityria i rosea and widespread contact dermatitis. The conti uous bath has a place in the treatment of pemphigus a d of burns (Riehl: J 94: 1058 1930). The starch bath, as recomme ded by Swe tre is made by cooking 2 cups of cornstarch (not laundry starch, which contains borax) until soft and adding this, with a cup of baking soda, to the tub of water at comfortable temperature.

The potassium permanganate bath has great utility in ntoeczematization dermatitis and fectious eczematoid derm titis, using ten 5-grain tablets to 15 gallons. It is u tidy i the home but indispensable in managing many a hospitalized patient. Proportionately smalle quantities may be made up for soaking an arm o leg the hands or feet, or as a douch i the treatment of mycotic vaginitis with prurit vulvae.

Soda baths and tar baths are sometimes employed n th t eatment of psoriasis and chronic dermatitis.

The oatmeal bath is often soothi g and comforting in widespread dermatiti or urti caria. A cup of oatmeal bo led to a jelly is poured to a cloth sac ove the drawn tub of water at 100 F. The sack is tied t ghtly and sq eezed about in the water; it prove ts the oatmeal from stopping the plumbing.

Bichloride of mercury, 1 12,000 (3 Gm or 10 f the Large Poison Tablets [U.S.P.] in 15 measured gallons of water) provides valuable though somewhat hazardou a tiseptic and astringent bath useful in widespread i fect ous dermatitis. One must learn how to use and when to stop such baths. Absorption when the epidermis is much eroded results in mercurialism, with diarrhea or worse, d many a skin does not tolerate mercury at all.

Cod-Liver Oil.—Externally used thi sub tance has received favorable reports in the treatment of burn (Council Report: J 1 1: 59 1943) It is soothing and protective may be somewhat be t rucidal (*Lichten telu: Lancet* : 10_3, 1939) and ma contribut some local ben fits of vitamin A.

Diets.—Correct and adequate nutrition is necessary in dealing with dermatologic patients, as it i in managi g illnesses of any kind. Especially in chronic lichenifying d rmatitis I have been impressed with the need for a high prot in liet ((Gay: ADS 61: 901 1950) II poprot inosis wa intelligently discussed from the dermatological stand point l y Lynch and Sul elv (J 147: 115, 10 1)

Di tary restriction i infantile ecr ma frequently produce malnutrition and in man aging this disease where restri tions based on skin allergy test are so commonly futile I believe in feedi g the bal y so that at lea t it does not it h on an mpty stomach. A di tary rror I correct almost daily i the overingestion of c ff in, which ma ks fatigu a d increases irritability

Diet tic is a larg sul ject fo a mall paragraph but the nutritional a pects of ma y dermatoses re discussed under treatm nt of individual diseases and in the section on metabolic dermatoses including avit minoses.

It is seldom in leed that a skin disease is in fact caused l y a food, a compared with the frequency with which f od allergy i imagined especiall by pediatricians, t be the *cause of an eruption.*

Un aturated fat in the form of lard gi n in large amounts, h lped a number of chronically eczemat u patient of F nerud et L (ADS 44 840 1941)

Di ting f r obesity often concern the dermatologist in man ging dermatitis of the legs. Extra riboflavin may h lp sebo rheic I rmatiti (q.v) and psoriasis. Many a pa tient with a n need supplementary iro and vitamin therapy and in this condition I have stressed the utility f the low fat li t restricting especially milk and butt rf t a a mea s for dimini hing the activity of sebaceous glands. See Avitaminosis; Starvation edema; Stomatit f ut itional lehency; Lichen h omimu mplex

Diuretics.— A dermat logi t seldom prescribes a i reti but occ nally th e trem welling f th low r extremities which may company sev re d rmatitis will respond fav rabl to the injection f 1 0 cc M re hydrin or t Neohydrin tablets.

Dusting Powders generally con i t in the main of corn tarch zinc oxide zinc stearat alamin and boric acid

R	Zinc xide Zinc stearat T lc	of each t 60.0

On may ad l antipru itic or ant eptic hem cals to this ach a camphor, 2.0 grams. Desen x pow l r coat i ing zin undecyll at a d undec linic acid, is usef l in the treat ment f t nea ped (q.v) The absorpti e property f pow l rs w st died l y R (JID 6? 310 1950)

Ephedrine ha pharm cologic prope ties imilar to epi ephrine but the d rat on of the ffect s relatively prolonged, and it i act e when gi en by mouth

Epinephrine, a potent vasoconstricto palliates rt caria (Welch J 116 2390 1941)

Erythromycin.—See Antibiot cs.

Ethylene Disulfonate deserves ment on because of the interest ng controversy re gard ng ts x te e G en intramuscularly a expensive preparation is dosed accord g t a compl x r tual nd is alleged to be fit many kinds of allerg disease Ketch m (JMoSMA 45 896 1948) i a beli ver and Bartlett (MRec 160: 467 194) reviewing 1500 cases so treated reached f vorable conclusions. The Council on Pharmacy (J 131: 1493 1502, 1946) f und the prod ct indisti guishable from pure d st lled water Th con t nued sale of this remedy on the ba is f ava lable evidence is an insult to the intelligence of ph si ans.

Foreign Protein, in the form of typho d or other vaccines, and various oth sub stances somet mes y eld benefit n a manu all derstood in psoriasis, urticaria, pruritus, and dermat ti f nknown cause Foreign protei therapy i dangerous and often harm ful n lupu erythematosus d pemph gu (Cec l an l Hektoen: J 10_ 1705 1846 1935) *Nonspec fic prot* therap recei ed appro l of W right (ADS 23 115 1931) who com mended njection of milk n f runculosis and idiopathic pruritus. See syphilis, treatment with fe e Piromen, a f ver inducing polysaccharide s thought by some authorities to have alterat e p ope t es seful a wide assortm nt of recalcitra t ailments of obscure cause (Kierland and Kulwin ADS 62 571 1950)

Gold preparations, especially gold sodium thiosulfate have been found useful in dermatology *Lupu erythematosu (q.v)* d cert n t bercul d m y respo d favorably Gold injections re dangerous see Dermatitis medic mentosa. I seldom use them.

Gramicidin.—See A tibiotics, Tyrothricin.

Health Resorts.—See Cipollaro (J 134 249 1947)

Histadyl.—See Antihistam ne Agents.

Histaminase, available as Torantil, is an enzyme wh ch destroys histamin the tox c substance thought responsibl fo anaphylactic responses. *Perhaps it has value in serum* sickness and hi es (Laymon and Cumming JID 301 1939)

Hydrillin.—See Antihistamine Agents.

Ilotycin.—See Antibiotics, Erythromycin.

Iodine and the Iodides internally are used in sporotrichosis, blastomycosis and actinomycosis. Iodides are not spirochetIcidal. Th potassium salt i given by mouth the sodium salt intravenously By now iodides have been retired from exhibition in the treatm nt of syphilis, but in this connection are of historical interest Topicall iodine is a valuable antiseptic (Nye J 108: 50 1937) being as effective a anythi g available against *Ps. aeruginosa* which is a difficult parasite to handle, even with antibiotics. In an occasional allergic patient iodine applied to th skin vesiculates. Iodides often cause dermatiti medicamentosa (q v)

Iron is of dermatologic value mainly for sore tongue due to secondary anemia. Patients with acne and oth r chronic dermatoses often need it See Haden (J 111: 1059 1938); Hall (J 151: 1 1953)

Keratolytics are agents for dissolving the corneum. Salicylic acid resorcinol, and alkalies are of this class. The keratolytic action of soaps is due to alkali. These fi d their usefulness in hyperkerat tic condition such as scaly tinea.

Lipocaic, Dragstedt s pancreatic xtract which diminI hes cholesteremia and aids fat metabol sm, ha been alleged to help psoria is, but seem to me dermatologically val les (Rewlett and De Kay: RockyMtMJ 3 : 347 1940 Wal h: JID 4: 50 1941)

Liver Extracts have thei place in treatment of dermal manifest tio of certain *anemias and avitaminoses. Their preparation was clarified by Teeter (J 1 7 973, 1945)* They are used in hepatic deficiencies and some int xication such as arse ical dermatitis (R ssell RJD 60: 378 1948)

Local Applications employed in dermatology can be classed a to form of application and pharmacologic purpose. Remedial agents may be prescribed in the form of baths, compresses, dressings, lotio s, oi tments, pastes, pow ders or plasters Their purposes are cleansing, soothing protective stri gent antipruritic antiseptic keratolytic, reducing stimulating e escharotic. Physical agents as well a medicaments are used.

Lotions.—Relief of irritability is often accomplished by moist dressings intended t exclude air by mild astringe ts, or by lotions. In oozing itchi g dermatoses, wet dressings of aluminum acetate (a level teaspoonful to the quart of water) or pot ssium permanganate (1 grain to the pint of wat r) offer con iderable immediate relief.

Burow s solution of aluminum acetate has long been a popular astringent lotion in the treatment of burns and oozing dermatoses. A useful modification is:

R	Aluminum sulf te	5 0
	Lead cetate	25 0
	Water	500 0
Sig.	Astringent lotion dilut as requ red t avoid irrita t effect.	

Boric acid and liquor alumi um acetate together were commended by Vörner (MünchMWchr 51: 1000 1903)

Goulard s extract (20% lead acetate in water) when diluted 1:50 is good in moist compresses.

Dalibour water i anothe astringe t im lari used (Anderson SouthwestM 23: 330, 1939; Riordan et al.: NYSJM 43 802, 194)

R	Coppe sulfate	1 0
	Zinc sulfate	5.0
	Camphor water	to 240.0
Sig	One teaspoonful to half a pint of water for moist dressings.	

Pick s liniment forms a transluce t jelly which dries as a film

R	Tragacanth	5 0
	Glycerol	5 0
	W ter	100 0
	Mix with grinding	
Sig.	Apply freely to relieve burning a d itching.	

In contact dermatitis on beaut tes to apply ny chemical when it i not k own whether the patie t is susceptible to irritation by it One may appl petroleum jelly and, over that, clean soft towels moistened with cool water, plain or isot nic with t ble salt in it, a dram to the quart. An irritated skin will in a few hours or days return to normal if f rther rrita t cont ct has been prevented and if secondary i fect on does not complicate.

Calamine lotion has a drying effect

R	Phenol	1 0
	Starch	
	Zinc oxide	
	Prepared calamine of each	20 0
	Glycerin	10 0
	W ter t	200 0
Sig.	Carbolized calamine lotion Shake and apply to allay itching.	

Calamine lotion may be modified by the incorporation of various substances such as alcoholic solution of coal tar or 0.05% bichloride of mercury. Bentonite, a clay, may be put in the vehicle though tragacanth is a good. It is common knowledge that calamine zinc oxide contaminated with iron oxide which is harmless. Experimentation with red, brown and black iron oxides will enable one to match a lotion to the complexion on which it is to be applied (Goodman: NYSJM 41: 580 1941).

A good cleansing antipruritic lotion is Pusey's liniment:

R	Phenol	1.2
	Powdered tragacanth	4.0
	Sodium benzoate (as preservative)	0.2
	Olive oil	120.0
	Water	to 480.0

Sig: Soothing lotion. Apply freely to itching.

Magnamycin.—See Antibiotics, Carbomycin.

Mercurials are useful antiseptics (q.v.) and have been thought to be valuable in the treatment of syphilis and lichen planus. The protoiodid by mouth, the salicylate in oil intramuscularly and the ointment for inunction were the common preparations.

Naftalan.—See Tars.

Ointments have a wide sphere of usefulness. They consist of lipids of various kinds, perhaps emulsified, in which divers medicaments are suspended or dissolved. White petrolatum jelly is the common vehicle but is not penetrant. Cholesterolized bases are more penetrating. Lanolin (wool fat) takes up watery solutions and is on that account a useful vehicle. Vanishing creams are watery emulsion composed mainly of higher fatty acids and wetting agent.

Ointments are generally not used if weeping exists. The addition of starch thickens an ointment and enhances its power to take up secretions. Ointments smeared over staphylococci dermatoses are likely to spread the disease.

Rose water ointment is the U.S.P. cold cream.

Many ointment bases are available from proprietaries possessing much elegance. No great advantage accrues from their use except the recognized virtues of a polyethylene glycol Carbowax, which is water-soluble and especially welcome in applying medication to the scalp from which it is easily washed out (Maynard: JID 8: 223 1947; Hopkins JID 7: 1 1 1946). Vehicles, their physical chemical and functional characteristics were discussed by Lane and Blank (ADS 54: 487 650 1946). Those who prescribe compounded vehicles and judge them overrated. See Goodman (ADS 45: 1101 194_; 49: 16 704 1944). In considering a medicament the skin, the vehicle must be bland and it must be compatible with the medicament it holds. Water-miscible bases and oil-in-water emulsions release antiseptics from 50 to 1000 times more effectively than grease bases or water-in-oil emulsions (Zheutlin and Fox: JID 11: 101 1949) but Aureomycin deteriorates in water containing vehicles, while Aureomycin in petrolatum is one of the most practical forms of this topical medicines.

Numerous ointment bases were discussed by Mumford and Mumford (BJD 53: 45, 1941) and by Perrin and Halpern (JID 16: 1951). Various formulas for protective ointment of emulsion type water-in-oil and oil-in-water with or without the use of emulsifying agents were given by Peel (AustralJD 1 1953) who discussed water-soluble and greaseless bases and the pertinent pharmaceutics. Ointment prescription effect and the influence of pH were discussed by Herrmann (BJD 54: 1 194). The types composition and pharmaceutical usefulness of wetting agent were discussed by Nazzaro (Dermatologica 4 185 1953).

Antihistamine Ointments.—See Antihistamine Agent.

Boric Acid Ointment is losing popularity because of its possible toxicity (Pfeiffer et al: J 1 8 768 1945). Cod liver oil ointment possesses no remarkable virtue (see J 121: 39 1944).

Covermark is useful for hiding blemishes even large macular hemangiomas. The formulas of cosmetics of comparable effectiveness were given by Klauder and Gross (ADS 41 744 1940) and Hellman (ADS 57 70 1949).

Sunscreening Preparations for shielding the skin from actinic light, such as Afil, are discussed under Sunburn (q.v.). They are needed in managing Lupus erythematosus (q.v.).

Lassar's Paste contains zinc oxide 25, cornstarch 25, petrolatum 50. To it 1 to 5% salicylic acid is often added, as well as 0.5 to 1% phenol. It is a thick, protective antipruritic substance of considerable utility.

Pelolds (mud etc.) have physical effect of some interest (Slager: J 1 4: 431 1944). Bentonite, hydrated luminum silicate clay, is a detergent and dispersion agent incompatible with acids and inorganic acid salt. It is prescribed by some dermatologists (Goodman: ADS 49 764 1944).

Protective Ointments, while low on the list of preventive measures, are often the only available means of protection. In other instances they protect the skin from irritants which may escape the other preventive measures. The face cannot be covered by protective clothing and often the work must be carried on with bare hands. When a protective ointment is used the worker removes it with soap and water after work and so removes at the same time what ever irritants are on the skin. This adds considerably to the protection supposedly given by the ointment (Schwartz: MCNAm 26 1195 1942, giving type formulas and composition of industrial protective creams and

cleansers) Varieties include vanishing cream facilitating removal of soil when washing invisible glove films which may be water-soluble or water-insoluble fatty water-repellent ointments, ointments containing nonirritant chemicals detoxifying specific irritants, ointments serving as vehicles for inert powders which form protective covering and agents protecting against photosensitization Lanolin and petrolatum afford more secure protective films than other substances and the addition of powders to them diminishes their protective efficiency

Sunscreening ointments are discussed under Sunburn treatment

SURFACE ACTIVE AGENTS for wetting, penetrating, emulsifying dispersing, solubilizing, foaming, and washing have occasioned much dermatologic interest (Speel; JID 6: 293 1945; Dumeling: ADS 43: 764 1941) The molecule of the wetting agent generally contains water-soluble (hydrophilic) and also lipid-soluble (hydrophobic) groups, because of which it becomes oriented at an interface and lowers surface tension. Methods of cleansing and protective applications and formula utilizing some of these were discussed by Klauder et al. (ADS 41: 331 1940) Much industrial dermatitis is caused by cleansing agents. Schwartz (PHRpts 56: 1788 1941) commended sulfonated castor oil 50, vegetable oil 48, and a wetting agent such as Duponol 2, as a soapless cleanser for industrial use. Accepting the utility of cleansers dependent on these for their effectiveness as substitutes for and often improvements upon, soaps, which are common causes of dermatitis, I am nevertheless hesitant to recommend them highly as adjuvants of therapy I am perhaps naively pleased with the results of treatment in which few bases are prescribed other than petrolatum and lanolin. It is true that penetration can be enhanced by the choice of vehicle (MacKee et al.: JID 6: 309 1943 43, 1946) and occasionally this is necessary A typical ongreasy ointment base (Downing et al.: ADS 50: 8 1944) of cosmetic elegance capable of being washed off easily is:

R	Sodium lauryl sulfat	0.8
	Cetyl alcohol	15.0
	Glycerol	8.0
	White petrolatum	14.0
	Water	35.0

ZINC OXIDE OINTMENT (zinc paste) does not absorb water but possesses some antiseptic power (Strakosch: ADS 49 8 1944) An emulsion base may be prescribed however

Neoarsphenamine.—See Arsenic, arsenicals; Syphilis treatment Dermatitis medicamentosa, arsenicals.

Neomycin.—See Antibiotics.

Nystatin.—Antifungal antibiotic; see Moniliasis treatment.

Parathyroid Extract is sometimes useful in calcinosis prurigo and papular urticaria. (Albright: J 117: 527 1941.)

Penicillin.—See Antibiotics.

Perazil.—See Antihistamine Agents.

Pituitary derivatives have been used to encourage the growth of hair Pituitrin may relieve the pain of herpes zoster Compare ACTH and cortisone.

Polymyxin.—See Antibiotics.

Prescriptions are listed in the index.

Pyribenzamine.—See Antihistamine Agents.

Quinacrine.—See Lupus erythematosus discoid treatment

Reducing Substances hasten keratinization and influence favorably such diseases as psoriasis and seborrheic dermatitis. Cornbleet (ADS 33: 625 1936) found the ability to reduce methylene blue greatest in dihydroxyanthranol (Anthralin or Cignolin see J 1 4 647 1944) while in order of diminishing potency were chrysarobin pyrogallol, juniper tar crude coal tar precipitated sulfur coal tar solution and ammoniated mercury

Chrysarobin is a medicine the dermatologic aspirant must learn to use skillfully On the skin it is oxidized to oxychrysarobin, chrysotoxin and chrysophanic acid, the first being therapeutically active and the last not (Strakosch: ADS 49: 1 1944) Petrolatum is the best base, although chloroform is also a vehicle suited to certain purposes. Its application induces erythema followed by peeling, and it is a classic agent in the treatment of psoriasis and dermatomycoses. In the eye which it may reach through misadventure, it provokes violent and hazardous conjunctivitis and keratitis. Hence it is rarely put on the scalp and is prescribed invariably with the warning to keep it from the face. A potent reducing agent, its action is neutralized promptly by potassium permanganate. Chrysarobin conjunctivitis treated with frequently repeated washes of the antidotal 1 5,000 $KMnO_4$ and cortisone eyedrops is not the fearsome complication it has been thought to be. A sophisticated patient can use it on the scalp safely

Resorcinol, meta-dihydroxybenzene is as useful as salicylic acid and similar in its properties. Its action is keratolytic and irritant (Strakosch: ADS 48: 393, 1943) It stains blond hair reddish. Euresol, a proprietary resorcinol monoacetate is often prescribed in a lotion for dandruff

Salicylic Acid, hydroxybenzoic acid, has the property of separating, swelling, and macerating keratinized epithelium. It is a useful antiparasitic substance. It is antipruritic in from 1 to 2% concentration in an ointment. An alcoholic solution is frequently prescribed in seborrheic dermatitis and tinea. As an active ingredient in Lassar's paste,

it serves as an antipruritic and keratolytic medicament effectual in an assortment of conditions. Salicylic acid reinforces the action of sulfur. On corns 40% plasters may be used. See Goodman (ADS 54: 6[illegible], 1946); Strakosch (ADS 4[illegible]: 16, 1943).

Salicylates.—Aspirin is a valuable sedative and analgesic.

Sedatives.—Opium is of little value as a rule in diseases of the skin. It frequently increases pruritus. Bromides are not satisfactory, being prone to intoxicate. Barbiturates depress the emotions, promote a desire to sleep and dull the responses. Aspirin (gr. v-x each 3 hours) may be taken freely to secure rest; rarely it causes urticaria or asthma. Aminopyrine (gr. v-xv) is useful. Pruritus (q.v.) is best controlled by local applications and therapy appropriate to its cause; the itching patient would sleep if he were relieved of his itching. The avoidance of caffeine (coffee, tea and some carbonated beverages) is often sufficient in itself. Benadryl has a useful sedative effect. Chloral hydrate deserves popularity.

Sodium Thiosulfate, commercially photographer's hypo, has been used widely with alleged good effect in metal intoxication, especially arsenic. It is said by some to help contact dermatitis and to be a *general detoxicant; this I do not believe. Extremely* the salt has utility in the prophylaxis of tinea and in the treatment of iodine burns. McBride and Dennie (ADS [illegible]: 63, 19[illegible]) popularized it. Mattice et al. (ADS 4[illegible]: 3[illegible], 1940) did not find that it increases urinary excretion of arsenic, nor did Abramowitz et al. (ADS 4[illegible]: 175, 1943). The Council on Pharmacy (J [illegible]: [illegible], 194[illegible]) omitted it from N.N.R.

Staphylococcus Toxoid is of little aid by itself, and should be used in treatment of the exotoxin. It increases *the antitoxic titer of the blood, yet produces no serious untoward symptoms.* (Anderson and Stokes: ADS 40: 3[illegible], 1939. See also J 104: 542, 1935.)

Streptomycin.—See Antibiotics.

Sulfonamides.—Sulfanilamide, p-aminobenzene-sulfonamide, is a derivative of a red dye. Erysipelas, scarlet fever, chancroid, chronic acrodermatitis, lymphogranuloma venereum, gonococcal infections and other bacterial dermatoses are often strikingly responsive to sulfanilamide therapy (*Strickler and Steiner: ADS 40: [illegible], 1939*). Sulfanilamide is usually tolerated in doses of one to three 0.5 Gm. tablets t.i.d., or in even larger quantities (see Dermatitis medicamentosa). Sulfapyridine [illegible] (p-amino-benzene-sulfonamido-pyridine) is remarkably effective against the same infections as sulfanilamide but causes nausea in small dosage. Sulfathiazole, antistreptococcic and to some extent antistaphylococcic, is another valuable sulfonamide medicine. Sulfadiazine is probably the safest. The utility of these, *welcome as they were a few years ago, has been superseded* to some extent by penicillin and other antibiotics. Dermatologists disapprove the topical application of sulfonamides in any condition. Sulfonamides find their main dermatological usefulness in cellulitis, erysipelas and other streptococcic diseases, lymphopathia venerea, chancroid, dermatitis herpetiformis (sulfapyridine and Diasone), leprosy (Diasone) and, according to some authors, discoid lupus erythematosus.

Sulfur probably exerts little influence except upon *the odor of the stool* when taken internally. It has been given in nail dystrophies. Externally it is a valuable antiparasitic. Its effect on the skin seems to be due to the formation of persulfides in the presence of the sulfhydryl radical present in cysteine and glutathione in the corneum. Petrolatum is better than an emulsion base in promoting the keratoplastic action of sulfur. The keratolytic effect of salicylic acid with sulfur is better than that of either drug alone, the base *being not important. (Strakosch: ADS 4[illegible]: [illegible]16, 1943; 4[illegible]: 3[illegible], 1943.)* A thick paste composed of 30 to 50% sulfur in petrolatum has antiphlogistic, reducing, antipruritic and parasiticidal influences useful in treating seborrheic dermatitis, pityriasis rosea, rosacea, psoriasis, erythrodermas and other diseases, according to Abramowitz (ADS 40: 823, 1939; NYSJM 43: [illegible]46, 1943), who stated that such concentrations are less irritating than weaker ones and seldom provoke sulfur dermatitis. Sulfur is used dermatologically principally in *the treatment of scabies, tinea, acne vulgaris,* seborrheic dermatitis and rosacea. The formula of an attractive vanishing cream preparation containing colloidal sulfur in [illegible] concentration was given by Combes (NYSJM 40: 401, 1940).

Tar.—Crude coal tar, or its alcoholic solution, is a valuable antipruritic valuable in the treatment of atopic dermatitis, lichen chronicus simplex and other disorders. A good prescription is as follows, modified from White:

℞	Crude coal tar	1.0
	Lanolin, sufficient to	mix
	Zinc oxide and cornstarch, of each	10.0
	Liquid petrolatum	10.0
	Petrolatum	to 100.0
Sig.	1% coal tar ointment	

Coal tar will not go into petrolatum directly, but lanolin will take it up, and several proprietary ointment bases will incorporate it nicely. Zetar is miscible in water and makes attractive and satisfactory ointments (Combes: ADS 56: 553, 1947). Downing et al. (ADS 49: 4[illegible]1, 1944) used 5% diglycol stearate in petrolatum as a base for their 6% coal tar ointment, in which 50% cornstarch changed the color from black to gray; the preparation was easily removed from the skin. The tars and their derivatives were reviewed by Obermayer and Becker (ADS 31: [illegible]96, 1935) and by Downing and Bauer (ADS 57: 985, 1948). Their composition is complex, but their empirical usefulness is not to be denied.

Coal tar photosensitizes and perhaps in part for that reason is beneficial in psoria is (q.v.) especially in conjunction with ultraviolet light therapy. Tars derived from the distillation of wood (oleum rusci from birch, oil of cade from j niper) and other tars, such as Ichthyol (a sulfonated bitumen, ichth mmol N.F.) Naftalan and Tumenol (bituminous in origin) were discussed by Sulzberger and Baer (YBD 1931 p. 17), these are not photosensitizers. I think them largely o errated. The selection of the right tar and its right concentration partakes to my notion of th intellectual climate of the medieval ages of dermatologic thought (Sutton: ADS 50: 36 1949)

ICHTHYOL is a bland nd soothing sulfonated bitumen of complex chemistry a tarlike substance of considerable popularity (Stewart et al.: ADS 45: 933, 194). KATT LAN is somewhat similar t Ichthyol in ppearance nd use. These are prescribed in an ointment base in a concentration of 10 t 25% for various manifestations of dermatitis.

Terramycin.—See Antibiotics.

Tetracycline.—See Antibiotics Achromycin.

Thephorin.—See Antihistamine Agents

Thiolutin.—See Antibiotics antifungal.

Thyroid Extract is specific in hypothyroid states and so metimes proves beneficial in acne urticaria, xanthoma, psoriasis and dry scaling derm titides. It administration diminishes lipemia. See Acne treatment

Tyrothrycin.—See Antibiotics.

Vaccine Therapy is often used in furunculosis, carbunculosi infectious eczematoid dermatitis, and dermatitis repens. In acne and sycosis, results a e dubious. Typhoid vaccine is useful as a means of provoking fever artificially (see Heat Therapy) Frei antigen is important in the therapy of lymphogranuloma inguinale. See Foreign Proteins.

Venom.—See Vertebrate Bites.

Vioform, an amorphous powder with the formula 5-chloro- iodo-8-hydroxyquinoline long used as a d sting powder for chronic granulating wounds a d tri homonad vaginitis, possesses in 3% concentration in petrolatum great virtue as an antiseptic in eczematized dermatoses such as exudative intertrigo, sycosis and mixed coccic dermatitis. It was introduced into dermatology by Sulzberger (YBD 1940 p. 16) whose studies of oxyquinoline antiseptics (Sulzberger and Kanof: USNMB 46: 822 1940) were revealing. Diodoquin is one of these (Leifer and Steiner: JID 1.: 703, 1949) but Vioform is the chemical that has become a tried and true friend of the dermatologic practitioner (Reque: Mim. Doctor 25: 203, 1947; Martin-Scott: BMJ 1: 837 1949; Sulzberge and Baer: ADS 58: 224, 1948) Vioform sometimes irritates (Saunders: ADS 54: 456, 1946) and it stains things yellow is not tolerated by persons sensitive to iodine and is incompatible with coincidentally applied mercurial medication; yet it is a significa t dermatologic medicament which I prescribe almost daily. The Ciba vanishing cream preparation utilizes sodium lauryl sulfonate, some stearyl alcohol spermaceti and glycerol. Seldom indeed is this injurious, and it is effective in eliminating staphylococc i from an infected skin. The incorporation of 2% sulfur yields a medicine fairly successf l in scabies, tinea and moniliasis, while the addition of Chloromycetin adds an excellent antistreptococcic and antipyocyaneus effect. Hydrocortisone 1% may be added dvantageously fo eczematous or atopic cases, or omitted, as one wishes. The following formula is one I prescribe with the expectation of removing almost any parasite likely to be present and of soothing a chronic dermatitis:

R	Hydrocortisone	0.2
	Sulfur precipitated	0.4
	Chloromycetin	0.2
	Vioform Cream	20.0
Sig.	HSCV antiseptic cream, for infected eczematous dermatitis.	

The topical application of Chloromycetin in this concentration entails no consequential hazard. The formula is a good one for dermatitis of the hands, otitis externa impetigo, infectious eczematoid dermatitis and bacterially infected tinea. One may use potassium permanganate soaks in conjunction with this, o boric acid poultices may be placed over it.

Vitamin concentrates have proved their efficacy in the relief of conditions due to their inadequate supply or utilization. See Avitaminoses.

MECHANICAL AND PHYSICAL AGENTS

Reference is made to the A.M.A. Handbook of Physical Medicine for accurate and detailed accounts of the use of physical agents. A condensed account of various physical agents used in dermatology including x-rays, radium, ultraviolet, high frequency currents, galvanic currents, and solid carbo dioxide, was given by Cipollaro (J 137: 134, 1948)

Instruments the dermatologist likes to have immediately at hand include suitable magnifiers, a microscope a scalpel with disposable pointed and round bellied blades forceps, needle holder and hemostats for minor dermatologic surgery a set of cutaneous punches probe curet, comedo extractor (I use magnifying spectacles, pointed scalpel and fingernails) sphygmomanometer stethoscope ophthalmoscope and otoscope reflex ham-

mer vibrator fork flashlight Wood's light hair clipper electric shaver needles and syringes sterilizer interval timer and special equipment as described hereinafter. Supplied with these things, a license to practice and a bookkeeper a young fellow could hang out his shingle but he must not overlook medical liability insurance.

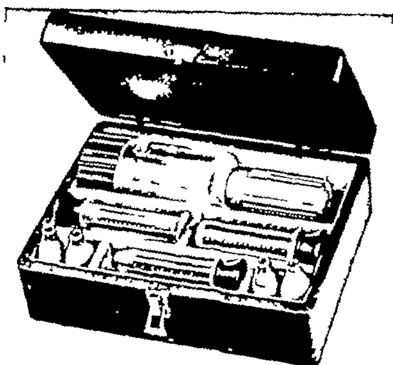

Fig. 41. Solid carbon [illegible] [illegible] [illegible] [illegible] [illegible] with [illegible] of this kind. (Kidde Manufacturing Co., Inc., Bloomfield, N. J.)

Fig. 42. [illegible] solid carbon dioxide firmly for [illegible] or [illegible] seconds to small [illegible] human [illegible] [illegible] results [illegible] cure with almost undetectable [illegible]

Refrigeration (Cryotherapy).—Pusey in 1907 introduced the use of solidified carbon dioxide nowadays obtainable as dry ice. A bit of this refrigerant whittled to appropriate shape and held in cotton to protect the fingers, is applied to the lesion for a period of from [illegible] seconds to a minute. The degree of freezing depends on the duration and pressure of application. A slush of solid carbon dioxide and acetone is also valuable. The agent causes erythema peeling blistering or deeper destruction and so is useful when these purposes are desired see Hemangioma, and Acne treatment (Alderson

ADS 37 234 1937; Carpenter: J 118 290, 1942) Liquid oxygen was thought easy to use and valuable by Kile and Welsh (ADS 57 57 1948) although I have been disappointed with it and with liquid nitrogen too

Actinotherapy.—Light irritates the skin and produces inflammation. It acts directly on the epithelium and the most superficial blood vessels. It induces sweating exerts an antiparasitic power and in overdoses may produce serious disturbance (see Sunburn) Its effect largely depends on the character of its constituent rays. If these are from the lower end of the spectrum yellow or red of long wave length, the skin is little affected but short wave lengths, the violet and ultraviolet may produce tissue destruction. (Cipollaro APhysTh 21 223 1940; Krusen APhysTh 22 199 1941 Council Report J 121 26 1943) Ultraviolet treatment has special value in tuberculosis of the skin (q v) and peeling doses cure pityriasis rosea and alleviate acne temporarily Combined with tar ointment it is a standard treatment of psoriasis (q v) but otherwise its indications in dermatology are few (Cleveland CanadMAJ 37 558 1937)

Locally satisfactory results are obtained from the use of 500 to 1 000 watt incandescent lamps in impetigo contagiosa and similar disorders. The effects are probably due to radiant heat and to the fact that drying abets the self-sterilizing of the skin.

Roentgen Therapy.—X rays produce degenerative changes in all tissues. Their effect is apparently proportional to the mitotic activity of the cellular structures.

The Primary Biologic Effect of Irradiation is one of cell injury When the degree of injury is small, the tissue eventually may be able to recover from it. Hence in general it is undesirable to irradiate normal tissue and one tries to irradiate not more of the normal tissue than necessary while treating a lesion.

Precautions must be taken to protect personnel working with radioactive materials from receiving enough radiation to damage them 0 1 r per day is the maximum allowable

Protection of the operator who should take every precaution to prevent irradiation of himself was described by Taylor (J 116 136 1941) Protection and radiation hygiene were fully discussed by Quimby and Pool (Radiol 41 272, 1943) see also Council on Physical Medicine (J 183 818 1948)

Biologic Action of X-rays depends on energy which is absorbed not on that which passes through The influence of wave length is negligible The effect on tissue is analyzable in terms of effect on cells. The action is necrobiotic although with small dosage the injury may be subliminal After a brief latent period, shorter with heavy dosage living cells treated with x rays manifest progressive turbidity and granular alteration of the cytoplasm, lose their motility and cease mitotic activity After a period of inactivity they may resume a normal function or they may suddenly die or their granular dissolution may occur promptly if dosage is heavy Histologically one finds cytolysis pyknotic degeneration, fragmentation and vacuolation. Cell types may be listed according to their radiosensitivity in order of greater to less lymphocytes, mucous cells of salivary gland and intestine spermatogonia epithelial endothelial young connective tissue cartilage muscle bone fat and nerve cells. Bacteria are insensitive, and, in general *doses which would kill parasites would be much more than sufficient to necrotize the tissues of the host*

Response of living cells to lethal amounts of x ray energy were studied by ultraviolet light microscopy by Montgomery and Warren (Sci 117: 589 1953) Profound changes became conspicuous 48 hours after the dose with loss of UV absorption by both the cytoplasm and nucleus, and nuclear swelling When ionizing particles were applied to particular small portions of cells as a microbeam a few dozen protons applied to chromosomes were found to produce severe aberrations but much more were required to be applied to cytoplasm to produce any effect reported Zirkle and Bloom (Sci 117 487

1953) Radiobiologic mechanisms were considered by Kulwin and Buley (ADS 70 417 1954) who discussed the physicochemical effect of the ionizing particle as it produces a track of ionization sheathed with a layer of hydrogen and hydroxyl ions capable of altering enzyme systems. The lack of oxygen increases protection against the damaging effects of x rays in many biologic systems (Latt Physiol Rev 33 35 1953) *Epilation following x ray treatment did not occur in small areas where the circulation of the blood was occluded by pressure* observed Schwarz (MünchMWchn 24 1217 1909) It required 2 or 3 times as much soft radiation to epilate in mice skin areas rendered anoxic by mechanical clamping as was required in controls in experiments of Strauss et al (JID 22 129 1954) but anoxia did not influence the size of the dose necessary to produce permanent alopecia

If one knows how cells react to x rays and of what kinds of cells the skin is constituted then one can picture the skin with permanent x ray damage it is a skeleton of anuclear fibrotic tissue in which epidermal accessory structures are lacking capillaries few fixed tissue cells wanting and epithelium sickly and thin See X ray and Radium Injuries.

The action on pathologic lesions of radium rays like x rays depends on the *sensitiveness of the particular varieties of cells affected* This applies to benign inflammatory and malignant processes. The leukocytes are the most sensitive of all human cells. Young connective tissue cells are comparatively sensitive and mature connective tissue cells are comparatively insensitive to irradiation. The most sensitive ocular structures are the conjunctiva and epithelium of the crystalline lens. Doses of radiation insufficient to cause an inflammatory reaction of the eyelids are not likely to cause the conjunctiva or lens to react *Doses sufficient to produce conjunctivitis may lead to the* formation of cataract months or years later especially in children See Warren (J 133 462 1947)

The testicles are not so sensitive as may be supposed and scrotal lesions may be treated with less concern than might be imagined according to Calloway et al (ADS 56 471 1947) who found that it required 900 r on the scrotum of the rabbit to cause sterilization

The abdomen of the pregnant woman must not be irradiated yet I have not seen an article on the facts pertinent to this proscription

Sequelae of dermatologic therapy were studied by Sulzberger et al. (ADS 65 639 1952) who presented conclusive evidence that total doses reaching 1000 r given for acne dermatitis and psoriasis resulted in no after-effects, and doses up to 1400 r did not produce cancer ulceration or dangerous sequelae

X RAY DOSAGE is cumulative If a particular area of skin receives therapy repeatedly the case record must show not only the dose given at any one treatment but also the total dose Meticulous records must be maintained Such records are a great comfort if a case goes to court for alleged malpractice If one uses x ray therapy one must expect sooner or later to be sued The defense must be watertight

Using the usual dermatologic machines and usual dermatologic doses of from 75 to 150 roentgen units (150 r is a rather large dose from the dermatologic standpoint) at 100 KVP a practitioner hesitates to exceed 1500 r total unless he is treating neoplasia The curative dose for skin cancer (q v) *is in the vicinity of 3000 r total and one expects this dose to result in* permanent atrophy One is willing to induce permanent changes with x rays, as with knife or electrocautery when ablation of tissue is the purpose of treatment Yet a surgical scar is in general to be preferred to a radiation scar for the latter may result in chronic ulceration requiring excision or in the evolution of keratoses or x ray carcinoma (q v)

Prior to adding more x ray therapy to an area previously irradiated one must know how much x ray therapy that site has received in the past. Inquiry is made of the patient, and letters are addressed to his previous doctors. X ray damage results from unwise prescription or erroneous delivery of the

planned dose such as omitting the filter when calculation was made for the use of filtered radiation X ray damage is avoidable Most x ray injuries I see these days have resulted from the patient s own carelessness the dentist held films in his patients mouths because he was in too great a hurry to teach the patient to hold them for himself or the surgeon was careless in fluoroscopy X ray as a tool has long enough been known and its potentialities for harm are sufficiently familiar by now so that burns resulting from stupidity are rather infrequent Whoever intends to use the agency must indeed possess wisdom and exercise respect for its capabilities.

Dosage — For the rough estimation of the dosage of unfiltered radiation Andrews used the formula

$$\frac{\text{current} \times \text{peak voltage squared} \times \text{time}}{\text{distance squared}}$$

and, substituting experimentally determined numerical values, he stated that with a particular apparatus, an exposure involving 2 milliamperes, 100 kilovolts (a spark gap between points of about 6 inches) and 3 minutes exposure at a distance of 8 inches produces mild erythema

Doubling the milliamperage doubles the dose.
Doubling the duration of exposure doubles the dose.
Doubling the voltage quadruples the dose.
Doubling the distance quarters the dose.

Materials placed between the anode and the recipient skin act as filters and obstruct the long (soft) rays much more than the penetrant short (hard) rays. Opacity depends on the atomic weight of the material of which the filter is composed. Tissues themselves filter the beam Since the first millimeter penetrated cuts out a certain percentage of the incident rays of a given wave length and the next millimeter cuts out the same percentage of the rays that reach it, the effect of thickness of filter is to obstruct the energy in the manner of compound interest Interposition of filters enables a dose to be given which is comparatively uniform in wave length so that only the hardest rays reach the skin, and the beam, being relatively homogeneous, is absorbed at a single percentage rate per unit of tissue depth. The *roentgen unit* is that quantity of x radiation which liberates one electrostatic unit of electricity when passing through 1 cc. of air at standard temperature and pressure This is the International Standard of x ray dosage, and the dose is measured in these units by means of an iontoquantimeter which in simplest terms, is a chamber, the contents of which ionized by the beam of radiation, are attached to a charged electroscope the rate of discharge of which measures the ionization and so measures the quantity of x rays.

The half value layer HVL, is that thickness of a filter which obstructs half the energy of the incident beam. HVL increases as the wave length diminishes, that is, as the hardness of the beam increases. About twice the thickness of skin will obstruct the same proportion of radiant energy as a unit thickness of aluminum The effect of soft rays per absorbed r rises in direct proportion to the HVL, and the differences in skin reaction to equal surface doses are due to differences in depth dosage (Ebbehj ActaD-V 32 117 1952) The quality of x rays selected for treatment of a given case should have HVL approximately equal to the thickness of the diseased tissue Grenz rays with HVL of from 0 1 to 0 4 mm of skin are suitable only for superficial dermatoses but for these they may be especially suitable

The threshold erythema dose is considered an important biologic measurement by Belisario (ADS 46 619 641 194.) who standard ed the use of a 1.0 cm. circular area on the proximal a t rior thigh for is measurement so that accurate comparison of results could be tested by various observers. Belisario stressed the tissue injury factor and the effect of oxygen tension. The usual practice in dermatologic therapy is to measure dosage by units a delivered in ai t the surface f the treated area, but this is crude measurement, as is known by both the ph cist and the b ologist. Its determination depends on that quantity of irradiation from a particular machine whi h produces faint but defi x te redness in a normal skin. Th erythema dose at 100 KV peak u filtered is about

300 r (MacKee and Cipollaro: ADS 41: 1 1940). The E dose increases with increased hardness of the ra[illegible] but remai[illegible] the best sta[illegible]d[illegible]rd test of dosage in th[illegible] opinion of Belisario (ADS 45 [illegible] 194[illegible]). Variabl[illegible] and complexities entering int[illegible] the ph[illegible]icist's estimation of [illegible] make the erythema dose (E) a[illegible] most logical[illegible] pra[illegible]tical one (Belisario: Brit J Radiol 23 [illegible] 195[illegible]).

DOSAGE CONSIDERATIONS.—Details of x ray theory and therapeutic technic require more extensive exposition than may be given here. Knowledge of the teachings of MacKee and Cipollaro (X Rays and Radium in the Treatment of Diseases of the Skin, Lea & Febiger, 1946) and adequate supervised instruction in the use of roentgenologic apparatus are essential.

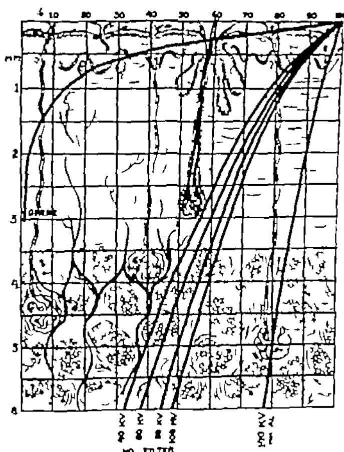

Fig. 76.—Roentgen radi[illegible]tion [illegible]bsorption curves, indicating depth dosage [illegible] modified by [illegible]oltage [illegible] filtration. (Cipollaro and Mutscheller: ADS 41: [illegible] 1940.)

Substances including tissues, which are irradiated become themselves sources of secondary irradiation during their irradiation. Secondary irradiation and backscatter provide a consequential proportion of the dose actually received within the tissues. On this account the size of the portal through which the rays reach the skin is significant. A larger dose as measured at the skin surface is necessary to deliver an equivalent dose within the tissues when the portal is smaller. At 120 KV without filtration added to that which is inherent in the tube the erythema dose as it varied with the portal was estimated by Goldberg (ADS 49: 346 1944) as follows:

Diameter	E dose	r units
10 mm	1.5	810
8	[illegible].5	850
6	3.5	1[illegible]00
4	5.0	1[illegible]00
[illegible]	8.0	2[illegible]00

The skin dose received exceeds the air dose measured at the skin surface significantly because of the exit dose which is that part of the incident energy which passes through The air dose does not adequately express the amount of radiation received by the skin Applied to the hand as pointed out by Andrews et al. (ADS 50 355 1944) at 65 KV skin dose exceeds air dose by 25% at 100 KV by 45% and at 135 KV with 3 mm Al filtration by 78% See Shafer et al (ADS 59 472 1949) on exit and backscatter factors in dermatologic therapy

Other considerations of dosage are elaborated by MacKee et al (ADS 47 490 657 1943) A time factor is concerned for a certain quantity of radiation must be administered before any cells are destroyed and cells recover from irradiation so that low intensity of radiation decreases its effectiveness. An area factor is concerned for the erythema is smaller than the mask which determines the portal by about 1.5 mm for unfiltered radiation and 3.0 mm for filtered. Therapy apparatus, furthermore does not deliver a beam which is uniform in intensity laterally from the central ray so that overlapping of fields cannot be done correctly unless the outer rays of the beam as well as the central rays have been calibrated.

SHIELDING —In administering a dose of x ray therapy to that part of the skin which one intends to treat it is essential that all the rest of the skin be shielded A metal cone attached to the tube delimits the beam effectively but the beam from the cone is further delimited, standardly with lead impregnated rubber laid on the patient in such a way as to control accurately the field to be exposed. Further control of the field is exercised by means of a sheet of 2 pound lead (of a thickness such that a square foot weighs 2 pounds) and the hole through the lead may be made any convenient and appropriate shape A Craftsman electric drill is an excellent tool for shaping small irregular holes, such as are required in treating verrucae keloids, hemangiomas and carcinomas. Another solution of the problem of shielding small, irregular fields was perfected by Wilson and Luikart (ADS 64 580 1951) utilizing a bismuth putty easy to prepare and easy to carve This putty was about 60% as effective as an equal thickness of lead. Lead foil 0 03 inch (0 76 mm) thick lets no energy through at 100 KVP (Landauer and Landauer ADS 61 864 1950)

RADIATION IN TREATMENT OF DERMATOSES.—In the following diseases roentgen therapy is especially useful

Acne	Granuloma pyogenicum	Lichen planus
Actinomycosis	Hemangioma	Lymphoblastoma
Blastomycosis	Hyperidrosis	Psoriasis
Bromidrosis	Inflammations	Sarcoma
Carcinoma	Keloid	Sycosis
Favus of scalp	Keratosis	Tinea capitis
Folliculitis keloidalis	Lichen chronicus simplex	Verrucae

X ray therapy is conspicuously contraindicated in lupus erythematosus. It does no good in pemphigus, dermatitis herpetiformis, diseases caused by animal parasites, or diseases due to primary physical or chemical injury Few bacterial diseases are benefited, other than furuncle carbuncle and erysipelas. When exudative dermatitis becomes worse immediately after x ray therapy there is likely to be a pathogenic micrococcus present Chronic dermatitis of the hands is a condition in which temporary benefits from repeated doses of x ray therapy are likely to be followed by eventual cumulative overdosage.

Seldom does a dermatologic patient receive so much x ray as to injure his hematopoietic system. Yet in the treatment of widespread dermatitis, this possibility must be borne in mind The standard 375 r 5-point epilation for tinea capitis does no harm, but the child may vomit 12 hours after receiving the treatment.

Radiation in Treatment of Inflammation —A furuncle consists of living staphylococci in the central region surrounded by fibrin and by living and dead leukocytes some of which have engorged some of the cocci This lesion is set within the dermis which consists in the main of collagenous and elastic fibers, fibrous cells, blood vessels and lymph vessels. The damage by bacterial activity is greatest at the center less peripherally it suffices to evoke vasodilation (redness) in the outer zone intracellular swelling and intercellular exudation of proteinous fluid as well as redness in the mid zone and necrosis at the center When x rays are applied the leukocytes dissolve the capillary endothelium swells blood flow is obstructed so that redness disappears, *the exudate is resorbed and no one knows what happens to the bacteria* Sometimes the lesion shows exacerbation for a few hours, but the customary clinical effect of roentgen treatment of a furuncle is to cause its prompt disappearance the effect is similar upon a carbuncle (usually) and is analogous in any other inflammatory disease Perhaps antitoxic substances are liberated (Bisgard et al Radiol 39 691 1942) Cellulitis is favorably influenced (DeHollander AmJR 48 811 1941) See Shaffer (JID 3 159 1940) Sutherland (AmJMSc 198 729 1939) Desjardins (J 116 225 1941 Radiol 38 274 1942); Edit (J 131 1424 1946)

Local sensitivity is abolished temporarily by x rays seemingly by their effecting the disruption of the cells on which local reactivity depends. The manifestations of contact dermatitis or fungous infection may be made to disappear but respectively the allergen is not removed or the fungus itself remains When *the skin regains its ability to react it does so. The clinical* cycle is disease treatment cure recurrence treatment cure —and eventually there results irremediable x ray damage The same old infection is still superimposed the more difficult to get rid of and medicolegal complexities arise

Radiation in Treatment of Neoplasms.—There are analogies between the application of radiation and the application of a caustic paste In either case cure if cure results, depends on destruction. In either case one does not know what the exact boundary of the destruction is going to be and in either case one does not command this boundary but simply intends that it will be sufficient Except in palliation and under uncommon combinations of circumstances I prefer surgical attack if it is feasible where with a single procedure one takes definitive steps to destroy that tissue which in one's judgment ought to be destroyed and leaves healthy that which one does not wish damaged. The surgical scar is not an x ray burn

Grenz (Infraroentgen) Radiation designates therapeutic electromagnetic vibrations ranging in the spectrum between the usual roentgen rays and the ultraviolet rays. No wave lengths are used longer than 1.7 angstrom units (spark gap equivalent of about ¼ inch between points of sewing needles) They are capable however even in therapeutic doses, of producing superficial atrophy and telangiectases. Absorption is almost complete in the external 3 mm. of the skin, so that while telangiectases may indeed occur sequels are rarely serious (Hollander JID 1: 15 1938)

The use of soft x rays, produced by a Chaoul tube close to the lesion under treatment, simulates the effect of radium, energy from which falls off rapidly as distance increases. *The equipment consists, essentially of a shock proof tube the rays emerging through* the 0.2 mm nickel target, which serves as anode window and filter alone. By daily treatment a huge total dosage may be built up according to the Coutard plan, and the radiation, originating actually in contact with the tissues that receive it produces locally typical roentgen destruction.

Low voltage therapy requires knowledge of how to diminish errors of dosage due to the lack of good voltage-regulating machinery according to *Pillsbury et al. (ADS 70 16, 1954)* who called attention to difficulties of dosage measurement and structural defects of some therapy units. Doses of at least 150 r are needed, *for* smaller doses accomplish nothing Erythema is produced by 500 r is more intense at 1000 r is sharp and accompanied by swelling at 1500 r A single dose of 3700 r produced atrophy Cumulative doses of from 4000 to 6000 r were followed for several years and no sequelae of consequence were seen. Early erythema fades into pigmentation usually within 7 days, and pigmentation may persist for several months (Domonkos JID 22 369 1954)

Radium possesses one great advantage over x rays in that it can be placed in the throat and similar cavities and brought into contact with diseased tissues difficult of access. The story of the discovery of radium and of Mme Curie's gram of the substance was interestingly told by Voll (Rad 17 37 1921). Radium taken internally enters osseous tissue permanently especially the mandible where its radioactivity eventuates in sarcoma. See Evans (AmJPubH 23 1017 1933 AmJR 37 368 1937 AnnIntM 11 1443 1938)

Radium as such does not have any therapeutic value. The tissue reactions which follow radium treatment are the result of the absorption of energy by the tissue from the radiations emitted by radium and its disintegration products, stated Desjardins and Williams (J 130 207 1946) whose article is extensively quoted hereinafter. An exposition valuable to the non physicist and accurate, is that of Hecht and Rabinowitch (Explaining the Atom Viking Press 1954) considerably more up to date with respect to atomic energy than this essay of Desjardins and Williams, which I nevertheless continue to quote

"Radium is a member of 1 of the 3 radioactive series which occur in nature. The atoms of a radioactive element eventually change into atoms of another element, and this change, or disintegration, is produced by the original atom losing mass and energy. The lost mass and energy are in one or more of three forms of radiations, called the alpha rays, beta rays, and gamma rays.

"Alpha rays are nuclei of helium atoms which travel at a velocity which may be as high as a tenth of the velocity of light. The emission of an alpha ray by an atom a loses its atomic weight 4 units and its atomic number (number of units of positive charge in the nucleus) 2 units. Although the energy of an alpha ray is quite large, it cannot travel far through solid materials; the greatest distance it can penetrate tissue is about 0.1 mm. and through materials of greater density the distance would be even less. The wall of all the ordinary containers used to hold radium or other radioactive materials is thick enough to stop all the alpha rays.

"Beta rays are electrons which travel at a velocity which may be as high as 99 per cent of the velocity of light. An electron has a mass of approximately one two-thousandth of an atomic unit of mass and has 1 unit of negative electric charge; hence the emission of a beta ray by an atom does not produce any significant change in its atomic weight, but it increases its atomic number 1 unit. The average energy of a beta ray is of the order of a tenth of the energy of alpha rays. Because of their greater velocity, smaller mass and smaller electric charge, beta rays are much more penetrating than alpha rays. Beta rays can travel through tissue a distance of approximately 10 mm. A thickness of metal sufficient to stop all beta rays is often called a beta-ray filter and for the commonly used metal these thicknesses are 0.5 mm. of Pt or Au, 1 mm of Ag or Pb, or 2 mm of brass, monel metal, or steel

"Gamma rays are electromagnetic radiations of shorter wave length than most roentgen rays, ultraviolet light, visible radiations, and radio waves. Like all electromagnetic radiations, they travel at the same velocity as light. The emission of a gamma ray has no effect on the atomic weight or atomic number of an atom. Gamma rays are generally emitted by the same atoms that emit beta rays. In general, the energy of the gamma rays is a little greater than that of beta rays, and they are much more penetrating than either the alpha or beta radiations. One centimeter of tissue reduces the intensity of the gamma rays about 5 per cent. A half inch of lead reduces their intensity about 50 per cent, and some of these rays can be detected through 6 inches or more of lead.

"It is not possible to predict when any particular atom of a radioactive element is going to disintegrate, but a definite percentage of the atoms present at the beginning of a period of time will disintegrate during that period. For each radioactive element the rate of disintegration is different and characteristic. Hence the period of time which elapses before half of the atoms disintegrate is called the 'half life period'; this also is characteristic of each radioactive element. The rate of disintegration of an element is not affected by chemical combination, extremes of heat, cold, pressure or vacuum, or by anything which can be done to the element" [except by procedures inducing atomic fission]

ELEMENT	ATOMIC NUMBER	ATOMIC WEIGHT	PHYSICAL STATE	RADIATION	HALF LIFE PERIOD
Radium	88	226	Solid	Alpha	1,590 years
Radon	86	222	Gas	Alpha	3.82 days
Radium A	84	218	Solid	Alpha	3.05 minutes
Radium B	82	214	Solid	Beta and gamma	26.8 minutes
Radium C	83	214	Solid	Beta and gamma	19.7 minutes

If a preparation of pure radium (radium being used as a specific example although any radioactive element could be used as well) is sealed in a tube, the tube immediately contains other elements. The amount of these elements will increase for a time and the amount of radium present will gradually decrease. However, since radium disintegrates slowly, *the amount present will remain essentially constant for many years,* and hence the number of atoms of radium disintegrating in any period of time—which is the same thing, the number of atoms of radon formed in any period of time—will remain essentially constant for many years. The amount of radon present gradually increases until the number of atoms disintegrating in a period of time is just equal to the number of atoms being formed (number of atoms of radium disintegrating) in the same period. From then on, the amount of radon present decreases as the amount of radium present decreases; the ratio of the amounts of all those present is always the same and radon is then said to be in equilibrium with radium. In a similar manner equilibrium eventually will be established between all succeeding members of the radioactive series. Between radium and radium C, equilibrium is established in about 2 months, but it takes only about 4 hours for equilibrium to be established between radon and radium C. The amount of radon in equilibrium with 1 Gm. of radium is called a curie and smaller amounts are measured in millicuries or microcuries.

Radium is commercially available only in the form of a salt, generally the sulfate, bromide or chloride, and generally a small percentage of the total weight of the preparation is the corresponding barium salt. However, the preparation is described as containing a certain weight of radium, which is the actual weight of the radium element present and not the total weight of the preparation. The actual amount of radium present is determined by comparing the amount of gamma radiation emitted by the preparation (after equilibrium has been established with radium C) with the gamma radiation emitted by a preparation whose radium content is known, or by measuring the rate at which radon is formed. Similarly the amount of radon contained in a tube is generally measured, after equilibrium has been established with radium C, by comparing the gamma ray emission with that from a tube of radium, since the intensity of the gamma radiation from 1 mc. of radon is the same as the intensity of the gamma radiation from 1 mg. of radium, when the two are in equilibrium with radium C. Most commonly the intensity of the gamma radiation is measured with an electroscope or other suitable instrument by determining the amount of ionization produced in a given volume of air.

"Since in ordinary radium treatment only the beta and gamma radiations are used, radium B and radium C are the only elements actually needed because they are the source of these radiations. However, they disintegrate rapidly and radium or radon is needed as a constant source for supplying radium B. An applicator containing radium will maintain nearly a constant amount of radium B and radium C for many years, while an applicator containing radon decreases in strength approximately a sixth every twenty four hours, or a half every 3.82 days, and does not have any therapeutic value after about a month because all the radon and radium B and radium C have disintegrated. Since radon is the only gas in the disintegration series, it can be separated rather easily from the rest of the series, and applicators containing radon are frequently used instead of applicators containing radium: so-called 'radium therapy' may be given with either type of applicator.

Treatment with radium can do more harm than good. To determine the best method of applying radium and the most suitable dose in each case requires training and judgment and the best results are obtained only by physicians who have had extended experience. For these reasons responsibility for treatment of this kind should be limited to qualified specialists.

"Ordinary radium therapy can conveniently be divided into three general types of application.

"In **External Irradiation** the radium applicator is either in contact with the skin or at some distance from the skin. Plaques containing radium, radon bulbs, tubes of radium or radon, and radium bombs are the common types of applicators used for external irradiation. [See Morrow and T[illegible]: [illegible] 33 [illegible], 193[illegible].]

PLAQUE APPLICATORS usually contain from 5 to 25 mg. of radium embedded in the surface of a glazed material having an area of from 1 to 8 square centimeters. The filter in plaques is very small, seldom more than 0.1 mm. of monel metal; hence most of the beta rays may be used. Plaques are generally placed in contact with the lesion to be treated and are used for surface lesions when irradiation is to be confined to a shallow depth. Although gamma rays also are emitted, their effect on deeper tissue will be slight during the time the beta rays produce a much greater effect on the superficial tissue.

RADON BULBS are thin-walled bulbs of glass, generally less than a centimeter in diameter, containing radon. Since the filtration of the glass wall is very slight, most of the beta rays may be used. Sometimes these bulbs are used instead of radium plaques.

"TUBES containing radium or radon generally have walls thick enough to absorb all the beta rays, *so that only gamma rays may be used.* Walls *thicker than a 'beta ray filter'* make a mechanically stronger tube but reduce the intensity of the radiation. The 'active length' (length of radioactive material) is generally about 1 to 2 cm.; the over-all length of the tubes from 1.5 to 3 cm., the outside diameter from 3 to 7 mm., and the wall thickness 0.5 to 2 mm. platinum equivalent (platinum or sufficient thickness of other materials to give a filtering effect equivalent to that of platinum). Often a few millimeters of rubber, bakelite, wood or similar organic filter is used between the tube and the tissue to absorb the secondary radiation from the tubes. Tubes generally contain from 5 to 100 mg. of radium, or up to several hundred millicuries of radon. Tubes are sometimes placed in contact with the skin, but more commonly they are separated a few centimeters from the skin.

RADIUM BOMBS usually contain from 1 to 10 Gm. of radium, which is enclosed in a large block of lead (or other dense metal) with an opening through which radiation can emerge. *Filtration is approximately the same as for tubes,* but the distance between the radium and the skin usually varies from about 10 to 40 cm.

"In **Intracavitary Irradiation** the applicators are placed in a natural cavity of the body, usually in order to bring the applicator closer to the lesion to be treated. The most common applicators used are the same radium and radon tubes which are used for external application. The tubes are often enclosed in rubber or similar material to absorb some of the secondary radiation from the tubes and to increase the distance between the tube and the tissue.

"In **Interstitial Irradiation** the applicators are inserted into the tissue to be treated. Radium or radon needles, containing from 1 to 10 mg. of radium or mc. of radon, with filtration of from 0.3 to 0.5 mm. of gold or platinum are often used. After the desired dose has been given, the needles are removed. Small tubes containing radon are often used, but these are never removed; they contain such an amount of radon, *usually from 0.25 to 2.5 mc.,* that the desired dose will be delivered while all the radon disintegrates. These are commonly called permanent implants, radon seeds, gold implants or gold seeds and generally are made of pure gold having a filter of 0.3 to 0.5 mm., an outside diameter of from 0.75 to 1.15 and a length of from 3 to 6 mm. They also may be made of platinum.

"During recent years, in dealing with resistant tumors, the tendency has been to eliminate most or all of the beta rays by using as a filter 0.5 mm. of platinum or an equivalent thickness of some other metal. The reason for this is that beta rays have a decidedly caustic or necrotic effect at short range, that is, on the tissues immediately adjacent to the radioactive

substance. This is commonly accompanied by severe pain. Elimination of beta rays by increasing the filtration prevents this necrotic effect and concomitant pain. Lead as a filter is generally employed only to treat superficial lesions.

"The dose of radiation delivered to the tissue—the amount of energy absorbed by the tissue from the radiation—depends on the amount of radium or radon used, the length of time of application, the arrangement of the applicators, the filtration and the distance between the source and the tissue. The biologic effect produced by irradiation depends on the dose and many other physical and biologic factors, including the rate of which the energy is absorbed, the volume of tissue irradiated and the dosage distribution throughout that volume, the kind of tissue, the phase of the life cycle of the cells, the blood supply and many other factors.

[Interstitial radium therapy technic was lucidly described by Lehman and Pipkin (ADS 631: 312, 1951; J 154: 4 1954).]

"Dose is generally expressed in milligram-hours or millicurie-hours, the former being used for radium salts, the latter for radon; the two terms describe practically the same quantity. In ordinary use, however there will be a slight discrepancy in their values if the change in value of the radon during the time of treatment is not taken into account. If the average value of radon is used, this discrepancy is practically eliminated for any normal period of treatment. To describe a treatment completely the amount of radium or radon, the time of application, the filtration, the distance from the lesion, and the type of applicator should be given. The roentgen (r) is a measure of the amount of energy absorbed from the radiation hence it takes into account the amount of radium or radon, time, arrangement, distance and filter. The dosage rate at a distance of 1 cm. from a point source of 1 mg. of radium filtered by 0.5 mm. of platinum, is approximately 8.4 roentgens each hour. When the entire dose is given within a few hours, about 1 000 roentgens of gamma radiation is required to produce an erythema of the skin. Among advanced workers there is an increasing tendency to express radium dosage in roentgens, but at the present time methods of measurement have not yet been perfected and simplified sufficiently to make this a general rule.

"The Maximal Safe Dose of radiation which a person may receive day after day called the 'tolerance dose' is generally considered to be about 0.1 roentgen each day. The dose received by persons working with radioactive materials should be measured by having them carry on their person photographic film or suitable dosage measuring instruments. When the dose which they receive is near or more than the tolerance dose added protection should be provided. It is advisable also to have frequent studies made of the blood of the personnel, for some of the earliest tissue changes produced by irradiation are indicated by changes in the blood."

Radium Dosage and Effects.—Gamma rays of radium are identical, except for their shorter wave length, with x rays. They have like properties but are highly penetrating. In the use of radium intensity is greatest at the surface of the applicator which is the source and the analogue of the tungsten target within the x ray tube. Intensity falls rapidly as distance increases from the radium applicator whereas x ray intensity within the depths of practical concern is comparatively uniform. Thus radium burns are in general smaller in all three dimensions than x ray burns.

The dose with radium or radon is estimated in milligram hours (or millicurie hours) per square centimeter at a given distance with filtration described, or milligram hours (millicurie hours) per cubic centimeter of tissue when needles or seed are implanted. Cole and Driver (AmJR 33: 69–, 1935) described their interstitial use of platinum needles of 27, 44 and 60 mm. length carrying 1, 2 or 3 tubules of radium each 15 mm. long. The over-all diameter of the needles was 1.65 mm., the wall being 0.5 mm., sufficient to filter out all the alpha and most of the beta rays. Such needles will destroy they found, 1 cc. of squamous-cell carcinoma in days. If placed 1 cm. apart each cubic centimeter of tissue receives 116 mg hr of gamma irradiation. They found that failure resulted more often from failure to recognize the dimensions of the tumor than from other reasons. Dangers in the use of radium and radon were elaborated upon by Cipollaro (J 116: 1906, 1940) whose conservatism is to be approved.

Gamma Ray Treatment using radium distributed on external applicators and molds was systematized so as to deliver correct dosage in a practical manner by Paterson and Parker (BJRad 7: 59?–632, 1934); see Squamous Carcinoma, treatment also Meredith et al (Radium Dosage The Manchester System, Livingstone 1947). See p. 1290

The Action of Radium Rays on a tumor depends on the kind of cells of which the tumor is chiefly composed. Each variety of cells in the body has a specific range of sensitiveness to the rays, and the sensitiveness of neoplasms corresponds closely to that of the normal cells from which the tumor derived. The sensitiveness of cells appears to depend chiefly on their life cycle mitotic activity. Radium rays appear to act mainly on the genetic elements of the cells and thus may cause cellular activity to be inhibited or be completely arrested and the cells to be injured or to disintegrate completely. The rate of this effect varies with each variety of cell and with the age of the cells.

Radon (Emanation).—There exist 3 series of radioactive elements, the uranium, actinium, and thorium series. Each member of a series is a chemical element. Each differs from the next in its series by either an alpha particle (helium nucleus) or a beta particle (electron). Emanation develops at known rates from each member of the series, and can be separated, sealed in tubes, and used separately. The half value period of radon is 3.8 days. A millicurie (mc.) is an amount of radon which will produce the same gamma ray effect as 1 mg. of radium. A gram of radium will produce 184 mc. of radon per day. Tubes containing radon may be implanted in a tumor or applied to the skin surface, or used in any way in which radium itself might be used. Histologic changes induced by radon were described by Melnick (?)(Chi 13: 84, 1940). Radon ointment can be used (Isaak, ADS 45, 840, 1942; Eadmow, JID 61: 316, 1939). Dosage was fully discussed by Quimby and Desjardins (J 112: 1033, 1939).

[When radon ointment is applied to the skin, there occurs considerable exhalation of radon from the lungs (Lange and Evans, Radiol 48: 514, 1947).]

Mesothorium is a radioactive substance in the thorium series. Thorium X bears the same relation to mesothorium that radon bears to radium. Its half value period is 3.64 days. It can be incorporated as ointment or liquid preparations and applied to the skin in the treatment of telangiectasis, eczema, psoriasis or other conditions. The activity of thorium X

is expressed in electrostatic units per cc. of the vehicle. With a solution in alcohol diluted to 100 to 250 esu per cc, Tinkus (JID 12: 41, 1949) reported benefit in seborrheic dermatitis, psoriasis and pruritus ani.

See also Coral (Lancet 1: 316, 1953), Sher and Howes (Radiol 56: 39, 1951), Lewis et al. (RockyMtMJ 49: 753, 1952), Witten et al. (JID 21: 249, 1953).

Radioactive Cobalt is comparatively cheap and effective in needles used as radium needles are used (Myers: Sci 107: 670, 1948). The gamma radiation from radiocobalt is monochromatic, needs no filtration, is easier to handle in designing apparatus than radium, gives no gaseous disintegration products, and is rapidly eliminated, if absorbed, rather than stored in the body. Its short half-life necessitates continual recalibrating.

See Warren (J 144: 417, 1950), Morrison et al. (Sci 115: 310, 1952), Herman (South MJ 45: 498, 1952), Barkell et al. (BritJRadiol 27: 1, 1954), telecurie therapy.

Radioactive Phosphorus, with a half-life of 14.3 days, emits only beta particles, the maximum tissue penetration of which is 8 mm. Exposures of 24 to 36 microcurie hours per cm produce mild erythema, while about 50 times that dose induces bullous epidermitis (Low-Beer: Radiol 47: 213, 1946). Solutions of P[32] taken by mouth are capable of yielding noteworthy palliation in some cases of lymphoblastoma (q. v.). The effect is inferior to x rays or nitrogen mustard in Hodgkin disease, lymphosarcoma and chronic lymphatic leukemia, though it is especially good in polycythemia vera and chronic myeloid leukemia (Stroebel: PSMMC 29: 1, 1954).

Topical use of radiophosphorus and radiostrontium, which are pure β emitters, was described by Low-Beer (GI 10: 60, 1954) who treated effectively keratoses and basal cell carcinomas by applying to them blotting paper trimmed to shape and soaked with P32 in Na_2HPO_4. The dose may be calculated in microcurie hours per sq. cm., or in r. See Witten et al. (JID 23: 271, 1954), β radiation with Sr90.

Other Radioactive Agents.—See Biological Effects of Beta Radiation (McGraw-Hill, 1951), recording some of the results of research done under the Atomic Energy Commission 1942 to 1946. High-energy alpha particles produced by the cyclotron can penetrate to a depth of 14 cm and force specific ionization concentrated in a narrow sphere near the end of the beam (Tobias et al.: CancerRes 9: 619, 1949). See Biological Studies with Polonium, Radium and Plutonium (McGraw-Hill, 1950) concerning especially the toxicity of radium.

Neutron injury was observed by Stone et al. (Radiol 35: 322, 1940); see Chatters (Sci 87: 262, 88: 231, 1938). The effect of neutrons on animals was attributed to secondary ionizing radiations by Tobias et al. (Sci 107: 115, 1948) and resembled that produced by P32.

The effect of high-energy electrons is mentioned in discussing the treatment of mycosis fungoides (q. v.).

Heat (Hyperpyrexia) as a therapeutic agent has been recognized during many centuries of medical activity. In recent times novel measures for producing and maintaining heat have been developed. More kinds of dermatitis are soothed by cool applications than by hot ones. Fever is thought to be a protective physiologic response although the nature of it is not understood. Since some parasites are killed or damaged by temperatures that human tissues may be able to tolerate, artificial fever therapy has a rational basis. Its status practically must depend on experiment. The means for producing fever is of no matter in itself, it is generally thought.

Methods of producing fever include baths, cradles, cabinets with electric lights in them (Brown et al.: BMJ 1: 67, 1943), electric blankets, medical diathermy machines, induction machines, foreign protein and malaria. Short wave radiation was found to provide simply comfortable warmth for the cultivation of many bacteria when Liebesny et al. (KlinWchn 12: 141, 1933) tested its effects. There is always danger of burns, exhaustion, heat stroke or cardiovascular accident whatever the means used and it should be borne in mind that a cure ought not to be more severe than a disease. Real utility of fever therapy existed in the preantibiotic treatment of syphilis (q. v.) and gonorrhea (Tauber and Goldman: ADS 41: 917, 1940; Krusen and Elkins: J 112: 1089, 1939). Atopic eczema may respond favorably temporarily.

Heat usually relaxes muscles, increases the transudation and rate of lymph drainage and the removal of intracutaneous dye, promotes vasodilation, so increasing the rate of blood flow, and induces temporary leukocytosis. Infra red treatment should last at least 20 minutes and cause erythema. Such radiant or incandescent heat is more penetrating than nonluminous energy which feels hot but penetrates only a millimeter. Conductive heat is least penetrant. It may be obtained with water bottles, baths, pads, blankets or the paraffin bath, which last I have found useless in dermatology.

See Council Report (J 142: 27, 1950) on medical diathermy; Wakim (J 139: 1091, 1949) on physiologic effects of heat and hypertherm therapy; Osborne and Frederick (J 137: 1036, 1948); Krusen et al. (PSMMC 22: 209, 1947) and Editorial (J 139: 928, 1949) on microwave (Radar) heating effects, which induce maximum temperature in the subcutaneous tissues and can blister as well as produce deeply buried burns.

Cautery—The ordinary electric cautery is simple reliable dependable convenient and economical With properly designed points, delicate destructive work can be done. By surface application sufficient only to vesiculate, one can destroy leukoplakia and seborrheic keratoses. Its instant effect on cells probably differs little fundamentally from the slower effect of x rays. See Jacobson and Aleon (ADS 61 842, 1950) Carcinoma treatment (p 1225)

Electrolysis and Ion Transfer—When the poles of a galvanic battery contact moist animal tissue a current passes. Soluble drugs can be introduced into the skin the positive sponge is moistened with the desired solution, the circuit closed, and the current turned on In this procedure the positive pole accumulates acid, vasoconstricts, stops hemorrhage increases tone and ionizes Cu Zn and Cd The negative pole accumulates alkali vasodilates, promotes hemorrhage relieves spasm and ionizes salicylates, iodides and salts.

Fig 71.—Post electric cautery an instrument of simplicity and utmost usefulness t the dermatologist in treating warts, nevi, keratoses and cancer

If a needle is used as the negative electrode and is placed within a follicle hydrogen ions accumulate about it and necrotize the follicular epithelium. This agency is used for the destruction of dilated capillaries and various small growths and is particularly valuable in getting rid of superfluous hairs. The source of current is of no consequence, provided it is direct. A current of 1 0 Ma. is required. Cipollaro (NYSJM 39 1475 1939) pointed out the hazards of unskilled use of this surgical ionization and disparaged as I do the multiple needle technic. Some operators use the high frequency current applied through the electrolysis needle for a brief instant in contrast with the 10 to 20 seconds required by the galvanic current. Great skill is required to prevent scarring (Karp ADS 43 85 1941 Erdos-Brown ADS 46 496, 1942) See Hirsutics (p 1328)

High Frequency and Fulguration Currents are alternating currents of 10[illegible] cycles or more per second obtained with a spark gap type of generator or a vacuum tube oscillating circuit. High frequency currents may be applied to the skin by means of vacuum electrodes, the resulting odor of ozone may have good psychotherapeutic effects. The high frequency caustic spark refers to the local application of a spark by means of an insulated pointed metal electrode, effective in destroying small cutaneous growths.

Short wave diathermy is used medically for heating, while long wave diathermy apparatus is used for various surgical effects, the energy being concentrated in a small region for the purpose of destruction of tissues.

Three forms of surgical diathermy are employed (Mackee and Cipollaro AMA Handbook of Physical Medicine 1950 p 294). (A) Cutting current or biterminal high frequency current obtained from the primary winding of the high frequency transformer. (B) Electrocoagulation or biterminal (sometimes monoterminal) high frequency current obtained from the primary winding of the high frequency transformer, and (C) Electrodesiccation, monoterminal high frequency current from the secondary winding of the high frequency transformer.

Endothermy and desiccation produce heat by the resistance of the tissues to the passage of the high frequency current. The applicator is cold when applied and is pointed. Accurate destruction can be achieved and the agents are used mainly in the treatment of neoplasms and verrucae. Keloid frequently follows the removal of small tumors by coagulation, especially those located over the sternum. See Cipollaro (ArchPhysMed 34: 621 1953)

Ultrasonic Vibrations are acoustical energy in frequencies beyond the limits of hearing of the human ear generated at high energy levels by the piezoelectric effect of controlled oscillating currents on quartz crystals. Frequencies of wide range possess biologic effects, which are interesting but at this time of limited practical value to dermatologists. Wood and Loomis (PhilosMag 4: 417 1927) were the first to describe biologic effects, while the ability of high frequency sound of about 9,000 cycles per second to kill *B coli* not through the agency of heat was noted by Williams and Gaines (JInfectDis 4 : 485, 1930) and similarly to kill streptococci, by Chambers and Flosdorf (PSExpB 34: 631 1936). Destruction of cells is associated with cavitation, the separation of gas and liquid, apparently outside the cells (Harvey and Loomis JGenPhysiol 15: 14 1931). See Bergmann (Ultrasonics translated by Hatfield, Wiley 1939)

The agent is in common use in research laboratories for mixing and dispersing substances, for fragmenting cells as in the preparation of vaccines and for sterilizing without extreme heat, although certainly extreme heating effects can be obtained (Hamre … t 5 … 70 1949; Nelson et al.: APhysM 31: 6, 1950; Woeber: AfDuS 155: 656, 1950; Schwarz and Carstensen: J 149: 1 1 1952). Templeton (ADS 67: 159 1953) reported interesting experiments in the dermatologic use of the modality. While a wart can be destroyed and cured by ultrasonic energy, the electric cautery is easier. Ultrasonic energy can be used to warm tissues, after the manner of diathermy (Meyer: AnndeD 79: 161 1952) and is certainly capable of doing harm.

See Herrma (ArchPhysMed 35: 200 1954), treatment of scars. Schwartz (SouthMJ 47: 854 1954), in osteoarthritis, peripheral vascular disease, varicose ulcers. Bauer (BritJPhysMed 1 … 97 1954), best effects in cases of neurologic causation. Council on Physical Med Rpt (J 15 … 140 1955), controversial value, applicability not yet limited.

DERMATOSES DUE TO PHYSICAL AGENTS

TRAUMATIC DERMATOSES

The skin is subject to injury by pressure friction, abrasion excoriation bruises, tearing, cuts splinters and the like. Xerotic skins have a relatively thin epidermal layer vulnerable to alkali The ease with which sufferers from epidermolysis bullosa or cutis hyperelastica are injured comprises a significant feature of these diseases. Hair and nails may be traumatized Permanent wave devices may pull a wisp so that parts of the scalp become sore and even temporarily denuded. A long toenail in a short shoe may be blistered loose in walking

Friction Dermatitis occurs in various jobs. The exact method of performing the job must be understood in order to clarify diagnosis and correctional effort (Tulipan and Appel MRec 154 443 1941) Occupational corns, calluses, and stigmas are of this nature (Ronchese J 128 925 1945 Occupational Marks and Other Physical Signs, Grune & Stratton 1948) Injury by siliceous spicules from certain sponges handled by oystermen (Corson and Pratt ADS 47 574 1943) and asbestos corns (Howell and Alden ADS 49 312, 1944) exemplify possibilities Shaving especially shaving against the grain, may provoke troublesome mechanical irritation of the face (Baer UCutRev 4 446 1941) and beard hairs falling onto the skin from an electric razor were reported as behaving like itch powder (Moore ADS 44 69 1941) Clothing is a common cause wool or starch being the usual offender

In infants, the nuchal flexures and medial areas of the thighs are likely to suffer from friction especially with wool starched garments and corduroy Chafing if severe disrupts the *epidermis sufficiently so that oozing and crusting* occur and secondary infection may complicate the situation. The page boy coiffure *may* result in chafing *of* the nape *of* the neck (Shellow ADS 40 91 1939) Compare the disruption of the corneum produced by repeated applications of Scotch tape as noted under Epidermis, separation of

Blisters due to the friction of shoes may sometimes be prevented by covering the skin with a bit of cellophane from the wrapper of a cigarette package (Hamilton)

Patch tests, as Tulipan and Appel pointed out are not helpful, for they do not reproduce the *mechanics of etiology* Efforts to cure such eczema by diet are even farther afield Petrolatum alleviates but cure requires elimination of the cause

Abrasions and Excoriations are recognized by linear discrete lesions where superficial layers of skin have been scraped away Protection and the prevention of secondary infection suffice in therapy After careful thorough cleansing a dressing of petrolatum or tetracycline ointment comfort a floor burn and allows it to heal.

Bruises are colorful because blood has entered the skin from broken vessels. If the accumulation of blood beneath the skin is large (ecchymoma) it may require evacuation, although resorption, if infection does not occur is usually complete. If not complete, organization of the clot takes place with a cicatricial result such as cauliflower ears.

Wounds of the skin require cleansing of edges hemostasis, neat apposition and a protective dressing. Scalp wounds rarely become infected. Débridement may be necessary if a crushing injury of the skin is untidy To minimize the scar of an elliptical excision held together by fine silk sutures, the sutures may be removed after 24 to 48 hours, applying Scotch tape to the wound to support it for the next few days.

Splinters may be of various sizes and materials going at the skin at various angles and to various depths. Good light magnifying glasses, pointed scalpel and needles and fine forceps aid greatly in their removal Wood and glass are not visualized by x rays. Glass spicules especially may be difficult to remove. One may wait, with aseptic protection, for the eventual purulent foreign body reaction until the splinter "festers out" when it

can easily be reached or expressed. *In getting at a fragment of wood or metal, a precise cut made obliquely toward the pathway of the splinter from beside it may have to penetrate only the corneum to enable one to grasp the splinter.*

Trichome Dermatitis is due to irritation by spicules, hairs and scales of the epidermis of plants, particularly the cow itch *tree of Australia (Laurence: MJAustral 2: 16 1935)*. Itchy papules on the extremities provoked by barberry thorn comprise another type of foreign-body dermatitis (Schwartz: ADS 37: 8 , 1938). Compare Browntail moth and Schistosome dermatitis.

Glass Wool and Fiberglas.—See Dermatitis venenata, *Industrial (p. 120)*.

Fracture Blisters.—Bullae may develop at the site of trauma in cases of fractures due to blunt injury accompanied by soft tissue damage (Buckley and Lobitz: NEngJM 249: 11 1953). They appear as early as 11 hours or as late as 5 days afterward and are due to simple separation of the epidermis from the dermis.

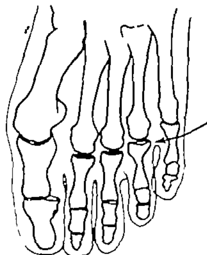

Fig 7.—Corn

Fig 3.—Callus (Dr Sam Sweitzer)

Figs 14 and 15.—Soft corn, attributed to pressure of bony spur on proximal end of proximal phalanx of fourth toe. (M ey PBMAC 15 610 1940.)

CORN

Corns are circular circumscribed slightly elevated hypertrophies of the horny layer cone-shaped with the apex pointing inward. Corns occur on the toes or other *places exposed to friction and pressure*. Generally smaller and more sharply circumscribed than calluses, a corn is distinguished by the presence of a horny core or tap the deep end of which presses on the tender cutis. Hard corns occur on exposed surfaces, and their tops are rounded and burnished. Corns arise as the result of pressure or friction, usually from ill fitting shoes. Orthopedic disorders often play an important role. Some occupations cause corns to develop. Occasionally a corn ulcerates because *of infection or pressure necrosis*.

Asbestos spicules may produced cornlike foreign body reactions (q v Howell ADS 49 312, 1944)

Corns are distinguished from warts by shaving off the excess keratin carefully so as to expose if present the tips of the elongated dermal papillae which characterize verrucae It is a grave error to give to a corn the large dose of x ray therapy which will cure a plantar wart.

Soft Corns develop between the toes and as a result of maceration and mycotic fermentation are soft moist and grayish. They are clinically rebellious lesions, attributed to mycotic infection primarily by Weidman (J 90: 499 1928) In treatment I know of no remedy more effective than Freezone an ether solution of salicylic acid in collodion mainly Circumspect applications of dichloracetic acid have cured several patients of mine The shoes should be wide toed and lightweight

Seed Corns are circumscribed plantar dyskeratoses which can be picked out only to recur They are not traumatic corns, verrucae arsenical keratoses, or punctate keratoderma but perhaps are volar seborrheic keratoses. Compare Verruca Plantaris.

Treatment.—The basis of successful treatment is to remove the cause The adoption of broad toed foot form shoes made of soft leather will often prove curative Orthopedic consultation and correction may be required. The lesions can be trimmed neatly with a sharp blade and removed temporarily by the use of 40% salicylic acid plaster A chisellike instrument is especially adapted to the trimming of corns, after which the cavity is painted with tincture of iodine See Filer (AmJS 29 444 1935) Thick sponge rubber soles worn exclusively for three months will cure corns, according to McFarland (ADS 67 278 1953) who described the thickening and loss of pigment of areas subject to pressure and friction and discussed the interrelationship of psychic disorders with mechanical lesions.

CALLUS

Symptoms.—A callus is a hyperkeratotic plaque due to chronic intermittent pressure and friction. The sites of predilection are the volar surfaces. The lesions are yellowish or brownish with slightly elevated, burnished surfaces. At the circumference they merge into normal skin Often occupationally determined they are seen on the hands of mechanics, blacksmiths, metal workers, stokers and oarsmen, on the fingers of harp and violin players and even on the lips of trumpeters. Bilateral calluses from friction are seen on the dorsa of the thumbs of leather buffers (Warren J 114 571 1940) The four brothers reported on by Mueller and Sugar (J 122 743 1943) who had the calluses under the great toes with ulceration were in fact sufferers with familial syringomyelia. Calluses do not arise spontaneously See Keratoderma climactericum some callused feet improve when the patient is given thyroid estrogen or cortisone.

Treatment.—The lesions are likely to undergo fissuring which is painful. They can be temporarily removed by applications of 20% salicylic acid in an ointment vehicle or by careful shaving Permanent relief can be secured only by removal of the cause, which may require orthopedic consultation.

SCAR

Symptoms.—Cicatrices consist of new connective tissue which replaces mesodermal discontinuities caused by trauma or disease. They are whitish or pink, and firm or atrophic in consistency Their outline approximates that of the lesions in which they develop Their surface may be depressed below the level of the surrounding skin, atrophic scars, the surface may be on the plane of the skin or it may be elevated, hypertrophic scars. Neatest cicatrices are those resulting from clean incised wounds when the edges have been held together In variola, syphilis, and herpes zoster the lesions are atrophic, white and soft. Hypertrophic scars develop as a rule from burns and following deep lacerated or infected wounds. They never extend beyond the

Fig. 76.—Sc f xten i third degree burns

Fig. 77.—Sca of old burn.

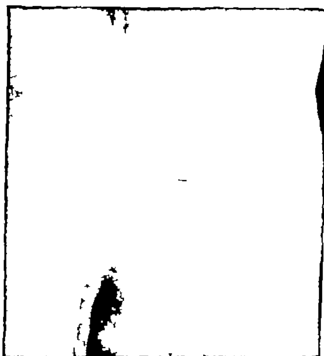

Fig. 78.—Atrophic stria of lumba region, seen in an adolescent (Wiener Skin Manifesta tions of I ternal Disorders, Mosby 1947.)

boundaries of the original injury a feature which distinguishes them from keloid Symptoms are commonly absent If present they are usually burning, prickling or formicating in character and due to nerve filaments that are caught in tiny amputation neuromas (Kredel Surg 8 98 1940) Scars tend to contract mainly in the diameter perpendicular to the lines of cleavage Occupational scars are seen on the right thigh of the right handed shoemakers from slips of the knife (Schwartz)

Treatment.—Irregular or hypertrophic disfiguring scars can sometimes be excised. The surface can be rendered smoother and less conspicuous by the use of solid carbon dioxide x rays or radium Blistering doses of ultraviolet irradiation diminish the conspicuousness of shallow scars it is thought (Fisher J 110 642, 1938) Methods of peeling the skin and the good results claimed were discussed by Eller and Wolff (J 116 934 1941) The surgical treatment of scars from burns, including those which are painful depressed, thick, thin and unstable or keloidal, was discussed by Davis (J 125 621 1944) The painful scar may be rendered painless not for a brief period but for a long time by infiltrating it with procaine (König DentMWchn 64 1872, 1938) See also Acne treatment

ATROPHIC STRIAE (STRIAE DISTENSAE)

Sharply defined linear atrophic lesions are often seen over the abdomen lower back, breasts flanks or lateral aspects of the thighs. Their disposition parallels the lines of cleavage and they are generally grouped in such a manner as to suggest that the skin has been overstretched They are sometimes red in color particularly in the early stage but they become whiter than the adjacent normal skin. The lines are slightly sunken They are without pain or tenderness.

These lesions symptomatically follow mechanical overstrain, as in pregnancy (lineae gravidarum) tumors, obesity and ascites. There is also a type which is apparently idiopathic, but the possibility that the lesions have been caused by either trauma or overextension can seldom be excluded. A common site is the lumbar region in young people Rosenthal (Lancet 1: 857 1937) denied in these cases a relation to posture The condition occurs in a period of rapid growth in adolescence and extreme flexion of the spine in the course of everyday life overextends the skin of the back, which may be presumed in these patients to be less than sufficiently elastic Both cases of Weber (Lancet 2 1417 1935) had their onset at puberty Among 834 feeble minded persons striae distensae were found by Butterworth and Wilson Jr (ADS 39: 703, 1939) in 39 and of these 30 had undergone rapid gain in weight. An association with steroid activity was postulated by Sisson (JPediat 45: 520 1954) who noted the common association of acne in his adolescent cases and who reported an incidence of 25% in 100 healthy children some of whom were preadolescent

Astonishing striae may be seen in basophile adenoma of the pituitary (Cushing J 99: 281, 1932 Hall et al.: Lancet 1 802, 1939) Schilling (MWelt 10: 259 1936) thought them to be a sign of hyperfunction of the pituitary anterior lobe though Cushing attributed them to the rapidity with which obesity is acquired. The administration of ACTH (see Dermatitis Medicamentosa) causes striae when it causes Cushing's syndrome

Their appearance in the patellar region in children who were recovering from severe illness, such as typhoid fever has been noted by many authors (Shepherd JCutDis 8 436 1890; 9 89 1891; Northrup TransAssnAmPhys 18: 197 1903; Bunch BJD 17 1 1905) Weight gain as well as weight loss may occasion their development. Among the tuberculous patients of Macrae Gibson (BJD 64 314, 1953) those who showed red lineae distensae were the ones who had gained on the average 4.7 lb. per month, while those who had gained only 2.2 lb. per month did not show the lesions, for the most part A tuberculous patient who became nephrotic was given ACTH, in desperation, suffered rupture of the belly wall through such a stria (Lawrence et al.: J 152 1526, 1953)

Pathology.—Bunch found alterations in the elastic tissue characterized chiefly by the distribution and new parallel arrangement of these fibers, the rearrangement having been brought about at the expense of the transverse elastic fibers which had ruptured and retracted to the edge of the lesion At the margins of the lesions the elastic tissue appeared denser than normal, probably a result of the presence of the broken, retracted fibrils. Rupture of elastic fibers seemed probably due to gradual stretching or tension rather than to inflammation Elbert (ADS 43 635, 1943) found, in the early stage of hypertrophic striae distensae, productive inflammatory changes with degeneration of elastin, and he propounded the theory that the toxic agent in these cases may be a product of a disturbance of the endocrine system. In discussing the paper Pusey emphasized the fact that there is a mechanical factor in the vast majority of these cases.

Treatment.—Nothing can be done to cure the lesions, which are permanent. Proper support to prevent overstretching of the skin may keep them from developing during pregnancy (Aagaard ActaOb-Gyn 28 1 1949)

See Rothwell (JCutDis 3 : 210 1919) case; Milian (ADS 1: 481 19 0) case; Hodel and Walter ([illegible]) 231: 182, 19 1); Allmendi ([illegible] 11 24, 1937) incidence 45% in tuberculous patients; Musser (AfDus 177: 732, 1938) White (ADS 31: 439 19) 1st girl.

THERMAL INJURIES BURNS AND FROSTBITES

Erythema.—See Erythematous dermatoses of undetermined cause

Erythema Caloricum and Erythema Pernio (Chilblains) are erythemas due respectively to heat and cold. The effects of radiant heat such as the long-continued application of an electric pad produce erythema ab igne In this condition, there is often accompanying inflammation and pigmentation is usual. Chilblains are purplish infiltrated lesions which develop on the nose ears heels, and other prominences as a result of repeated exposure to cold They are common in damp, cold climates, such as that of London, and occur especially in persons who habitually suffer from cold hands and feet, and who are said to have *chilblain circulation*. *Marmoraceous redness of* the arms and legs, more pronounced on the dorsal surfaces, is notable in many persons especially those who are long accustomed to being not warm enough The skin is cool and puffy and it may become hypertrophic to a degree that justifies sympathectomy which results in vasodilation warmth and relief See Pernio

Fig [illegible]—Erythema ab igne marmoraceous appearance induced by hot pad
Fig [illegible]—Frostbite, showing results t telangiectasis. (Dr Stuart Way)

Burns range in extent and severity from slight localized redness to widespread tissue necrosis. They may be divided according to severity (1) burns of first degree characterized by the presence of the inflammatory signs of heat, pain, redness and swelling due to *necrobiosis of epithelium and superficial vessels* (2) burns of second degree characterized by these symptoms, plus vesiculation and exudation due to epithelial necrosis (3) burns of third degree, including all thermic injuries of the skin which result in necrosis of both epithelial and connective tissue substance Primary shock in extensive burns *is like other surgical shock, and* is to be treated with plasma, blood transfusion, dextrose oxygen, sedation, heat and perhaps adrenal cortex extract (Harkins J 119 385 1942) In burns that destroy nerve endings, pain may be wanting but shock appears in a few hours. In severe burns the patient should be treated for shock at once whether he shows it or not Aldrich (NEngJM 217 911 1937) stated that delayed shock which comes on after from 10 to 20 hours, attributed to histamine by others, is simply inadequately treated primary shock the viscosity of the blood is increased even more in capillaries than in veins, so that the patient suffers erythrocytic

emboli, which cause fatal anuria ulcerative colitis, and focal necrosis of adrenals, lymphoid tissue heart muscle and other organs. Intoxication which comes on still later Aldrich thought to be bacterial intoxication, although this is open to question (McClure J 113 1808 1939) It may be prevented by maintaining bacteriostasis of damaged areas. Pyemia, erysipelas and tetanus are among the complications one anxiously avoids. When vibrissae are burned, look out for laryngeal and tracheal involvement, include high humidity in therapy and be prepared for tracheotomy When nails are blistered off digits are usually lost

Standardized thermal injuries were applied to various parts of the body by Benjamin and Cornbleet (ADS 68: 530 1953) Down the leg from knee to ankle they found a gradient of diminishing rate of healing, but this was not evidenced when the patient remained abed. Bed rest reduced the absolute time of healing which was apparently affected by gravitational factors.

Controlled thermal injury was investigated experimentally by Williamson and Scholtz (JID L: 41, 1949) with special reference to the injury necessary to incite blister formation. Blisters always resulted when heat of 146 F was continued for 10 seconds. If 122° was applied for 10 minutes, the interval before blistering appeared might be as long as 4 hours. *The histologic changes in the basal cells were found to be typical.*

Burns in Children are tragic and largely preventable. The causes were studied by Bleck (J 158 95 1955) who listed (1) ignition of clothing from such sources as fireplaces, trash fires and stoves, in 159 cases; (2) direct contact with flame as falling into fireplaces in 8 cases; (3) gasoline and kerosene fires, in 51 cases; (4) hot liquid burns, as from pulling a kettle off a stove in 9 cases; and (5) miscellaneous causes, in 4 cases. Education of all persons who care for little children should result in the prevention of a high proportion of such accidents.

Cosmeticians Burns.—Deep little burns are often caused by inept use of permanent wave machines. Severe burns can result from ignition of celluloid combs.

Electric Burns.—Next to bone, the skin offers greatest resistance to the passage of electricity since the greater the resistance the greater the burn, severe skin burns are *common, especially of the hands. With voltages of from 5,000 to 10,000 charring is* swifter and more definite than with lower voltages, which generally cause tissue damage not immediately manifest as desiccation or charring Relatively small skin damage may coexist with serious injury to deep structures, particularly tendons and their sheaths, so that sometimes what appears to be a superficial injury evolves as a grave and far reaching one. The *customary classification of burns as to degree is not appropriate in describing* electrical burns (Edwards and Bowles AmJSurg 47: 299 1940) See Electric burns of the mouth.

Hydrofluoric Acid Burns are comparatively painless for several hours despite deepening necrosis. They are best treated by applications of sodium bicarbonate solution and magnesium oxide paste, injecting under them 10% calcium gluconate to stop their progress (Jones JIndustHyg 21: 205 1939)

Phosphorus Burns *are extremely painful and slow to heal because of the formation* of P_2O_5, which combines with tissue fluid to make phosphoric acid. Emergency treatment requires immersion in water or wrapping with wet blankets to smother the fire, later picking out bits of phosphorus while swabbing with warm 5% solution of sodium bicarbonate. Copper oleate, prepared from the sulfate mixed with soft soap, inactivates by combining with phosphorus to form copper phosphide (McCartan and Fecitt BMJ 2: 316 1945).

PROGNOSIS.—Of 1,574 burns, *death was the result in 8.2% of those due* to scalds, 31.2% of those due to ignition of clothing and none in those due to contact with flames or hot solid bodies (Lütken UgeskfLaeger 20 409 1937) The outlook depends on promptness and effectiveness of treatment, as well as extent of injury Of 250 burned children, all who lived to the tenth day survived 14 deaths occurred, pneumonia topping the list of contributory causes (Lavender J 118 344 1942) Among 8 000 deaths reviewed by McClure (J 113 1808 1939) *almost half involved children under 6* years of age and four fifths of these were preventable. Loss of plasma protein was important, also tissue anoxia due to hemoconcentration and circulatory failure. *Liver cell damage perhaps due to absorption of toxin formed in the* burn, was conspicuous. The possibility of recovery is to some extent inversely proportional to the area of the burn Berkow (ASurg 8 138 1934) estimated the area in adults of head 6% upper extremities 18% trunk including genitals 38% and lower extremities 38% Of the lower extremities, the feet comprise one-sixth, the legs one-third, and the thighs one-half. In children under 12 years, the head is larger and the lower extremities smaller Burns exceeding 50% of the surface are extremely grave.

If metabolic demands of the tissues are met, shock adequately treated, hemoconcentration corrected (hematocrit kept under 50), rigid asepsis maintained and toxicity successfully combated, the outlook is favorable (Pemberthy and Weller, SGO 74: 428, 1942).

Intravenous injection of fluorescein sodium, 10 cc. of 20% solution, followed by illumination in ultraviolet light distinguishes second degree burns which glow yellow from third degree burns which look purple or black (Dingwall and Andrus, AnnSurg 120: 377, 1944).

TREATMENT.—For small burns, soothing and protective lotions such as cool moist packs and petrolatum are all that is needed. In burns of second degree the vesicles should be incised and drained aseptically, loose epithelium removed and an antiseptic dressing applied. Tetracycline or bacitracin ointment or sterile petrolatum gauze may be recommended. Butesin picrate is unsatisfactory because eczematous reaction to it is common.

In the treatment of severe burns, the surgical principles according to Allen and Koch (SGO 74: 914, 1942) are (1) prevent and combat shock, (2) convert an open contaminated wound into a clean one, (3) cover the wound with the simplest possible dressing which does not increase tissue damage, does allow for drainage, exerts uniform moderate pressure and is easy to remove, (4) keep the injured parts at rest and (5) secure healing with the minimal loss of function and of time. Restlessness and rapid pulse are constant and important signs of fluid loss and indicate the immediate need for plasma. The administration of oxygen is a valuable adjunct to treatment. The most important source of infection is the mouth of the person who treats the burn and this must be masked. Soap and sterile water aseptically used are best for cleaning a dirty burn, and fine-meshed gauze sterile and impregnated with petrolatum is the best dressing. It is covered with mechanic's waste or sponges to provide a resilient covering held in place by a retention bandage that furnishes even pressure without constriction.

The blister fluid contains about 75% as much protein as the blood plasma and plasma must be restored adequately. Freeman et al. (J 122: 924, 1943) would give at once 50 cc. for each 1% of body surface burned, 40% of this amount later during the first 24 hours and an equal amount within 72 hours.

Swelling, which accounts for great loss of protein and fluid into the interstitial spaces, may be controlled with pressure bandages or even plaster casts (Levenson and Lund, J 123: 272, 1943; Harkins, J 125: 533, 1944).

In attempting to control infection, one (1) blocks admission of pathogens to the burned area at the time of doing dressings and (2) blocks their entrance between one dressing and the next (Colebrook et al., Lancet 1: 893, 1948). A trained team can do these things, for asepsis requires masking and education of personnel who handle burned patients, as well as proper bandaging and strict attention to detail. Antisepsis with antibiotics is also essential.

Azotemia occurs early and usually is reversible as urinary output approaches normal, but in some severe cases it does not disappear. Hypoproteinemia and inversion of the A/G ratio must be watched for and are met by increasing alimentation (Taylor et al., NEngJM 229: 855, 1943).

The value of cortisone in burns is debatable and so to be adjudged not conspicuous. Whitelaw (J 145: 85, 1951) thought ACTH afforded excellent support in 4 cases. Plastic surgeons at this time are not enthusiastic.

For extensive burns, Davidson (SGO 41: 202, 1925) recommended aqueous solution of tannic acid applied by spray. Coagulants other than tannic acid can be used. Dyes, such as gentian violet, are useful, but Cohen (BMJ [illegible] 251, 1940) found in war experience that tannic acid and silver nitrate are preferable. The eschar produced by tannic acid is inflexible [illegible] to curl at the edges, and infection [illegible] not readily be detected beneath it. [illegible] kept [illegible] is more likely to occur in deep burns and may have its onset [illegible] 7 days. [illegible] wet dressings [illegible] time [illegible] be preferred in small second degree burns. Blisters [illegible] 4 hours before tannic [illegible] already infected and should not be so treated. Burns of hands and fingers should be treated with a grease, not with tannic acid (MacCollum, J 116: 2371, 1941). Tannic acid [illegible] now days [illegible] doing more harm than good, though [illegible] infection spreads under the eschar and intoxication with liver damage occurs (Lee and Rhoads, J 125: 610, 1944).

Continuous bath treatment wa described by La ender (AmJSurg 45: 534 1939) Continuous irrigation of the b rned part within an enveloping bag wa recommended by Pearson et al. (BMJ 1 41 1941)

A casein gel treatment was advocated by Curtis et al. (J 147: 41 1951) The partially hydrolysed casein on the burned area is covered with gauze impregnated with zi c acetate and it form a semipermeable membrane which prevent exudative protein loss and supports the damaged capillary bed, providing splinting and relief of pai It enables early grafting minimizes infection and is simple in application.

Acid débridement wa invented in the search for means to selectively digest and remove th necrotic slough. Pyruvic acid 8% in cornstarch paste at pH 1.0 was said to clean slough in 4 days so that grafts could be applied early (Conn r and Harvey: Ann Surg 120: 362, 1944) Pyruvic acid, 0.9% (0.1 molar) in starch paste wa studied by Sulzberger et al. (AnnSurg 1..5: 418, 1947) and adjudged safe simple and practical, capable of hastening granulation. Phosphoric acid, 0.1 molar likewise maint ined a pH of 2.0 and was effecti e In a water-soluble vehicle 0. molar phosphoric acid was used by Schweitre and Brad her (NEngJM 44 0. 1951) Its application caused burning pain for from 15 to 30 minutes, controlled with Demerol A dam of petrolatum impregnated felt strips wa used to prevent the mixture from seepi g away and petrolatum strips and fluffed gauze covered the phosphoric acid gel. Dressings were changed ea h 4 to 48 hours, and separatio of the lough was hastened mechanically Epith lium apparently wa not damaged, and areas encompa ing first, second an l third degree burn could be treated beneath the same dressing

Unde some circumstances, the entire burned rea should be excised. A patient may be placed und r a cradle with electric light a the source of radiant heat and the tire rea i covered with sterile gauze kept wet with hypertonic saline

To meet adequately the emergency of a disastrous fire is a terrible responsibility By way of being prepared to do so one will profit from studying the report of Cannon (Surg 15 1 8 1944) co cerning the famou Coco nt Grove tragedy See Enyart and Miller (J 135: 93 1953) on disaster management of the xplosion and fire occurring aboard the U.S.S. Ben i gton 31 \ 26, 1954 util zing the exposure treatment and electrol te replacement by the rule of 9 the surface area of the head a d neck i 9% of the total body surface each upper extremity i 9% each lower extremity i 18%, and the front and back of the trunk are each 18% the remai ing 1% being ccounted for by the genitalia an l perineum. The Hell ood fire resulted in pneumonic death in 13 newborn babies w thin 3 days afterward, reported Cox et al. (BMJ 1: 94., 1953)

Flash burn from explosion may be serious and are common in war A protective cream ha value (B lIUBAMD 76: 7 1944)

The prevention of burns and sc lds which occur i d about the home was of concern to Colebrook and Colebrook (Lancet : 181, 1949) Ed cation of the public plays an important role in preventive efforts, as well as good design of hazardous grates and appliances.

Injuries Due to Cold are called cryopathies or frostbites, and they include trench foot immersion foot chilblain and pernio They may be of any degree of severity acuteness or chronicity and extent of involvement Lewis (BMJ 2 795 837 869 1941) described the effect of light freezing as productive only of transitory local erythema. Exposure of the skin to −10° to −15° C. for 20 seconds induces redness followed by itching and swelling and a wheal typical of the response to acute physical injury The wheal subsides in a few hours, to be followed by local redness and tenderness for about a week, with peeling Exposure to −15° for 60 seconds results in blistering within an hour or two Severe freezing induces necrosis due to vascular thrombosis which appears within a few hours.

Early symptoms of frostbite may be absent, but it is usual for painful burning sensations to be followed by numbness Symptoms are related to the temperature the duration of exposure and the medium in which the exposure took place In high-altitude flying anoxia combines with cold to increase the destruction of tissue Blanching and vesicle formation pallor and coldness, bluish discoloration due to venous congestion, and necrosis and gangrene are seen. Late sequelae well described by Shafer and Thompson (AD 72 335 1955) are pain hyperreactivity to cold hyperhidrosis and various dermatologic orthopedic and neurologic changes.

CLASSIFICATION of cold injuries was given by Pratt (OP 7 34, 1953)

FIRST DEGREE FROSTBITE.—The part subjected to cold for a short time, or to a lesser degree f cold for a longer time hows erythema a d spasm with burning and tingling sensations, and recovers without loss of tissue although there may be some peeli g.

SECOND DEGREE FROSTBITE.—Actual tissue destruction takes place usually limited to skin. Anesthesia and paresthesia accompany marked reactive hyperemia, and wheals and superficial blebs occur. Secondary infection may increase the tissue loss.

THIRD DEGREE FROSTBITE.—These are reactions to extreme cold. The parts do not recover completely, subcutaneous tissues are damaged, extensive injury may be fatal and tissue loss varies with trauma, secondary infection and effectiveness of treatment.

FOURTH DEGREE FROSTBITE.—The injury includes loss of muscle and bone.

FIFTH DEGREE FROSTBITE.—Anoxemia and stress exposure produce deep freezing, the skin being shiny and tense with subcutaneous hemorrhages. The main attack on such problems is by means of prevention.

PATHOLOGY.—There are both cellular injury and local ischemia due to *clotting in peripheral vessels, Pratt believed. Gangrene when it develops, is* of a cyanotic avascular type leading to black, dry necrosis perhaps glove-like and requiring to be split along the fingers to prevent constriction. Secondary infection capable of altering the picture completely is of great importance. *There can be no single pathologic description of frostbite just* as there is no set picture in a burn. Friedman (AmJClinPath 16: 634, 1946) found no essential difference between the pathologic lesions of trench foot and of high altitude frostbite.

Frost Injuries in Warfare were well described by Lieberman (NYBJM 44: 115, 1944) who listed types: erythema and edema, blisters, superficial gangrene, gangrene of skin and subcutaneous tissues, gangrene of an entire acral part, injuries to deep tissues with or without accompanying skin lesion, and chronic relapsing cutaneous manifestations such as chilblains and other forms of erythrocyanosis. Frostbite at high altitude depends in *part on vasospasm and anoxemia, for fingers are more susceptible than cheeks (Davis et* al. BGO 77: 561, 1943). Shelter foot was seen in London in 1940 and 1941 among individuals who sat up all night without compensating rest in the horizontal position during the day (Greene, Lancet 1: 303, 1940; 689, 1941). Swelling of the feet was painless at first, and spread up the leg. It did not occur in wardens who, though exposed to equal cold and damp, were frequently on their feet. Shelter foot, immersion foot and trench foot are basically similar.

Immersion foot (trench foot) occurs when the feet are long exposed to cold and wetness. This may develop even when the temperature is above freezing. Dilation and engorgement of vessels of skin and subcutaneous tissues occur along with agglutinative thrombi composed of red cells and platelets (BullUSAMD, Feb., 1945). Numbness is accompanied by swelling and waxy white areas with scattered cyanotic spots. Swelling increases rapidly when the parts are warmed when redness, hyperemia, bounding pulse within the parts and intense pain supervene. Depending on severity of injury, blebs which may be bloody and ulcerations develop, tissues may turn black, and dry or moist gangrene becomes manifest (Webster et al.: JB&JS rg 4: 655, 194). Recovery may be complete or chronic neuralgic pains may begin or hyperhidrosis with soggy fragility of the epidermis may be a sequel, along with hypesthesia.

Late sequelae are fairly common, including chronic peripheral vascular disease, subjective cold, eczema and plantar ischemia (Fausel and Hemphill, BGO 81: 50, 1945). Sympathectomy may then be desirable (White, NEngJM 228: 11, 1943). The indications for *sympathectomy according to Shumacker and Abramson (AnnSurg 1..3: 902, 194)* who reviewed the effects of the measure as performed on 49 of 100 Mayo Clinic patients, include extensive gangrene, excessive sympathetic tonus, and pain on weight bearing. It is not appropriate in the majority of cases. See Goldstone and Corbett (BMJ 1: 19, 1944); Ungley et al. (BJSurg 33: 17, 1945); Southworth (NEngJM 233: 673, 1945.

PREVENTION OF FROSTBITE.—Elderly persons and people with diabetes or arteriosclerosis must not be allowed to suffer overexposure. Clothing should be carefully planned and adequate and the extremities especially must be protected. Men working out of doors in cold weather should be required to enter *shelter and warm up periodically* and hot drinks are helpful (Brahdy, J 104: 529, 1935; 108: 369, 1937).

In military life discipline must be enforced with respect to extra pairs of dry socks and shoes, the avoidance of remaining long in a cramped posi*tion and the necessity for keeping moving. Water collects within watertight* boots, which are not satisfactory. The avoidance of trauma as from vigorous massage, must be taught and enforced. Bodily cleanliness diminishes the liability to infection, which can greatly increase the damage of even a minor *frostbite.* Frequent inspection is requisite. Loose clothing, the horizontal sleeping position and limited duration of exposure contribute to the welfare of those who must be exposed.

TREATMENT OF FROSTBITE.—The immediate care of cold injuries is extremely important. Further exposure to cold and wet must be ended. Cases with tissue destruction must be put at strict bed rest. Treatment for shock must be instituted, and Pratt approved of whiskey as a vasodilator. Nicotine must be prohibited. Dirty wounds must be cleansed and the cleansing procedure must avoid trauma. Prevention and control of infection require the early use of antibiotics, cultures and sensitivity tests. Sterile dry dressings are advised and the use of ointments is frowned upon as increasing the liability to moist infectious gangrene.

Overheating of frozen tissues is a grave error but debate has not as yet been settled whether the parts should be warmed gradually or brought up to body temperature more promptly. Rapid warming but not heating seems to be gaining approval (Edit. J 148 940 1952). Pratt favored a temperature of 65° to 60° F., pointing out that vascular damage with stasis and edema, is reasonably treated by preventing the delivery of more blood to the part than can be drained from it. Cool therapy relieves pain. It was observed that patients would themselves put their injured parts out the window to obtain comfort and many stated they suffered less in lifeboats on the sea than when put into warm surroundings.

In rabbits experimentally exposed to acute severe frostbite rapid thawing appeared to increase the severity of tissue damage, edema, pain and gangrene reported Arena and Blair (Surg 37: 175, 1955). Ice crystals in the tissues of hamsters did not necessarily result in gangrene but if the frozen tissues were beat, then gangrene resulted (Smith: Lancet 1: 1-55, 1954).

The frostbite cases of Edwards and Leeper (J 149: 1199 1952) occurred in military personnel, whose acute stage of freezing thawing exudation and initiation of necrosis had already taken place. The subacute stage was marked by resolution of necrosis and the commencement of vasospasm and acrosclerosis. In these patients, relief from chilling had been denied, so that vasoconstriction from refrigeration was abetted by hunger, exhaustion, anxiety, blood loss from wounds, hemorrhage and shock, and tobacco smoking. Superficial necrosis was always more extensive than underlying gangrene, and observation for several weeks was necessary before any amputation was performed. It was not possible to predict accurately which patients would show long-lasting effects, but these authors suggested that waiting two years for spontaneous disappearance of symptoms would be ample before performing sympathectomy.

Anticoagulant therapy probably ought to be instituted early. Heparin was used in experiments performed by Lange and Loewe (SGO 82: 256, 1946) and appeared to save tissues which otherwise would have been lost. Lange et al. (PSExpB 74: 1, 1950) prevented red cell sludging and diminished the extent of gangrene as compared with control animals when they used heparin at once in such dosage as to keep the coagulation time 22 minutes or longer all the time for at least 5 days. Pratt advised giving heparin 50 mg. intravenously at once, along with 30 to 70 mg subcutaneously. Testing coagulation time 3 hours later, more heparin in doses of from 30 to 70 mg. should be given subcutaneously so as to keep the coagulation time between 20 and 30 minutes. An oral anticoagulant (Tromexan 1,200 mg. or Dicumarol 400 mg.) should also be given. After the first 24 hours, oral anticoagulant therapy was continued (Tromexan 600 to 900 mg. Dicumarol 300 mg.) to keep the prothrombin time some two to three times the normal. Pratt would continue such therapy for some 3 weeks, or until the fate of the part has been determined. Hemorrhagic complications, the urgency of a surgical procedure or any other contraindication can be met with specific drugs (protamine for heparin, vitamin K for Tromexan or Dicumarol) so as to stop their action.

The period from the second to the twelfth week is of utmost importance to the patient, Pratt stated. The extremities should be kept dry, clean and exposed to air without weight bearing until the wound is healed or separated. Antibiotic and anticoagulant therapy continued. Sterile saline soak for an hour a day will aid a separation of sloughs. Chemical sympathetic blocking agents such as Priscoline or tetraethyl ammonium chloride may be helpful and Mephenesin, by relieving smooth muscle spasm, is useful in controlling pain, often preferred by the patient to opiates. Early sympathectomy does not prevent or limit the extent of gangrene, according to Isaacson and Harrell (Surg 33: 810 1953); its applicability is to the late sequelae particularly.

Vasodilation may be obtained with Hexamethonium, which was considered by Mowrey and Farago (M Surg 110: 249 1952) to be as effective as lumbar block. The technic of sympathetic block was given by Simmons (BMJ 2: 884 1945). Block induced early in the course of frostbite brings about cessation of pain, rapid subsidence of edema, more active circulation, quicker demarcation of nonviable tissues, better granulation and faster healing, according to Shumacker (SGO 93: 727 1951). Sympathectomy is to be considered on the basis of the response to sympathetic block.

The guiding surgical principle in treating frostbite is restraint. All authorities agree that amputation should be delayed, even for three months, until the situation becomes clear. Early surgery is requisite of course to control otherwise uncontrollable infection and to drain abscesses if they occur. Final surgical therapy involves amputations and grafts. The surgeon is given plenty of time to reach his decisions. Hyperhidrosis and the tendency to macerate, vulnerability to secondary infection and dependent cyanosis are annoyances which may continue for years. Sympathectomy can be expected to help them a great deal.

Pernio (Chilblains).—The pernio syndrome may include the acute form of chilblains, the chronic form of chilblains and perhaps immersion foot or trench foot. According to Allen et al. (Peripheral Vascular Diseases, Saunders, 1946) it seems that a similar mechanism operates in all these conditions and has as its outstanding feature a reaction of the peripheral blood vessels to cold. Clinical features are similar and such differences as occur in the nature and extent of the symptoms and signs are due to differences in severity, length of exposure and variability of vessel response to cold. The single name "chilblains" is adequate to embrace all the manifestations of erythrocyanosis crurum, dermatitis hiemalis and nodular vasculitis, in the opinion of Lynn (SMJ 39: 720, 1944) who denied the value of separating these conditions as dermatologic entities. Yet he emphasized the distinction between acute and chronic chilblains: prolonged and repetitious exposure to cold in persons who are prone to chilblains leads to changes that persist and to pathologic lesions that are irreversible.

Pernio was described by Shaefer and Sanders (JMoMA 38: 159, 1941) as a specific peripheral vascular disease in persons sensitive to sudden changes of temperature. Whether it represents solely a vasomotor reaction of allergic origin or is due in part to chronic inflammation is undecided, but there is some permanent change in the walls of peripheral vessels so that minute vessels are dilated while arterioles are constricted. Wigley (Pract 157: 343, 1945) described mild and severe forms and recommended in treatment improvement of the general health, the administration of cod liver oil and iron, the avoidance of extremes of temperature and adequate protective clothing. Nicotinic acid was recommended by Gourlay (BMJ 1: 336, 1948). Histologic studies were made by McGovern et al. (AmHeartJ 22: 583, 1941).

Acute Pernio is experienced by a child who goes out into the snow or cold wet weather without adequate protection for feet and legs and develops dermatitis characterized by its bluish red color and slight edema in its area of distribution. Intense itching and burning are aggravated by exposure to warmth. The manifestation exists for several days, but gradually fades. Sometimes brown pigmentation persists for several weeks. Rarely purpura develops in the affected region during the acute stage.

Chronic Pernio is seen in susceptible persons who have been repeatedly exposed to cold and in whom develop recurring and chronic cutaneous lesions, which are erythematous, ulcerative and hemorrhagic and which often leave residual scarring, fibrosis and atrophy of the skin and subcutaneous tissues after healing. The lesions usually are active during the cooler months and may subside completely during the warm season, when the diagnosis is obscure because the etiologic significance of cold is overlooked. Such cases have been called erythrocyanosis, Bazin's disease, dermatitis hiemalis and lupus pernio. Confusion has resulted, according to Allen et al. (Peripheral Vascular Diseases, Saunders, 1946) from failure to distinguish this syndrome from tuberculous erythema induratum (q.v.) from which it is differentiated by histologic examination. Compare nodular vasculitis.

The lesions are of various sizes, elevated and horseshoe-shaped, reddish or slightly cyanotic, perhaps vesiculated or ulcerated. On healing atrophic

violaceous scars develop Histologic changes comprise (1) angiitis with intimal proliferation, thickening of the arterial walls, and periarterial and perivenous infiltration of lymphocytes, monocytes and neutrophils, (2) necrosis of the fat panniculus, and (3) chronic inflammatory reaction of the subcutaneous tissues, in which giant cells may be found

The typical patient with chronic pernio, as described by Allen et al. (1946) is a woman who complains of recurring erythematous, and ulcerating lesions of the lower extremities. These made their appearance in adolescence or early adult life, and at first appeared at the onset of cold weather and disappeared during the summer On exposure to cold, burning and itching sensations developed in the affected regions, the lower part of the legs. Red, slightly elevated lesions from matchhead to dime size appeared over the anterior and posterior leg region of involvement and sometimes on the dorsum of the feet and on the toes. Blisters developed on these and the color of the lesions deepened in its violet hue Superficial ulceration ensued with a hemorrhagic cyanotic base but with little exudation. Pain was at first present but later subsided. Healing eventuated within three to five weeks spontaneously and pigmentary residual persisted. When new crops of lesions appeared the procedure was repeated. In such cases crops may appear over a period of several months. During the active stage the lower extremities are cool and slightly cyanotic in a cool environment The legs may be somewhat edematous. Livedo reticularis may be present The peripheral arteries pulsate Evidences of occlusive arterial disease are absent.

Livedo Reticularis is characterized by a local and prominent mottling and blotchy or reticular discoloration of the skin of the extremities, of reddish blue color Williams and Goodman (J 85 955 1925) divided cases into three groups (1) cutis marmorata manifested by mottling of the skin on exposure to cold with disappearance on warming (2) livedo reticularis, idiopathic with bluish red mottling more intense than in cutis marmorata and persisting in spite of temperature changes and (3) livedo reticularis symptomatica in which mottling persists but evidence of some other disease affecting the cutaneous vascular system is also present

See Rheinacher (Surg 13 237 1943), case involving lower extremities cured by lumbar sympathectomy Yorke and Klaber (BJD 61 17 1948) case legs and ankles, with recurrent blisters and scarring, associated with Raynaud's phenomenon Ebert (ADS 49: 219, 1944) resemblance of pattern to lesion resulting from intra-arterial emboles, Becker (ADS 50: 114, 1944) stroking area causes pattern to disappear followed by return of bright red blood, proving pathologic process nonobliterative, Barker et al. (AmHeartJ 21 592, 1941) a peripheral arteriolitis Feldaker et al (AD 72 31 1955) livedo reticularis with summertime ulceration.

Erythrocyanosis (Acrocyanosis)—Almost constant coldness and bluish discoloration of the fingers, hands, toes and feet for many years are the features of acrocyanosis. These changes, while more intense in cold weather persist in a warm environment. The color is deep purple when the skin is cold and red when it is warmer Scleroderma does not develop but swelling and puffiness occur particularly in cold weather and some areas may become painful. Atrophy or ulceration does not take place. No evidence of occlusive arterial disease is to be found Acrocyanosis is distinguished from Raynaud's disease by the persistency of its color change and the absence of pallor In erythromelalgia the region of color change is hotter than normal, while in acrocyanosis such regions are cool. Cyanosis in the presence of occlusive arterial disease is related to ischemia and is not true acrocyanosis.

A bluish red network involves generally the legs being supramalleolar in distribution, and the forearms it is greatly intensified by exposure to cold or friction. Only a small drop in temperature suffices to bring on the appearance of vermilion spots which accompany purplish infiltrates. The causative mechanism probably is partial obstruction of arterial supply due to cold sensitivity for nerve block temporarily relieves the condition. It is likely that vasomotor instability of psychosomatic origin plays a part in causation for cold moist hands and feet, with dependent cyanosis, characterized the sufferers from this disease. In therapy continued warmth, such as that provided by central heating is helpful.

See Ebert (ADS 16 426, 1947), Clouston (CanadMAJ 40 166, 1939); Lewis (BMJ 2 837 1941); Wrong (CanadMAJ 46 520, 1942); Barker et al. (AmHeartJ 21 592, 1941)

ACTINIC INJURIES

Sunburn is a common symptomatic erythema (q.v.). Persons differ in susceptibility, blonds being especially sensitive. Erythema limited to the exposed areas has its onset within a few hours after exposure begins, the interval depending on susceptibility and dosage. Vesiculation is characteristic of severe exposure, and extreme cases are sometimes seen. If a large area is involved, in addition to pain, smarting, burning and swelling there may be severe constitutional symptoms, including weakness or collapse, fever, chills and even delirium. Secondary infection may complicate the condition. Maximum intensity is reached within 12 to 24 hours after exposure, and recession of signs and symptoms then begins. Peeling follows and is accompanied by itching. More or less temporary pigmentation ensues. Sometimes sudamina (q.v.) follows sunburn because of temporary hyperkeratotic obstruction of sweat ducts (Thomson: Lancet 1: 17[illegible] 1951).

Pigment production is probably not the main agency of acquired tolerance, for pigment in the basal layers of the epidermis does not protect the rete, which is the site of vesiculation when that occurs; thickening and increased opacity of the corneum which develop after exposure are the protection, according to Blum and Kirby-Smith (Sci 95: 703 194[illegible]).

Increased tolerance of sunshine follows administration of estrogenic hormones (Lancaster: South MJ 32: 313 1939), or [illegible] and cortisone suppresses to some extent the skin reaction to ultraviolet (Jarvinen: BMJ [illegible] 1951).

The welding arc provokes actinic injury, especially conjunctivitis (Rieke: J 122: 734 1943), but glasses, clear or tinted, protect the eyes from ultraviolet injury (Blum: WarM 4: 389 1943). Fluorescent light contains some ultraviolet energy and was reported as a cause of irritation by Bresler (J 140: 1344 1949) and James (ADS 44: 236 1941). Such artificial light perhaps may be harmful to patients with lupus erythematosus.

Chronic actinic injury is an occupational disorder of farmers, sailors and other outdoor workers (see Senile keratoses; also Light sensitivity dermatoses).

Physiologic Effects of Ultraviolet Light.—Antirachitic action takes place in the lowermost horn cells. Erythema results from action in the basal layer of the epidermis and the superficial portion of the corium. The basal epidermal cells are stimulated, and increased amounts of the products of their activity are set free; it is these substances which result in local hyperemia and which act also on distant parts of the body when absorbed and transported. Ultraviolet light produces maximum burning effect at a wave length of 2,96[illegible] A.U. The longest wave capable of burning is at 3,150 A.U. Too intense action kills the basal cells of the epidermis, so that ultraviolet irradiation is shock treatment, and its value depends on the individual's reaction to it. Care should be used to avoid overexposure. Not only may painful sunburn result, but more deep-seated injury may occur, as indicated by nervousness, apprehensiveness, and insomnia (Laurens: J 111: 2385 1938).

When parts of chromosomes were exposed to UV light by Uretz et al. (Sci 120: 197 1954), the movement of the chromosome from the centrosome region was inhibited only if the kinetochore was included in the irradiated part.

Treatment.—A soothing, cooling, protective mixture like calamine lotion is beneficial, or modified zinc oil may be prescribed.

℞	Phenol	0.3
	Menthol	0.06
	Zinc oxide ointment	
	Wool fat	15.0
	Limewater to saturation	
Sig	Soothing liniment.	

Sunburn is well alleviated by inunction with mineral oil and wrapping the parts with soft towels moistened with boric acid or aluminum acetate solution. The patient must be kept warm if extensive wet packs are necessary. Vesicles should be incised, and tetracycline ointment is valuable in combating or preventing infection. Later a bland greasy preparation is comforting.

A good preventive is [illegible] drams of zinc oxide in an ounce of Aquaphor. Phenyl salicylate (salol) 10% in liquid petrolatum, and stearates are also efficient in protecting the skin. A protective lotion may be prescribed, of skin-tinted red ferrous oxide 1.0, yellow ferrous oxide 1.3, titanium dioxide 15, bentonite 3, rose water to 100. Dark red vet. petrolatum is effectively opaque (Luckiesh et al.: J 130: 1 1946). Para-aminobenzoic

acid, 15% in Ruggles cream protects against rays of 2,000 to 3,100 A.U (Rothman and Henningsen JID 9: 307 1947) Pyribenzamine inhibits sunburn because the absorption curve of the chemical has a high extinction peak in the erythemogenous parts of the spectrum (Kline and Baer JID 10: 397 1948) A layer of zinc oxide paste generously powdered with talcum is effective. A fil containing 5% each of menthyl anthranilate and titanium dioxide is a good sun screen. Hemphill (NoWM 50: 4 4, 1951) combined phenyl salicylate 1.0 antipyrine 5.0 and sodium para aminobenzoate 5.0 in Almay emulsion base 100. Hydroquinone is unsuitable being both allergenic and toxic according to Draize (ADS 64: 585 1951) Para-amino benzoic acid was thought superior to its sodium salt by Fisher (ADS 68: 723, 1953) who gave the pharmaceutics of preparing a vanishing cream containing PABA 4.5, water 6.0 hydrophylic ointment 6.0 and base q to 30.0. Evaluation experiments of Ba ber (JID 23: 4 1954) indicated that the sun screening effect *of the tannic acid and PABA compounds were superior and that menthyl anthranilate was* inferior in effectiveness. Neo-A Fil (Texas Pharmacal Co.), containing 3% digalloyl trioleate in a vanishing cream base is commendable; it is said to block completely solar radiation from 2,000 and 3 150 A.U but it may cause contact photosensitization (p 147)

See Sharlit (ADS 32: 390, 1935) Strakosch (JID 5: 1 1942), Russell and Anderson (Lancet 2 247 1950), Bachem and F tus (AIPhysTh 20 49, 1939); Schwartz and Peck (Cosmetics and Dermatitis, Hoeber 1947 p. 144); Partington (ClinSci 13 425, 1954) vascular responses t UV not due to release of histami

X RAY AND RADIUM INJURIES OF THE SKIN

The influence of x rays and radium is necrobiotic (see Treatment x ray effects) Some kinds of cells are more susceptible than others to this effect, which is proportional to the quantity of x ray energy absorbed. Judicious use may be made of this phenomenon unfortunate results are radiation burns.

Fig 81.—Radiation trophy of kin and nails. (Dr C P G Wakeley)

Symptoms.—Gilchrist (BullJHH 8 17 46 1897) recognized the specific skin disease caused by x rays. Reactions vary in degree erythema, vesiculation, or even gangrene may result Reaction appears after from 2 to 10 days, the sooner when more severe In mild acute reactions, the redness, which is accompanied by tenderness, burning and itching disappears within two or three weeks, leaving temporary pigmentation such as follows sunburn. There may be periodic recrudescences of erythema which rapidly diminish in intensity but are observable for several weeks. In chronic cases which result from excessive employment of doses which if taken singly would not give rise to erythema the skin becomes thin, dry atrophic wrinkled, telangiectatic and pigmented Keratoses may develop and some of these may become carcinomatous. Nails become thinned, striated and brittle. In severe burns

marked dermatitis develops with vesiculation followed by more or less necrosis. Ulcers thus formed are covered with thick tough, adherent, brownish or grayish membranes and are exceedingly painful They heal slowly if at all Radium burns are similar but are smaller in all three dimensions.

Fig 32 —Roentgen dermatitis with chronic ulceration.

Fig 33 —X ray dermatitis of cheek, with consequent carcinoma. (Dr John Butler)
Fig 34.—Alopecia resulting from roentgenography with primitive equipment (Dr Frederick O Harris)

The most common cause of x ray burns is failure to insert filters when treatment is planned to include their use (Saunders and Montgomery J 110 23 1938) Mistaken diagnosis, inadequate records of previous radiotherapy improper calibration, faulty fluoroscopic technic unwise therapy in diseases for which x ray is only palliative, and stupid disrespect for or ignorance of, the harmful potentialities of exposure are other causes (Leddy and Rigos AmJR 45 696 1941 Garland J 129 419 1945 Curtis ClevClinQ 9 3 1942)

The hands are involved in a high percentage of cases of roentgen injury and a large proportion of the patients are doctors, dentists and x ray technicians (Mason AmSurg 17 1121 1951) Frequently repeated small exposures seem to promote the development of cancer more than intensive ex

posures. The treatment is likely to be of necessity excision. Fingertip burns from using x ray diffraction apparatus may simulate infections or thermal burns; interesting cases were recorded by Watrous et al (J 152 513 1953)

Shoe-fitting fluoroscopes entail significant hazards, and these devices should be decried (Hempelmann NEngJM 241 335 1949 Edit J 139 1004 1949) Their output is from 12 to 107 r per min with a mean of 38 r per min., according to Lewis and Caplan (CalifM 72 26 1950)

Fig. [illegible]—Multiple carcinomas and roentgen atrophy of gluteal region caused by x-ray therapy of pruritus ani.

Pathology—Early there is edema of the epidermal cells, followed by degeneration of nuclei. *Vascular endothelium is similarly affected. Severe doses* cause necrosis, hemorrhages and obliteration of small vessels. Fibrous tissue nuclei swell and fragment, and collagenous tissue takes a mucoid appearing stain. The epidermis becomes flat and atrophic and appendages are lost (Harvey EdinMJ 49 529 1942)

Chemical analyses of epidermal changes in the mouse produced by soft x rays showed calcium diminished by 50%, while epidermal lesions resulting from the application of methylcholanthrene contained 50% less calcium than normal (Toosy; CaRes 11: 361, 1951)

The scars of radiation burns show light blue fluorescence at the periphery in Wood's light, while scars from mechanical, chemical and electric burns are not fluorescent, according to DeMent (Sci 103: 631 1946)

See Carcinoma, etiology x ray; Erythema, symptomatic, following x-ray therapy

Treatment.—In severe cases, excision followed if necessary by grafts, may be necessary Pain is relieved at once. Aloe vera, a gelatinous material applied as a poultice and effective largely because of its physical properties, was reported on favorably by Loveman (ADS 36 838 1937) Tchou (ADS 47 249, 1943) Cole and Chen (ADS 47 250 1943) and Lushbaugh and Hale (Canc 6 690 1953) In mild roentgen dermatitis, astringent soothing lotions, such as aluminum acetate alleviate Boric acid ointment or Neobase with 0.5% phenol is a suitable bland protective tetracaine 0.5 to 1.0% may be added. Sellers (JMichSMS 41 59 1942) recommended Theelin in oil, 10 000 units per cubic centimeter locally Late cases may be helped by superficial desiccation (Cannon NYSJM 40 391 1940) or major surgical effort may be required (Bevan SClinNAm 1 935 1921 Ghormley and Fairchild Surg 7 737 1940) Chronic ulceration in postirradiation scars responded favorably to weekly infiltration with about 0.5 cc. of penicillin, 50 000 units per cubic centimeter into each 1 cc. of affected tissue, after preliminary infiltration with

1% procaine reported Lamb and Bover (JID 11 3 1948) Ulceration may be due to low grade infection Chlorophyll ointment received the approbation of Holmes and Mueller (AmJRoent 50 210 1943)

Fig 46.—Acute x-ray injury showing hydropic degeneration and karyorrhexis of epidermis. (Dr F D Weidman.)

Fig 47—Chronic x-ray dermatitis atrophy of epidermis, dilation of vessels, advanced degeneration of collagenous tissue absence of appendages. (Dr George M. MacKee, from McCarthy Histopathology of Skin Diseases, Mosby)

Corticotropin ameliorated the symptoms and prolonged the lives of mice which received 300 r total body irradiation and it appeared to help patients with radiation sickness due to therapeutic irradiation (Taber Radiol 57 702, 1951) Preliminary cortisone dosage reduced the reaction and damage produced in the skins of guinea pigs by large doses of x ray energy as compared with controls, reported Houghton et al. (BMJ 2 1313 1954)

Aurofac the residue of Aureomycin production is notably beneficial in radiation sickness, Mark Marks told me

Cathode Ray Injuries of the skin and eyes were reported on by Robbins et al (Radiol 46: 1 1946) The injuries resulted from a few second exposure to scattered electron from a 1,200 KV electrostatic generator There were three phases in the reactions, the last appearing four weeks after exposure The primary reaction resembled intense sunburn and the secondary reaction comprised edema and bleb formation. No lesion was deeper than the dermis although some lesions underwent ulceration. The reaction appeared sooner than severe roentgen ray injuries caused less pain, healed more rapidly and did not produce tanning though the late effect of both were similar

ATOMIC ENERGY INJURIES

The medical effects of the atomic bombing of Japan during World War II were reported by Keller (J 131 504 1946) Timmes (USNMB 48 219 1948) and others. In addition to mechanical effects, burns and suffocations due to conflagration, many casualties were caused by actinic flash and fewer by ionizing radiation. Actinic injuries were numerous and severe and were ill attended for the most part, to some extent because of the catastrophic proportions of the havoc inflicted Infection was usual and added its major contribution to the disastrous effects of burns, yet the keloidal sequelae were not too common, according to Warren (MilSurg 102 93 1948) Novy (ADS 61 379 1950) examining Hiroshima survivors 3 years afterward saw only ordinary scars of flash burns. Scars, keloids, alopecia and cataract from radiation were described by LeRoy (J 143 1143 1947)

In preparing to meet atomic attack burn casualties in the thousands must be expected and their care planned for (Evans J 143: 1143, 1050; 145: 134, 1951) Flash burns will constitute the majority of the casualties. Superficial burns are the ones that are painful, for deeper burns destroy nerve endings. The area immediately beneath the air burst of an atomic bomb is subjected to the combined effects of blast, gamma and neutron radiation and intense heat' Evans wrote The devastation here will be so great as to result in practically total loss of life (immediate or delayed) so medical attention must in the main be directed to the survivors outside the 1,500 yard zone, from 1,500 to 4,000 yards. Thermal injury in survivors outside the hypocenter zone will be of three types: the flash burn, contact burns from ignition (or heat transfer to skin) of clothing and deep burns from contact with flame encountered during entrapment in or escape from burning buildings. [Evans figures have to be revised to accord with refinements in the construction of atomic weapons.] The atomic flash burn differs from ordinary burns of civilian life only in that it results from exposure of the skin to a large amount of radiant energy (infrared, visible and ultraviolet) in a very short rather than a long period of time.

The principles of management of flash burns in no way differ from those for other thermal burns (q.v.) Acute radiation injury is discussed by Dunham et al. (J 147 50 1951) as it concerns atomic energy phenomena. It is to be distinguished from irradiation sickness, which results from therapeutic irradiation from surface radiation injury from exposure to radioactivity other than atomic explosion and from the selective deposition, such as in bone or thyroid, of radioactive substances inhaled or absorbed. The initial nuclear radiation from an atomic bomb explosion consists of gamma rays and neutrons emitted during the first one minute. The syndrome of acute radiation injury due to exposure of the whole body will affect especially those who are completely exposed, while various degrees of exposure will be experienced by those who are to various degrees shielded by the aggregate of the various amounts of matter (preferably several feet of earth and concrete) situated between the nuclear reaction and the individual. Casualties can be classed as uncomplicated radiation injuries and radiation injuries complicated by burns and wounds.

Three fairly distinct forms of uncomplicated acute radiation injury may be summarized (1) very severe cases (whole body exposure of 600 r or more) with malaise nausea and vomiting beginning within 2 hours, rapidly developing severe leukopenia, diarrhea and rising sustained fever during the next few days, and death in coma and delirium within two weeks, often showing purpura and epilation shortly before death; (2) *severe cases* (exposure of about 400 r) with nausea and vomiting occurring a few hours after exposure but not persisting more than 24 hours, lymphopenia on the second day a period of relative freedom from symptoms but with some malaise and fatigability persistent lymphopenia and fluctuating leukopenia but developing serious illness at any time up to the 20th day showing any or all of these symptoms epilation purpura, oropharyngeal ulceration, diarrhea, fever severe leukopenia, infection, sepsis, and death, which is the fate of about half such cases, especially those with untreated sepsis or with predominantly hemorrhagic symptoms and (3) *mild or moderate cases* (exposure of from

Fig. 91.—Keloidal scarring following flash burns, showing protection afforded by shoulder straps. (Armed Forces Institute of Pathology.)

200 to 400 r) with vomiting a few hours after exposure no definite symptoms except moderate lymphopenia during the next two weeks, and later some epilation, especially of the scalp malaise, sore throat petechiae diarrhea and weight loss. In general few who are farther than a mile from the hypocenter will experience severe radiation injury (Hiroshima experience) Early appearance of symptoms is indicative of severe injury See Bowers (J 145: 63, 1951)

If vomiting occurs on the day of the bombing and is followed by diarrhea, prostration and fever survival is improbable (Cronkite: Radiol 56: 661 1951) If vomiting occurs on the day of bombing and is followed by an asymptomatic period of from 1 to 3 weeks before purpura mucosal ulceration and epilation appear survival is possible If there is no vomiting within 24 hours survival is probable unless complications intervene such as thermal burns mechanical injuries or epidemics.

Treatment from the beginning should be directed at minimizing the effects of the tendency to hemorrhage and inability of the individual to combat infection. The patient is sensitive to physical activity and should not be transported long distances. Replacement of fluids, restoration of electrolyte balance and sedation are the first measures. Later come control of infection and treatment for hemorrhage and anemia. Those patients who are going to die do so despite treatment. Those who can be salvaged belong to the group who may be considered to be suffering from a self limited illness which they are to be tided over Antibiotics and transfusions are the mainstays of these efforts. Later in dealing with the postirradiation syndrome nutrition becomes an important problem, along with the control of communicable disease (Allen et al.: J 145 704 1951)

Casualty control and organization of physicians in case of atomic war are discussed by Bauer (MilSurg 103: 65 1948) Jacobson et al. (J 130 128 1949); Behrens (Atomic Medicine Nelson 1949 pp. 416) The organization of Civilian Defense and the training of large numbers of civilian personnel do not concern us here.

Radiation Accidents that resulted from temporarily uncontrolled fission reaction were reported on by Hempelmann et al. (AnnIntM 36 279 1952) Beta ray burns of the hands in four persons engaged in handling radioactive materials were described by Knowlton et al. (J 141: 239 1949) Erythema and tingling began in the first day with edema for two or three days longer and were followed by a latent period of from 3 to 5 days, then by secondary erythema and vesiculation, which healed in three weeks, leaving atrophy Biologically speaking, x rays, gamma rays, alpha and beta particles and neutrons differ for the most part only in the distribution and the magnitude of the destruction produced wrote Ingram (Sci 111: 103, 1950) The seriousness of the hazard encountered in work involving any type of radioactive isotope is dependent in part on the half life of the isotope under consideration. Other factors being equal the longer the half life, the greater the hazard. Ingram discussed the safety measures requisite to working with these substances.

See Liebow et al. (AmJPath 25 853, 1949), pathology of atomic casualties Haddow et al. (Biological Hazards of Atomic Energy Oxford Univ Press, 1952) Shirabe (MilSurg 113 251 1953), atomic bomb casualties in Nagasaki Behrens et al. (Atomic Medicine, Williams and Wilkins, edit. 2, 1953) National Research Council of Japan (Medical Report on Atomic Bomb Effects, Tokyo, 1953) Lenihan (Atomic Energy and Its Applications, Pitman, 1954) physics, reactors, weapons, hazards, medical and other applications of atomic products Byrnes et al (J 157 21 1955) choroid and retinal burns may result from looking at detonation from a distance of several miles.

DERMATOSES DUE TO CHEMICAL AGENTS

DERMATITIS FROM DEFATTING

Solvents and surface active agents, including soaps abstract oil from the skin. Frequent subjection of the integument to them results in damage which is chemical in origin but is not a sensitivity phenomenon. Individuals vary in their susceptibility to this abnutzung dermatitis, the red haired and xerotic patient being especially vulnerable Disease is more likely to occur during winter months when artificially heated air is of low humidity and sebaceous secretion is at its seasonal minimum.

Like dermatitis caused by primary irritants defatting may damage any skin. The hands are the usual site and occupation such as that of the housewife is a predisposing etiologic factor Soap takes out oil more effectively when used with hot water and the girl with chapped hands will accept good advice when one explains, You can t wash dishes free from grease with cold water

Manifestations of dermatitis from defatting include dryness and inflexibility of the skin, especially over the knuckles and hyperkeratosis, with some scaling and perhaps fissuring Treatment promptly relieves if contact with the defatting agent is sufficiently reduced and the skin is lubricated with hydrous wool fat or an equivalent. See Campbell (IndustHyg 7 5 1947)

CONTACT DERMATITIS

Symptoms.—Dermatitis venenata (contact dermatitis, eczematous or allergic dermatitis) is dermatitis due to cutaneous reaction to chemical substances when they have touched the skin. All degrees of inflammation from simple hyperemia to gangrene may be encountered Most cases are at first itchy then erythematous, and are limited to the regions touched by the irritant Later they become papular and vesicular and pustular if secondarily infected. The lesion may spread beyond the borders of the zone of original contact and widespreading manifestations may appear scattered over the body depending on conveyance via fingers or clothing and on the degree of cutaneous reactivity to the contactant. See White (Dermatitis Venenata An Account of the Action of External Irritants Upon the Skin Boston 1887)

Included within the meaning of dermatitis venenata are all inflammations of the skin provoked by contact whether the agent is a primary irritant which acts with substantially equal effect upon all skins (nitric acid lye) or is a sensitizer which acts with various intensities on different skins because of hypersensitivity Some chemicals are both primary irritants and sensitizers (ADS 45 1167 1942)

The argument that poisoning and allergic reactivity are different only in a quantitative way insofar as contact dermatitis is concerned was discussed by Anderson (IndustM 12 584, 1943) in a thought provoking manner

The eruption which results from a single contact with the offending substance is self limited It disappears spontaneously within a few days or weeks. Repetitions of contact are often the case however The response of the sensitive skin may become progressively more intense with spread of reaction far beyond the original site

The clinical picture and the history that the patient gives intimately depend on the time intervals involved daily association with a deleterious agent evokes continuous and chronic disease while occasional flares result from and denote corresponding occasional contacts. Thus investigation of

etiology in a given case requires intelligent questioning of the patient for periods of freedom from disease are as significant as periods of activity A period of freedom from disease denotes the fact that whatever the patient did touch during that time was not poisonous to him. The time interval from the moment of contact until dermal injury is apparent may be a matter of moments with primary irritants, but ranges from 4 to as much as 72 hours with allergens. Thus when an allergic reaction first starts, one is keenly interested in what was touched perhaps 12 hours previously

Fig. 92—Ulcers due to droplets of chromic acid solution used in chrome plating.
Fig. 93—Wristwatch strap (leather) dermatitis (Dr F Ronchese.)
Fig. 94—Iodoform dermatitis (Dr J W Perkins)

Fig. 95—Onychia caused by sugar in a bakery employee (Dr Clyde L Cummer)

The first manifestation of the allergic reaction is usually itching followed by redness A patient can be taught to be alert to these facts, and many a patient, instructed by a dermatologist solves his own problem of what contact damages him. Teaching the patient to profit from a flare is not ordinarily difficult to do Certainly flares, so interpreted, supply valuable clues as to what to suspect and what to utilize for patch testing (p 128)

Continuous or frequently repeated exposure results in disease which reaches maximum intensity and either remains unchanging or spreads in extent. Dermatitis may become universal, a form of exfoliative dermatitis (q v) and this may take place suddenly suggesting that degree of sensitivity may increase abruptly

Lesions of contact dermatitis are notably itchy as a rule more so than their appearance suggests. The hands, forearms and face are the sites of

Fig. 96.—Dermatitis from shoe strap.

Fig 97—Carved wooden ornaments of a necklace provoked dermatitis where they touched the skin.

Fig. 98.—Eczematous reaction t scalp lotion (Dr J Lamar Calloway)

Fig. 99.—Dermatitis from sunburn preventative. (Dr J Lamar Calloway)

predilection, although no region is exempt. The variations of area and of severity of involvement are not limited.

Such morphologic and out-of-date names as erythematous eczema vesicular eczema chronic eczema and fissured eczema are not sufficient to identify the disease and to satisfy the need for interpretation. Eczema I define as dermatitis of undetermined cause Dermatitis always has a cause though this may be difficult to identify Dermatitis due to a dye paraphenylendiamine for example might at different times in one person manifest a variety of morphologic forms, ranging from bullous inflammation to lichenification Merely to name it acute erythematous eczema at one time and chronic lichenified eczema at another would imply failure to comprehend the phenomena manifested.

If sharp distinction is lacking between chemical traumatic dermatitis and allergic contact dermatitis, except number frequency and intensity of contacts, it is equally lacking between contact dermatitis and the hyperergic reaction to the products of parasites reaching the skin from upon it within it or via the vascular system from distant foci, dermal or elsewhere When one judges from the hands alone one cannot differentiate between pompholyx

Fig. 100.—Contact dermatitis of eyelids, i this instance due to nail lacquer (Dr Wm. L. Dobes.)

Fig. 101.—Preauricular p tch of contact dermatitis due to nail lacquer (Dr Wm. L. Dobes.)

due to sensitivity to chemicals of known composition, and pompholyx caused by dermatomycosis of the feet. Arsenical dermatitis due to intravenous medication looks like contact dermatitis and perhaps is not fundamentally different from it. If one identified all cases of dermatitis venenata dermatomycosis, dermatophytid, bacterial dermatitis, dermatitis dependent on focal infection (bacterids) on food allergy or on nutritional deficiency and combinations of these, then few cases of eczema would remain undiagnosed.

Irritation provoked by medicinal chemicals, such as mercury is dermatitis venenata of medicinal origin. Dermatitis venenata includes the effects of both primary irritants and sensitizers. I recognize that the etiologic emphasis in the one class is to be placed on chemical trauma and in the other class on allergic reaction. There seems, however, to be no hard and fast line of distinction to be drawn between the two One must interpret the hyperergic response as the physiologic response to some sensitizing irritants, just as a purulent inflammation is to be expected as the physiologic response to *Staphylococcus aureus*

Eyelids are tender tissue readily capable of becoming swollen and itchy and are often involved in contact dermatitis. Flexural folds (neck, antecubital popliteal) and the delicate skin of the genital region are commonly attacked. These regions are probably often sites of the mediate contact, noxae

being carried by the fingers. Dermatitis caused by shoe dye, garters or stockings may provoke eyelid inflammation. Repeated attacks of swelling and itching of the eyelids, with redness, infiltration and loss of flexibility are practically always due to dermatitis venenata. While drops containing

MEN WOMEN BOTH SEXES

Fig 102.—Men. Cosmetics include ...

atropine may be the cause in a given case of itching lids, one must usually seek noxae through the whole gamut of air borne, water borne, medicinally or cosmetically applied, occupational, seasonal or other contacts with any part of the entire body surface. Fungus allergy may provoke an exactly

similar response For the most part eczematous reactions do not differ with different allergens there are exceptions (see Nickel and Chromium dermatitis)

HARDENING, the phenomenon of development by the exposed individual of ability to withstand contacts at one time injurious to him is commonplace especially in industry The workman stays on the job despite his dermatitis, unless the injury is extreme and he has perhaps 9 chances out of 10 of becoming hardened, as Schwartz (MichSMSJ 39 179 1940) demonstrated See Peck et al. (IndustM 14 214 1945) The private practitioner is likely to see only the patient who for unknown reasons failed to harden.

Pathology—Studies of especial excellence are those of Miller (ADS 56 678 1947) and Polak and Mom (JID 13 125 1949) The earliest change in allergic eczematous dermatitis is primary microscopic vesiculation appearing in the stratum mucosum, epidermatis, constituting cytoplasmic alteration and lysis of a few Malpighian cells (vésiculette primordiale of Civatte) preceding spongiosis. Vesicles are formed by confluence of these tiny lesions along with the canals resulting from intense spongiosis. The phenomenon was interpreted as perhaps toxic rather than allergic by Miescher (Dermatologica 104 216 1952) The dermal inflammatory process is nonspecific appears later and seems to be secondary to the epidermal change In some cases the dermis is the shock tissue and the epidermis secondarily becomes acanthotic, hyperkeratotic and variable in thickness. Leukocytic infiltrates in allergic disease contain a relatively high proportion of eosinophils.

Epidermal and dermal sensiti ity not rarely coexist (Templeton: J 1?7: 003 1945) Epstein (AnnAllergy 4: 429 1946) coined the name dermitis for contact dermatitis wherein epidermal hypersensitivity was not the significant feature but intracutaneous tests of the dela ed t berculin type were positive He observed such cases with sensiti ity to Rivanol, nickel and penicillin. Epstein (AnnAllergy 10: 633, 1952) offered an interesting hypothesis regarding the immunologic nature of contact dermatitis: The antigen is to be thought of as a complex of a simple chemical hapten joined with a prot in to form a protigen' and a given hapten may so join with any of several different proteins so a to give rise to various protigens, thus accounti g for various clinical mani festations of disease producible by one chemical substance Conceivably a hapten may not form a conjugate nd yet may alt r body-own proteins so that they become antigenic with resultant autosensitization' (q.v.)

The derml may be the shock organ i contact dermatitis, as wa shown by Epstein (TransADA, 1953) who described both immediate urticarial and delayed eczematous and tuberculo d reaction to patch tests with nickel and chromium in certain patients. Thu his pat h test sometimes elicited dermal reaction without epidermal and, furthermore he found individual who ha l contact dermat tis but evi ced no reaction on patch testing

Etiology—Review matter on allergy The problems of altered reactivity are gradually becoming clarified It seems safe to make these generalizations (1) all human beings can develop hyperreactivity to some things under some circumstances (2) the degree of reactivity in a given person varies with the manner of contact and quantities, durations and time intervals involved (3) clinical manifestations depend on (a) the reactive tissue whether dermal epidermal or both, (b) degree of reactivity (c) location, duration, intensity and frequency of contact and (d) bacterial medicinal, and other complications superimposed. Little is known about why sensitivity appears. Its onset may be sudden after years of previously innocuous contact. The farmer with ragweed dermatitis is an adult who met the allergen for years without having had symptoms. Burns, abrasions, moisture heat tinea, staphylococcic dermatitis and hyperhidrosis render a person more vulnerable. Some people are prone to develop sensitivities and other are not

Of some 230 cases seen in private practice drugs caused 71 weeds 31 clothing 21 cosmetics 17 soaps 11 physical agents 5, nickel 4 and matches 2, in the experience of Wilson (NebrSMJ 22 310 1937) Osborne and Hallett (NYSJM 42 1929 1942) listed numerous common irritants, and the causes in 250 cases were reported by Howell (ADS 53 265 1946)

While chemical sensitization may succeed dermatomycosis—a matter of significance in industrial dermatology—it is likewise common for nonparasitic

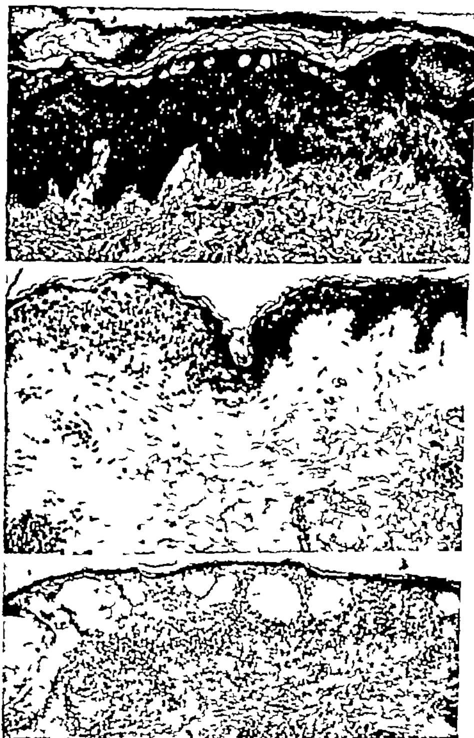

Fig. 103.—Pathology of dermatitis venenata. *Top*, Edematous degeneration of superficial epidermal cells, poison ivy. *Middle*, Slight epidermal edema and mild inflammation, patch test with mercurial antiseptic. *Bottom*, Vesiculation and inflammation, patch test with turpentine. (Miller: AD&S 56: 678, 1947.)

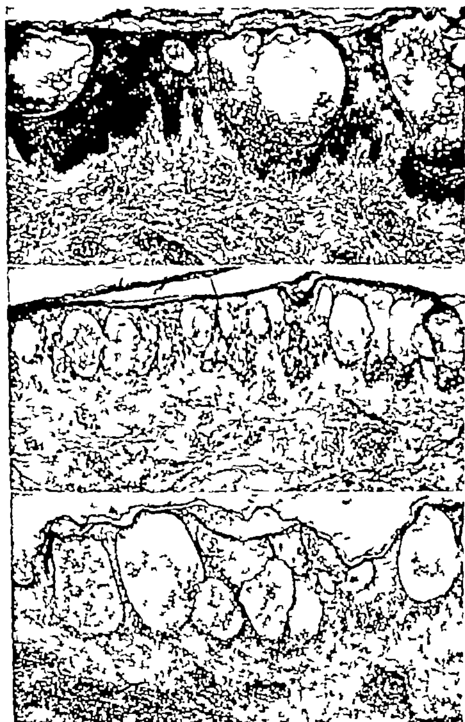

Fig 104.—Pathology of dermatitis venenata. *Top* Intense vesicula epidermal reaction to hair dye. *Middle* Vesiculation in eczematous dermatitis. *Bottom* Intense vesiculation, poison ivy (Miller ADS 56 678, 1947)

contact dermatitis to become complicated with *parasitism dermatitis of the* neck becomes complicated by seborrheic dermatitis from the scalp, or ivy dermatitis by micrococci from the pharynx or dermatitis of the hands by monilid from inconspicuous vulvovaginitis, or perianal and pedal epidermophytosis by medicinal dermatitis. It is such combinations which comprise the confusing cases once called eczema See *Chronic dermatitis of undetermined cause*

EXPERIMENTALLY it is possible that sensitization to some simple chemical substances may be induced by injection of conjugates of the simple substance with certain proteins such as red blood cell stroma (Landsteiner and Chase JExpM 66 337 1937 73 431 1941) Conjugation with staphylococcus toxin may render autogenous proteins such as rabbit skin antigenic to the homologous or even the same animal (Hecht et al JExpM 78 59 1943)

Allergic reactivity to a simple aliphatic acid acetic anhydride was observed by Weil and Rogers (JID 17 227 1951) Sulzberger and Baer (JID 1 45 1938) studied dermatitis produced experimentally by related, simple chemicals of known composition (chlornitrobenzenes) and *showed that the* ability of each to produce contact dermatitis in human beings paralleled the ability to produce skin sensitization in guinea pigs, and that this property seemed related to the lability of the Cl and NO_2 groups. Wise and Sulzberger (AmM 28 4 16 1933) studying the reaction to butesin picrate described 3 time periods, those of (1) refractoriness, which may persist for months despite contact (2) incubation of 9 or 10 days and (3) development of reaction 16 to 48 hours after the contact after allergy has, during the refractory period come into existence Subsequent contacts, after sensitization has been accomplished take place promptly skipping the refractory period

The nature of antibodies responsible for contactant allergy has not as yet been determined they must be local have not been isolated and are not passively transferable (Leider and Baer JID 10 425 1948) When sensitivity has developed to one chemical, reactivity to primary irritants of other chemical varieties is not influenced (Haeberlin JID 10 27 1948) The studies of Rokstad (ActaD-V 26 1 1946 suppl. 15) using turpentine derivatives were interesting the toxic *primary irritant* effect was of short latent period 24 hours or so and erythema swelling even pustulation developed depending on intensity of exposure the purely eczematous effect in sensitized persons might appear within a few hours or might be delayed even 3 or 4 days and the most intense exposure flared earliest. If during the sensitizing exposure the skin is necrotic the necrosis appears to protect against the development of eczematous reaction

Eczematous sensitization is highly specific (Rostenberg and Kanof JID 6 201 1945) yet cross sensitizations and group sensitivities do occur and have been studied extensively in the search for elucidation of the obscure nature of sensitization phenomena

Sensitization from the initial substance *may spread so as to embrace other* substances of related or nonrelated chemical nature and a person who has contact dermatitis is twice as susceptible to other materials as a person not so affected (Sulzberger and Rostenberg JImm 36 17 1939) Group specificity in epidermal allergy follows a pattern similar to that of serologic reactions, write Rothman et al. (JID 6 191 1945) Patients of Leifer and Steiner (JID 17 233 1951) sensitive to Vioform and Diodoquin were also sensitive to Quinolor and Sterosan manifesting a group sensitivity to halogenated hydroxyquinolines and they were furthermore sensitive to three carboxylated pyridines

Cross sensitization to the para group was studied by Sidi and Dobkevitch Morrill (*JID 16 299 1951*) *Serious accidents can* be caused not only by an agent which has sensitized the patient but also by chemically related substances. The sulfonamide and local anesthetic groups are the most hazardous.

Parallelism between the abilities to excite mitosis and to evoke sensitivity was noted by Bujard et al. (Acta Allergica 6 161, 1953) Nonsensitizing primary irritants induced necrosis but did not stimulate mitosis, it was observed in testing the effects of several benzine derivatives.

The route of spread of sensitization continues to be a baffling problem (Rostenberg ADS 56 222, 1947) If skin is circumvallated by incision and the island so produced then sensitized by dinitrochlorobenzol the island may be sensitized while the remainder of the skin remains nonallergenic. In controls, sensitization of a spot produces sensitization of the whole So skin contact sensitization seemed to spread via the cells not by way of the blood (Schreiber and Müller DWchn 107 1393 1938)

Eczematizing chemicals were applied to circumscribed areas of skin which were circumvallated to form islands after 6 12 and 24 hours by Rostenberg (JID 8 345 1947) Despite circumvallation sensitization became generalized in all instances, suggesting that the simple allergen formed an antigenic conjugate at the site and this was absorbed via lymphatic or other routes.

Experimental sensitization of the skin to dinitrochlorobenzene was studied by Haxthausen (ActaDV 20 257 1939 23 438 1943) who reported his transplantation of sensitized skin from one identical twin to another replacing the donor area with nonsensitized skin from the normal twin. Three weeks after transplantation previously normal skin growing in the sensitized twin had become sensitive and the previously sensitized skin now attached to the normal twin was not reactive The capacity to react did not move with the full thickness transplant but the presence or absence of this capacity was determined evidently by influences outside the transplant

The white blood cells were thought to transmit dinitrochlorobenzene allergy in guinea pigs by Haxthausen (abs BJD 64 313 1952) but Baer et al (JID 18 53 19 217 1952) were not able to achieve passive transfer of contactant allergy in man by means of white blood cells obtained from eczematous donors. Experiments of Curtis (ADS 65 149 1952) with protein extracts from the skin of allergic donors likewise failed to demonstrate antibodies. Heparin appears to inhibit the development of allergic dermatitis according to Haxthausen (JID 19 203 1952 21 237 1953) who reported inconclusive results of intradermal transfers of living lymphocytes from sensitive persons in an effort to transfer their reactivity

Human skin explants were exposed to dinitrochlorobenzene poison ivy antigen and old tuberculin by Everett et al. (JID 18 193 1952) No difference in capacity for growth was exhibited by explants from sensitive and nonsensitive donors.

Experimental sensitization of various creatures other than man was reviewed by Rostenberg and Haeberlin (JID 15 233 1950) Chickens, ferrets monkeys and pigs have developed sensitizations. The evidence is questionable in the case of dogs, rabbits and white mice

Testing the effect of nervous exhaustion on susceptibility Guy (ADS 66 1 1952) subjected guinea pigs to repetitious electric shocks so as to cause them to lose appetite sleep and weight The animals then showed increased sensitivity to contactants.

Diagnosis.—That dermatitis is due to external irritant chemicals can generally be inferred promptly from the clinical examination I know of no easy way to learn contact dermatitis, saving long experience One must possess familiarity with the irritating potentialities of all the things which may touch various parts of the body in individuals of both sexes and any age. This knowledge is gained gradually as one reads about thinks about, and sees dermatologic patients. If a physician knows a good deal about contact dermatitis, he knows the major portion of practical dermatology for dermatitis venenata and its complications constitute a high proportion of dermatologic work.

In general the onset is acute and the lesions itch. The edges of lesions are likely to be fading rather than sharp because an irritant usually touches

the skin in greater concentration at a central site and in lower concentration peripherally. Pus is not present until secondary infection occurs. When the complaint of itching seems out of proportion with the amount of skin disease seen, contactants are probably at fault.

The experienced dermatologist knowing all the other things that might be wrong with the skin will diagnose contact dermatitis by exclusion—a rash that isn't something else is contact. To control contactants is essential in the management of almost any dermatitis for an element of contactant trouble is present in almost every case of dermatitis the physician handles. If it was not there to start with his medicines may provoke it.

Location of onset is the first clue to the nature of the noxious agent. The manner of reaching the skin obviously influences the location. Allergens *reaching the skin as air borne dust settle in greatest concentration on ex*posed parts, moist parts, and where clothing constricts. Itching eyelids are almost invariably due to contact dermatitis (Hazen ADS 49 253 1944; Ratner J 103 180 1934)

The longer the dermatitis has endured the more difficult it is, as a rule, to discover the allergen. Soap and medication are the commonest causes of contact dermatitis with a long continuous history. Flares give clues: contact must have been made within a few hours before the flare. The patient's understanding and cooperation are of primary importance in the search. In the usual case it is imperative for the physician to give the considerable time necessary for the patient's enlightenment (Sulzberger and Rostenberg J Allergy 6 448 1935)

Identification of the cause can be a complex and tedious business. It is *easiest in persons of good intelligence some of whom suffer contact dermatitis,* recognize the cause, cure themselves and never visit a doctor. The history helps one decide what substances to do patch tests with, and skin tests (q v) may be used advantageously although they often are largely a waste of time and energy (Sutton ADS 59 36 1949)

Diagnosis is proved by cure of the disease when irritants are avoided and identification of the causative irritant by positive reaction to contact with it.

Good references to study with the object of learning diagnosis include Sulzberger and Kerr (J Allergy 4 326 1933); Odland (NoWM 34: 9 1935); Fasal and Cornbleet (J 105 1062 1935); Wilson (NebrSMJ 22: 310 1937); Sutton (JMoSMA 44 451 1947). The patterns of contact with various things touched by the hands were carefully investigated by Waldbott and Shea (ADS 57 975, 1948; see Waldbott: Contact Dermatitis, Thomas, 1953). In dermatitis caused by shoes (Niles: J 110 363, 1938) vesicular eruption appeared on the feet when the offending shoes were worn and disappeared when they were not. Dermatomycosis was ruled out by the relationship of flare to the wearing of the shoes, by positive patch tests, by absence of demonstrable fungi, by severity of the itching which seemed disproportionate to the visible dermatitis, by freedom of interspaces from involvement, by predilection for the dorsum of the foot and by limitation of dermatitis to those areas of skin which were in contact with the shoes.

SKIN TESTS are immunologic procedures designed to ascertain the skin's capacity to react. They can be so standardized as to show whether cutaneous tissues have acquired some alteration in their capacity to react to certain agents. They are never the sole diagnostic method, and positive reaction is never proof of causal role while negative reaction never completely exonerates an agent, wrote Sulzberger and Baer (YBD 1943 p 7 1944 p 7). Performance, interpretation and exhaustive tabulations (diseases, concentrations and precautions) of skin testing are given in the 1943 reference.

Agents and their concentrations suitable for patch testing were listed by Rostenberg and Sulzberger (JID 2 93 1939)

Tests for sensitivity are of the contact, scratch and intracutaneous types. The intracutaneous test requires the least of the irritant material to cause re susceptibility to external irritants. These tests serve to reproduce a disease in miniature under controlled conditions. Passively transferable elements occur

in the blood serum of idiosyncratic individuals (Prausnitz and Küstner Zentralbl f Bakt 86 160 1921) In some instances, allergens affecting the skin are absorbed through the colon or via the respiratory route. In general, allergens that damage the epidermis are fat-soluble and produce vesiculation, while those to which the dermis reacts are water-soluble and evoke wheals. Contact tests (patch tests) are used to determine contactant irritants while scratch and intracutaneous tests are aimed at reaching the mesodermal issues with the allergen Passively transferable Prausnitz Küstner antibodies are likely to be present when the mesoderm is reactive and are absent when the epidermis is the shock tissue

Quantitative patch testing technic was designed by Dunn et al (JID 6 323, 1945)

Patch tests were carefully evaluated by Warren (SouthMJ 36 425 1953) and untoward results of such tests were studied by Epstein (JID 5 55 1942) Downing (ADS 44 63 1941) and Swineford and Radford (SouthMJ 41 667 1948) They are capable of initiating previously nonexistent allergy

Faults of patch tests include the fact that they do not reproduce physical properties (Siegel and Meltzer ADS 57 660 1948) A patient might tolerate the use of a soap three times a day and suffer damage using the same soap twenty times a day patch testing could not reveal this. Nor would patch testing incriminate wool trousers which in stationary contact with the skin did no harm but which through friction induced by walking scraped the legs raw Fallacies of patch tests and their deficiencies in diagnosis were discussed by Downing (NEngJM 219 698 1938) A case in which an industrial commissioner required a patch test with a notorious sensitizer resulting in severe disability and much medicolegal complexity was reported by Downing (ADS 44 63 1941) See Edit (J 156 500 1954) For the [patch] test to be highly effective it must be followed by a usage trial Of major importance is the fact that the patch test is continually subject to change and refinements and that absolute reliance upon its results in all cases of contact-type dermatitis is not justifiable (Council on Industrial Health Rpt J 156 497 1954)

The chief value of patch tests is corroborative wrote Rostenberg and Sulzberger (ADS 35 433 1937) when they are applied with skill and discernment as to what to suspect Practical application in occupational disease along with warning that unnecessary or unwise testing may cause severe reaction was discussed by Downing (ADS 48 514 1943)

When patch tests are repeated weekly in standard concentrations upon known reactors, the results are not always identical but are fairly consistent and the repetition of patch tests does not reduce sensitivity (Witten and Shair AnnAllergy 7 32, 1949) Strong concentrations of potential sensitizers used for patch testing may indeed induce sensitization which did not previously exist (Bechet NYSJM 39 829 1939)

PROPHETIC PATCH TESTING was designed by Schwartz and Peck (PHRpts 59 1 1944) to indicate the possible sensitizing effect of a new chemical substance intended for commercial applications such as would place it in contact with the skins of many people The substance must be tested upon at least 200 individuals who must be retested later to determine whether the initial test induced the development of sensitivity If even two or three individuals out of 200 subjected to prophetic testing showed intolerance the substance would be hazardous indeed if introduced widely among the population. Statistical validity of such testing was investigated by Henderson and Riley and by Knudsen (JID 6 227 231 1945) Their mathematical analyses indicated the number of reactors among groups of various sizes necessary to yield data of statistical significance See Schwartz et al (Occupational Diseases of the Skin, Lea and Febiger 1947 pp 59 306) Cox and Dehne (ADS 61 611 1950)

One may evaluate the capacity of a chemical to sensitize by performing repeated tests upon the same subjects, testing daily for 5 days, waiting 7 days, and then retesting (Brunner and Smiljanic ADS 66 703 1952)

Controlled use tests were preferred by Traub et al. (ADS 69 399 1954); in combination with prophetic patch testing the procedures predict the likely incidence of dermal reactions including the effects of prolonged contact

Excitant Causes of Dermatitis Venenata.—The list is almost interminable (Weber ADS 35 129 1937) Frequent chemical causes are strong acids and alkalies turpentine nail lacquer rubber cleansing agents, occupational hazards, incompletely polymerized plastics, medicines, wood tars, cosmetics, fabric finish, mercurial compounds and formalin. The concentration of the irritant is an important consideration (Rostenberg and Sulzberger JID 2 93 1939) Mucosa as well as skin, may be the site of contact inflammation which does not differ from contact dermatitis. Cheilitis and stomatitis, and dermatitis of the face or even of the hands may be caused by tooth paste mouthwash prostheses and other things.

ANIMAL SUBSTANCES occasionally incite dermatitis venenata although when fur is the cause the allergen is usually dye sometimes insect repellent

Among irritant items may be mentioned the resinous substance of beehives (Umansky DWehs 48 177 1934) the carpet beetle (Cormia and Lewis NYRJM 48 2037 1948); fishermen s Dogger Bank itch from the sea chervil (Bonnevie abs YBD 1948 p 168); coral (Preston BMJ 1 645 1950); swine itch in packing house employees (US Dept Agric Bureau Anim. Ind. Mar 1931) butcher s dermatitis from handling freshly killed carcasses (Schwartz JIndustHyg 13 233, 1931) See also Caterpillar Dermatitis and Occupational dermatitis in food handlers.

CLOTHING DERMATITIS is at first located at the actual site of usual contact. The noxious agent is usually a resinous fabric finish (Schwartz et al. J 115 906 1940) When nylon hose first became popular itching of the dorsa of the feet was often observed to have been caused by them. Faint redness with severe itching soon appeared on the legs and thighs, later spreading to hands and forearms due to contact during laundering which women usually do for themselves, and to the eyelids, later becoming universal

An abietic acid ester gum was the irritant in cotton underwear reported by Kell (ADS 47 242, 1943) Dermatitis from men s shorts, provocative of extreme discomfort and swelling of the genitals, was commonplace in 1942 (Costello and Ryan ADS 46 264 1942 and others) Many synthetic resins are potent sensitizers to be met not only in garments, but in glue plastics, etc and the dermatitis they cause while extremely pruritic may persist for weeks after contact has ceased (Schwartz JID 4 459 1941) Clothing dermatitis was excellently reviewed by Schwartz and Peck (J 128 1209 1945) Dyes, mordants, impregnations and the textile itself may be irritant as well as the finish. In shoes, the chlorophenol antimildew glue dye polish chrome or formol tanning agent or other component may be the specific irritant (Shaw ADS 49 191 1944) The fungicide was at fault in the case of Gaul and Underwood (IndianaSMAJ 42 22, 1949)

When a garment is suspected of being the cause the patient is instructed to wear nothing but clothing which was already 6 months old at the time his dermatitis began Such clothing previously worn and found harmless, may be trusted unless subsequently it was exposed to chemical contamination. It is probable that an injurious agent would be removed if the garment were subjected to repeated cleansing with carbon tetrachloride followed by soap and water and thorough rinsing Boiling alone will not remove it Soap starch, bleach bluing laundry antiseptics or substances from cleaning fluid may remain in a fabric rendering it irritant even though it may not have been irritating at the time of purchase Garment dermatitis is a serious matter of significance to the public health One wishes hypoallergenic garments could be purchased Recommendations regarding nonallergic bedclothes were given in QMN (J 142 1330 1950)

Fabric finish can be removed by 2 soakings in carbon tetrachloride followed by soap Schwartz told me

Paraphenylene diamine much purer than it used to be is seldom a cause of fur or hair dye dermatitis, and the requirement of prevue open patch test

ing, before its use on the hair discloses the susceptible individuals (Schwartz SouthMJ 46 769 1953)

See also dhobi mark dermatitis (p. 149) and glass wool and Fiberglas (p. 136). See Epstein (ADS 41: 1046 1940) clothing dye cases, contact dermatitis, photosensitization, hidradenitis, lichen chronicus, urticaria; Dobkevitch and Baer (JID 9 203 1947) azodyes in nylon stockings and cross-sensitivities Scott et al. (JPed 28 712, 1946) aniline laundry marking of nursery textiles caused cyanotic dye poisoning responsive to treatment with methylene blue; Anderson (ADS 61: 111, 1950), nylon hair net as vinyl rash on face Carpenter and Danner (USNMBull 43 754 1944), irritation from Navy blue uniform Davies and Barber (BJD 56 33, 1944) textile dermatitis in military personnel, Cox (BJD 54 22, 1942) chemicals in fabrics, Fleming (JID 10 281 1948) the array of hazard of dyes and fabric finishes, many of which are strong sensitizers, and it should be tested before exposure of the public to them; Mauersberger (Matthews Textile Fibers, Their Physical, Microscopic and Chemical Properties Wiley ed. 6, 1954), Hollander (AD 71 735, 1955) irritation by silvery metallic strands in woolen garment, Harris (Handbook of Textile Fibers, Harris Research Lab., Washington, D.C., 1954) physical and chemical data on textiles.

CLOTHING — DIAPER DERMATITIS is a name for any rash of a baby's nether parts. Diapers may retain enough detergent to irritate after home laundering; those done by diaper washing companies are nonirritating unless they have been treated with an antiseptic such as phenyl mercuric acetate (Dobes J 128 281 1945) Friction baby oil medicines soap wool, fabric finish of waterproof panties the mother's nail lacquer monilia, bacteria and *Acarus scabiei* often cause dermatitis of buttocks and thighs of babies.

"Napkin rash" has been attributed to ammoniacal decomposition of urine and boric acid powder and boric acid rinses of diapers may be tried. Since the diagnosis of "napkin rash" is about as explicit as that of "athlete's foot" critical evaluation should be made of such possible causes as soap baby oil antiseptic diaper rinses and other contactants, or scabies, infectious impetiginoid disease or moniliasis, or pityriasis rosea See Gordon (BMJ 1 383 1940) Forman (Pract 146 238 1941)

CLOTHING—SHOES AND LEATHER GOODS are often a source of trouble Tanning methods and leather chemistry are given by McLaughlin and Theis (The Chemistry of Leather Manufacture Reinhold 1945) Gaul and Underwood (ADS 60 649 1949) listed the primary irritants and sensitizers used in the fabrication of footgear dyes, tanning chemicals (Formol chrome) felt adhesives, rubber asphalt, impregnated fabrics and other substances, including antimildew polish and irritating footpowders may be at fault Shoes may be tight ill-shaped or impervious to sweat and so cause skin disorders on the feet. Not all rashes on feet are due to fungi. Rubber is the usual irritant the antioxidant the likely irritating ingredient thereof in thermoplastic box toe shoes (Shatin and Reisch ADS 69 631 1954)

See Niles (J 110 343, 1938) Burgess (CanadMAJ 47 27, 1942) Schwartz (PHRpts 51 423, 1936) wrist watch strap Pirila (abs BJD 60 147 1948 hatband thioprene in artificial leather

COSMETIC DERMATITIS.—Cosmetics including perfumes, hair dyes scalp cleansers, and tonics, depilatories, deodorants, face powders, creams bleaches, lotions, rouge, lipstick and nail preparations may contain many potentially provocative chemical constituents (Tulipan ADS 38 906 1938)

Compositions and hazards of numerous cosmetics were briefly elucidated by Wolcott (ADS 41 64, 1940)

See Chilson (Modern Cosmetics, Drug and Cosmetic Industry N Y., 1934) Harry (Modern Cosmeticology Hill London, 1948) Lynch (MinnM 20 519 1937) main features of cosmetic dermatitis Downing (ADS 64 561 1951) dangers of dyes, cosmetics and permanent wave chemicals on scalp and hair Behrman et al (J 140 1208 1949) cold wave process generally safe Schwartz (I ternat Congr Allergy 1951 p 715) skin testing and prophetic patch testing of each kind of cosmetics.

A typical dermatitis paralleling the blepharal margins is produced by the antioxidant of the rubber of eye lash curlers (Curtis ADS 52 262, 1945) Lipstick dye may cause systemic allergic phenomena as well as cheilitis (Hecht J 113: 2410 1939; Zakon et al.: ADS 56 499 1947) Dentifrices provoke cheilitis and dermatitis of the cheeks and chin, and even dermatitis of the hands at times (Belshauser ADS 41 693, 1940) The yellow dye of a leg make-up was the faulty ingredient identified by Ellis (ADS 49 197 1944) Hair lacquer caused much trouble at one time the irritant being synthetic resins (Schwartz: PHRpts 58: 1623, 1943) and the mother's hair lacquer irritated her infant in 2 cases recorded by Plotz (AmJDisChild 68: 409 1944) Hair dye poisoning, even a fatality was discussed in an interesting editorial (BMJ 2: 490, 1943)

In nail lacquer a formaldehyde-sulfonamide resin caused cases of Simon (SouthMJ 31: 157 1943) while nitrocellulose and solvents, as well a synthetic resins were noxious in cases of Dobes and Nippert (ADS 49: 152, 1944; see also Madden: ib 49: 19, 1944; Osborne et al. ib. 44: 604 1941 Silver a l Chicago JID 9: 361 1929) Nail lacquer dermatitis rarely affects the hands but provokes circumscribed lesions readily confused with parasitic rather than chemical dermatitis of the areas to which fingers go such as eyelids, ears trunk, and vulva. A pruritic patient with any dermatosis such as scabies, is well advised to omit nail lacquer until her skin is clear for where she itches she will scratch, and she may develop nail lacquer dermatitis as a complication. Nail lacquer dermatitis was the subject of interesting studies by Keil and VanDyke (ADS 50 20 1944) in whose patients the chief irritating ingredient of the lacquer was a toluene formaldehyde-sulfonamide resin. Group sensitization to related chemicals was frequent including sulfonamides and formaldehyde

Fig. 105 —Dermatitis venenata caused by leather hatband. (Dr F Ronchese)
Fig 106 —Dermatitis venenata of face caused by hair dye. (Dr Howard Fox)

Fig. 107 —Personal contact dermatitis such as might be caused by lipstick, dentifrice, chewing gum medication. It was caused by nail lacquer (Dr Wm. L Dobes)

Hair lacquer for upsweep coiffures may cause dermatitis of ears, neck and eyelids (Howell J 123 408, 1943; Epstein: ib., p. 409 Halley SouthMJ 37: 37 1944; Schwartz AnnAllergy 1 16. 1943) Lacquer pads are often at fault, likewise spray net, etc. Ink eradicator may contain sensitizing lacquer (Dowling ADS 44 465 1941)

Base coat for fingernails, composed of phenol formaldehyde resins and synthetic rubber in methyl ethyl ketone often caused in 1948 and 1949 hypertrophy of the nail bed and onycholysis, usually painless and without indications of inflammation These changes disappeared from clinical view when the cosmetics were removed from the market. Patch test results were various, and allergy seemed not to be the explanation. See Onycholysis also Winston and Sutton (JKansMS 49 3 1948); Layman and Rusten (MinnM 31 L.15, 1948), Sulzberger et al. (JID 11 67 1949) Sullivan (BullJHHosp 84 11 1949) Hein and Rogl (ADS 61: 971, 1950) Framess et al. (J 149 828 195.)

Jewelry dermatitis is likely to be due to nickel, chromium lacquer or the accumulation of irritant chemicals underneath, such as soap under rings (QMN J 144: 725, 1950)

Hair dyeing with synthetic organic dyes of the paraphenylenediamine group was discovered about 1890, according to Thomas (Pract 165: 171, 1950) This group of chemicals contains potent sensitizers. Sensitization is slow to develop and patch tests should be performed prior to each application, even in persons who have not previously reacted (Lawrence: JID 8: 177 1947) Hair dyes have produced much less dermatitis since 1937 than before that time because of improvements in their manufacture the prophetic patch test, and instructions on the package requesting predyeing open patch testing regulated by law the modern paraphenylenediamine dyes are not unduly hazardous (Schwartz and Barban: ADS 66: 233, 195_) Reiches (ADS 63: 619 195_) reported 3 cases, however

Permanent waving requires softening the hair with an alkaline sulfide followed by heat setting and then rinsing, or a cold process with thioglycolate followed by an oxidizer (Goldman et al.: J 137: 354, 1948) Cold wave chemicals are usually innocuous the beauty operator standing greater hazard than her client. The possibility of allergic response to wetting agent and perfume ingredients always exists as well as to the essential waving chemicals (Lehman: J 141: 84_, 1949) Ammonium thioglycolate in the concentration advised for home waving is seldom harmful if used according to directions (Brunner: ADS 65: 316 195_) If the softening solution is applied too long or too concentrated, the hair may break off, producing temporary baldness without dermatitis followed by normal regrowth (Reiches and Lane J 144: 303 1950) Permanent wave solution once ran into an ear canal and perforated the drum reported Sataloff and Wilson (J 14 : 1183 1951)

Hair straightener is powerfully alkaline and burns from it may produce depigmentation (Lewis: J 11 : 86 1939)

Miscellaneous cosmetic irritants include the following methyl heptine carbonate, perfume at one time popular in lipstick (Baer ADS 32 726, 1935); Lash Lure (Bureau of Investigation J 101 1916, 1933); triethanolamine a wetting agent which is seldom injurious (Curtis and Netherton ADS 41 729 1940) rubber sponges used for applying cosmetics (Furman et al. JID 15 223, 1950); blue toilet tissue (Brattman: ADS 65 737 1952) monoglycerol para-aminobenzoate the sun screen ingredient of T rtan, occasionally a violent irritant, requiring in my experience no 7-day incubation period to blister the patient (Fatelsky ADS 62: 711 1950); Teel, a liquid dentifrice, producing maculation on fingers (Hix ADS 43: 847 1941); liquid lip rouge (Schomberg ADS 45 18_ 1942); citronella oil (Keil JID 8: 327 1947) aminoazotoluine, a yellow, fat-soluble dye used in shoe polish and semisolid inks for ball-point pens (Mears and Mortis-Scott: BMJ 1 1143, 1953)

Industrial and Occupational Dermatitis.—Since dermatitis venenata is of vast significance in industrial medicine its control assumes important proportions; and its recognition, prevention and treatment have been the subject of intensive study (Schwartz et al Occupational Diseases of the Skin, Lea & Febiger 1947) The principles of interpretation are those of contact dermatitis. The principles of treatment are in general, the prevention of contact by avoidance use of suitable protection such as gloves, chemical detoxification of harmful substances before they have produced damage identification of noxae as well as susceptible employees by means of patch tests and similar testing of materials before they have been admitted to public use

Recognition of occupational dermatitis, the definition of primary irritants, the identification of sensitization thresholds and the prevention of dermatitis were elucidated by the report of the A.M.A. Committee on Occupational Dermatoses (J 122 370 1943) Instructive papers on working out specific problems were presented by Schwartz (SGO 68 58 1939) Stigmas of occupation, such as scars and calluses, were interestingly collated by Ronchese (J 128 925 1945)

See Downing (NEngJM 237 788, 1947) and Schwartz (JMo MA 42 771, 1945), Lane et al. (J 118: 613, 1942) Birmingham and Campbell (Occupational and Related Dermatoses, Public Health Publication #364 Govt. Print. Off 1954) abstracts literature 1943 1953

The difference between poisonous (or toxic) and allergic reactions is essentially a difference in degree of toxicity Toxic and allergic reactions cannot be distinguished except by differences in quantity of noxa argued Anderson (IndustM 12 584 1943) While desensitization cannot be achieved, yet there are chemical antidotes for some kinds of poisoning Spontaneous desensitization does occur however (Koch abs J 121 87 1943) see Hardening

Pre-employment examinations are helpful in screening out persons with dermatoses liable to aggravation by contact with the substances to which the proposed occupation will subject them. A clean shop with good ventilation and neat housekeeping shielded and modern machinery, tidy showers, cleansing facilities and locker room—all contribute to health of the workers and prevention of dermatitis. See Edit. (BMJ 1 277 1949)

INDUSTRIAL DERMATITIS, DIAGNOSIS.—As part of a symposium concerned with the problems of industrial dermatology Sulzberger and Finnerud (J 111 1028 1938) contributed this clarifying tabulation:

CRITERIA OF THE FIRST ORDER FOR PROOF OF INDUSTRIAL NATURE OF DERMATOSIS

Inception.—The dermatiti appears at any time during a period of *industrial ex*posure or even after a lapse of a reasonable incubation period following the cessation of the industrial exposure (usually a maximum of from to 3 weeks)

Amelioration.—The dermatitis regularly disappears or i repeatedly impro ed within a reasonable period of days, weeks or even months aft r cessation of the causal industrial exposure While this is usually the case retention of causal agents, complication or ensuing polyvalent sen itization may prolong the course even for several years after the last industrial exposure

Recurrences and Exacerbations.—The dermatitis shows a tendency to recur or to become exacerbated when the worker returns to the identical industrial exposure afte a period of absence provided there ha been no change in wo king conditions, in the pa tient s manner of working or in his susceptibility

CRITERIA OF THE SECOND ORDER: ADJUVANT CRITERIA

*The dermatitis appears first in the areas of maximum exposure and is usually con*fined to them. In a small percentage of cases it spreads to appare tly unexposed areas or may begin there o m y even become generalized.

The character and localization of the dermatitis correspond to the character and localization of dermatiti known i oth r cases to have been caused by exposure to the same or similar industrial hazards. While many different substances and procedures can produce similar or identical eruption there are certain classes of subst nces and of procedures which regularly produce fairly characteristic lesions.

The application of the presumptive *causal age ts to an u affected site close to the* site of the dermatitis produces a reaction, provided this application is made either during the active phase or after the proper interval following the cessatio of th dermatitis.

The cuta eous tests produce reactions of the same fundamental nature a the derma tosis under i vestigation.

Othe workers similarly occupied are or have been imila ly affected.

The dermatitis appears soon (days or weeks) after the patient begins work involving ew potential hazards.

The dermatitis i proved to be of possible occupational ature; that is, it is shown to be of the type which may result from the industrial exposure sustained. I this con nection it must be determined that the dermatiti der consideratio is not a no industrial dermatosis, such as seborrheic dermatitis, psoriasis (including pustular psorias) para psoriasis, lichen planus dermatitis herpet formis, m ltiform erythema certain types of nonindustrial fu gous and other infectious processes, nonindustrial impet go and other pyoderma acrodermatitis continua, nonoccupational drug eruptio s, herpetic eruptions, nevoid anomalies or malformations of the skin, nonindustrial dermatitis exfoliativa, cir cumscribed ne rodermatitis, atopic dermatitis and, particularly noni dustrial co tact dermatitis. It must be borne in mi d that the prese ce of nonindustrial dermatosis by no means excludes coexistence of ind strial dermatitis. The existe ce of nonin l strial derma tosi may pred pose to industrial dermatitis and, on the othe hand, industrial exposures may elicit attacks of such noni dustrial dermatoses or prolong their courses or prod ce exacerbations of them.

THE DERMATITIS IS ERRONEOUSLY CONSIDERED TO BE NONINDUSTRIAL BECAUSE

It is accompan ed by the fi ding of fungi or other microorganisms in the lesions or a a distant focus. Fungi, pathogenic and nonpathogenic, and certain other microo gan sms, e.g staphylococci streptococci, yeasts and molds, re almost u i ersally found on the ki of ad lts in the United States. Their demon tration does not constitute proof that a dermatos s of onoccupational nature.

It i accompanied by a c taneous reaction to test with extracts of fungi or of ce tain other microorganisms. Such reactions are too common to be of weight in ruling out the ind strial nat re in a given case they merely show that the patient has previousl had se sitizing exposure to the same microorganism or to one immunologically related to it they are comparable to react ons to tuberculin in the general population.

The reactions to patch tests with the substances f the ind strial exposure are nega tive. Such egat ve results of patch tests cannot be consid red conclusive. They may be due t (a) local diff re ces in sensitivity The areas tested may not be hypersens t ve while othe areas, part cularly the areas involved, may be hypersensitive. (b) Chronologic differences n sensit vity A person s skin, sensitive at the time of i dustri l conta t may be no sensit e to th a tual causal subst ces t the tim of test g c) The fact that the ctual causal substance r substances, o the ca sal combi tion, o causal inter mediates may not have bee ppl ed. (d) The fact that the concentration employed may have bee too weak, that th test application may hav been otherw se inadequat or that the vehicle employed may have been i correct o ma have preve ted penetrat on r e erted some *protective o neutralizing effect;* e.g water instead of sweat, fat or oil i stead of aa queous vehi le or vice versa acid instead f alkali or vice versa. (e) The fact that the test neve accurately reproduces th actual conditions of ind trial exposure.

Repeated contact friction maceration heat cold, sweat or other industrial agents or processes may be necessary additional factors enabling the substance, giving negative results in the test to cause dermatitis under the conditions of industrial exposure.

THE DERMATITIS IS ERRONEOUSLY CONSIDERED TO BE INDUSTRIAL DISEASE:

It is a dermatitis affecting a worker in an industry notorious for the occurrence of that type of dermatitis. For example dermatitis venenata may be due in the specific case to nonindustrial exposures home exposures to dyes, cosmetics toilet articles, insecticides, clothing paint varnishes or plants, or exposures to substances encountered in avocations such as photography painting or sports.

It is accompanied by a reaction to a patch test with a substance or substances encountered in the industry. Such a reaction to a patch test cannot be considered conclusive (a) it may be due to the application of a primary irritant or of a primarily irritating concentration; and (b) since the test never accurately reproduces the conditions of actual industrial exposure a reaction may mean simply sensitivity of the skin to a certain substance when applied in a certain concentration and manner at a certain time to a certain site while the same substance may be incapable of causing dermatitis under the actual conditions of industrial exposure and (c) see Latent allergy

---

INDUSTRIES COMMONLY AFFECTED.—Workers in certain trades are prone to skin eruptions, and many cases are seen in connection with the Workmen Compensation Act. Analyzing more than 500 occupational cases Klauder (ADS 48 570 1943) found the causes fell in the category of trauma in one-fourth, primary irritant in one-fourth cleansing agent in one-sixth sensitizers in one-eighth, and petroleum products and water maceration in about one-tenth each. Specific causes found in more than 3,700 cases were reported by Klauder and Gross (ADS 63: 1 1951) Wet work and the methods of cleaning the hands were especially important factors. Exposure of the hands to alkali diminished the normal acid mantle for almost 4 hours. Over 3,000 cases were surveyed by James and Bleiberg (JIMSocNJ 46 445 1931) Etiologically their cases were classed among those due to primary irritants, sensitizers trauma wet work maceration cleansers, petroleum products, infection and miscellany

CEMENT WORKERS are likely to be harmed by alkali. Lime is slaked in perspiration on the skin which becomes dry hard, thick and liable to painful fissuring Ulcers of the nasal mucosa as well as of the skin, may result. Secondary infection with mycotic or coccic organisms is likely Prevention lies in control of dust and cleanliness of the workers. Goggles protect the eyes, talcum helps keep the skin dry (Lether BMJ 2 702, 1937) and boric ointment protects the nostrils (Meherin and Schomaker J 112 1322 1939) Chromates in cement may account for some cases of cement allergy and a patch test with chromium should be made (Spier and Natzel AfDuS 193 537 1952) Chromium was found but not in great quantity in two-thirds of the various German cements tested.

FOOD HANDLERS.—Cleansers and detergents take their toll among these people Chrome ware and polishes are handled by restaurant employees, who also may wash dishes and come in contact with the sometimes irritating sterilizing chemicals that city health departments require such as Microlene (Sterling J 127 219 1945) Waitresses have the same kinds of dermatitis of the hands that affect other women, with their creams, lotions and nail lacquer Cooks are subject to irritation by flour and flavorings as well as burns which would be trivial if not mistreated. Baker s eczema has often been caused by ammonium persulfate a flour improver (Prakken and Postma NederlTijdschr 1938 p 367 Zündel and Jentsch abs YBD 1939 p 100 Jentsch abs YBD 1941 p 65) Sensitivity to this is sometimes lost when the chemical is avoided for a year or two Flour may act as an inhalant sensitizer giving rise to positive skin tests to wheat oats or rye (VanDishoeck and Roux abs YBD 1940 pp 113 114) and urticarial lesions, different from what ammonium persulfate causes (Id JAllergy 12 481 1941) Vanilla was reported to be an allergen to which some workers became hardened by Gougerot and Basset (ReocfrancD 46 1329 1939) Cinnamon is a common irritant (Epstein Ohio MJ 46 659 1950) it may reach the skin of the hands by way of a tooth paste (Leifer ADS 64 52, 1951)

See Contact Photosensitization, Plant Dermatitis; ... Frank (ADS 33 ... 1936) beef ... Newton (ADS 34 ... 1936) chicken blood, OMN (J 132, 894, 1946) chicken pickers and fowl mites Hopkins (MarylMJ 1 ... 1952 ADS 67 ... 1953) mushrooms ... et al (AnnAllergy 4 ... 1946) mango Burks (AnnAllergy 12 ... 1954) onion and garlic dermatitis in housewives Morris (IndustMed 23 ... 1954) trauma, over treatment, soaps, detergents and tinea causing dermatitis in food handlers.

Glass Wool, Fiberglas and Similar Spicular Irritants.—While the mechanical irritation of spicules is a major element in causing dermatitis, the alkaline content of rock wool made by *blowing air and steam through molten* blast furnace slag or silliceous rock, is also of consequence (J 113 1756 1939)

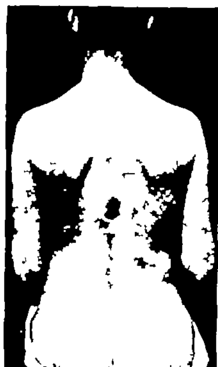

Fig 108 —Cement dermatitis (Dr Howard Fox)
Fig. 109 —Chrysarobin dermatitis (Dr D B H. Cleveland)

Fig. 110 — Asbestos corn (*Alden and Howell ADS 49 312, 1944*)
Fig 111 —Fibers of amosit asbestos (Alden and Howell)
Fig 112 —Foreign body reaction to asbestos fibers (Alden and Howell)

These substances are used for insulation, packing cushions, and the manufacture of textiles for garments and seat covers. They may be treated with synthetic resin fillers, which may sensitize (Schwartz ADS 55 258 1947)

Fiberglas may incite dermatitis of consequential severity traumatic and usually occupational affecting especially xerotic blond persons. The forearms legs, flexures and groins become red and itchy following exposure, but

not vesicular as in allergic contact dermatitis. The rash is transitory and dry. Washing with water immediately after exposure reduces irritation, but some persons cannot work with the material. Contaminated clothing may incite dermatitis in other persons, and spicules on the worker's skin may be transferred to members of his family by way of the bed linen (Pellerat abs YBD 1947 p 581). No sensitization was proved by Sulzberger et al. (IndustM 11 482, 1942).

Protective clothing and greases are not effective in controlling this microtraumatization, but changes of garments, good ventilation, loose work clothes and the free use of showers without soap immediately after exposure will succeed. See Hein (J 124 187 1944).

Pyrotenex, an electric conductor consisting of copper tubing packed with glass fiber produces similar trouble. Ward (BMJ 1: 905 1952) observed glass spicules protruding from the skin in his patients. Tight sleeves, a barrier cream and rinsing the forearms with running water prior to washing with soap are measures helpful in control (Cameron BMJ 1 1240 1952).

Miscellaneous Industries, Irritants and References

See Schwartz, Tulipan and Peck (Occupational Diseases of the Skin Lea & Febiger 1947)

Agriculturists	poison ivy, ragweed, other plants; ticks chiggers; *fertilizers*, sprays, insecticides, fungicides, milk can cleansers, irritant soaps, chlorine in privies; sunlight, causing cancer
Aircraft manufacture	zinc chromate primer resins, glues oil acid fumes (Hall: J 125: 179 1944)
Automobile workers	cutting oils, solvents, brake fluid, paint lacquer
Bakers	flour or sugar; cottonseed oil and potash, the former being used in bread, the latter in pretzels whitening agents; essential oils of flavoring
Barbers, Hairdressers	quinine mercury capsicum arsenic, sulfur Cantharides, various dyes and cosmetic substances
Briquette makers	coal tar pitch, causing photosensitivity melanosis, tar acne keratoses, epitheliomas
Butchering	anthrax, foot and mouth disease, erysipeloid, hog itch, acute pemphigus, onycholysis from pancreatic juice verruca necrogenica
Candymakers	sugar chocolate cinnamon, oil of cassia, citrous oils, vanilla, other flavoring agents
Canning	fruits, vegetables, citrous oils, peach juice and fuzz, pineapple juice, figs, tomatoes, potatoes, carrots and lettuce
Carpenters	various woods, sawdust, plywood adhesives
Chemists	many irritants handled by them
Cigarette paper	dermatitis of fingers (Tye JID 14: 77 1950)
Citrous fruit industry	trauma, maceration, paronychia, monilial interdigital dermatitis, lemon oil irritation, dye hazards (Beerman et al. ADS 38: 225, 1938 Birmingham et al.: AIndustHyg 8: 57 1951)
Coal miners	no particular specific occupational dermatitis. Feet should be kept dry. Good ventilation, efforts to reduce dust, and early reporting of the presence of disease advised (Knowles BMJ 2: 430 1944)
Compositors	benzine, bichromate
Cooks	cleansers, soaps, insecticides, flour bleach (benzoyl peroxide)
Cosmeticians	cold wave thioglycolates, hair dye (paraphenylenediamine) cuticle softeners, nail lacquers, hair bleaches and shampoos
Dentists	local anesthetic chemicals, soap, prosthetic plastics, metals
Dermatophytosis in industry	see Downing (J 125: 196, 1944)
Diesel engine workers	rust inhibiting bromate dermatitis, treatment with 3% BAL in zinc ointment (Cole J 140 718, 193_) hydrocarbon solvents and chrome are major problems (Guy ADS 70 239 1954); see Plunkett (Min M 37 330 1954)
Electricians	chlorinated hydrocarbon dielectrics
Electroplaters	cyanide various acids, chromates
Electrotypers	copper sulfate hydrochloric acid
Explosives manufacturers	T.N.T. tetryl, picric acid and picrates, mercury fulminate, ammonium nitrate (Schwartz J 1_5: 186 1944); see War Material (p. 150)

Exterminators	arsenic formaldehyde fluoride lead, Pyrethrum, DDT
Finger paint	see Tobias (J 13 : 533, 1949)
Fish i dustry	trauma and infection, bites redfeed dermatitis (Schwartz and Tabershaw: JIndustHyg 27: 273 1945)
Fi bermen	bites, abra ions, stings infections
Foresters	poisonous shrubs sprays, repellent
Furriers	arse ic d estuffs, i secticides
Gasoline	toxicology see Maeble (J 11 : 1963 1941); Biederman (J 106: 2236, 1936)
Glue	resin glues in wood man facture: protei glues, natural resin glues synthetic resin gl es, combination ; urea an l phenol formaldehyde resin dhesives cause most of the troubl in maki g plywood. Control measures protective cloth ing cl an ing facilities, hardening Alkaline gelatin; phenol formaldehyde urea formaldehyde styrene alkyd allyl resin (Schwart et al.: PHRpts 58: 899 1943)
Grocers	sugar a d flour cleansers roach powder
Ink, fl escent i vi ible	see Bloom and Weiner (JID 11: 197 1948)
I terior decorators	dyes a d fabric fini hes
Laboratory workers	infecti ns acquired in laboratories; re safety measures, see Sulki and Pike (J 147: 1740 1951)
Laundry work rs	alkaline soaps, sy thetic det rgents, antiseptic after rinses (phenyl mercuric compound) bleaches
Machine tool operators	cutting il cleansers, antiseptics i oils
Milliners	dyes, arsenic
Nurses	mercury formaldehyde medicated alcohol, l resol other antiseptics morphi penicillin, streptomyci soap cosmetics
Painters	turpentine solvents, arsenic linseed oil dyes, alkali pai t removers
Petroleum workers	oil, gasoli e clea sers
Pharmaceutical wo k rs	see Dalton a d Pi rce (ADS 63: 60 , 1951)
Photoengraving	ld aniline brom um alkali formaldehyde glue
Photographers	pyrogallol M tol c stic soda chromates dyes, lacquers, colo process chemical d sensitizers (Wei sberger: Sci 110: 438 1949)
Ph icians and surgeons	contactants, infections radiation i jury (Epstein J 147: 1751 1951); antiseptics, local anesthetics rubber gloves trauma from scrubbing
P neapple d stry	proteol tic enzyme, brom li removes epidermis of finger tips, calci m oxalat needles cause mechanical damage and itching (Polo i : BJD 63 441 1951)
Plate print rs	inks solvents d es, cleansers (Neal a d Emmons: PHRpts 54: 89_, 1939)
Polishers f m tal	oxalic cid, turpe tine bichromate
Pott ry wo kers	cobalt put into wet clay to ne tralize color of yellow iron oxide impurity (Pirilä ActaD-V 33 193, 1953)
P t rs	arsenic artificial coloring hydrocarbon i i k chromate in photostats, cleansers
Railroad h ps	petroleum chlorinated hydroca bon solv ts, chromates in f el oil cra kcase oil a d coola ts. Control by suitable cleansi g protecti clothi g protective cream, educa tion of wo kers (Schwartz JIndustM 1: 10 492 195_) See Diesel engine workers.
Seamstresses	t xtile finishes, d es, wool, thread, yarn
Shoemakers	chrome-tanned leather dyes, cements, polishes solvents, rubber See Clothing shoes nd leath goods.
S lk ha dl rs	antimildew m y irrit t (Goodman Diseases of Tradesmen, by Ramazzi i, Medical Lay Press, 1933)
Stenographers	cleansers cosmetics (rarely carbon pape)
Tanners	b chromat hydrochloric acid
Toilet seat	from pa nt antisept cs, detergents varnishes (Tulipan In du tM 9 303, 1940)
T rpentine	terpene derivat ves, pinen, camphor menthol, eucalyptol; oxidat on of stored turpent ne makes t more irritati g than the fresh substance (McCord J 86 1979 1976 Riedel KB Wchn 19 1034 1940; R kst d BJD 59 115 194 ; Hellerstrom and Lunden abs YBD 1951, p 145; Hellerstrom a d Thyresso ActaD-V 23 51 195_)
Weld rs	actinic burns, hromium fumes, zi c hloride ammonium chloride, fluoride fluxes
Wood preservatives	phenyldichlorarsine; thyl mercuric phosphat etc. (Sayers and Dudley: PHRpts 53 1209 1938; Vintinner: JIndust Hyg 22 297 1940)

INDUSTRIAL DERMATITIS.—MEDICOLEGAL ASPECTS OF OCCUPATIONAL DERMATOSES constitute a specialty within themselves. The physician, being an expert witness and not a lawyer, is called upon to give his views as clearly and accurately as he is able, and to play no favorites.

An attorney in selecting a physician to serve as an expert witness will appraise his competency integrity experience and ability to articulate (Enggas, pers. comm., 1953) Strict neutrality is a difficult but advantageous position to maintain, for the cross examiner can use bias in the expert effectively to discredit him. Decisions regarding what is occupational dermatitis and what is not, and how much disability has been caused and what compensation is just are the prerogative of the commissioner or the jury The physician possessed of special medical knowledge and good case records will influence the judgments rendered but has no further responsibility for them His opinions will carry weight proportionate to the clarity of his thinking his investigation of the case and his presentation of the facts, but he owes nothing more than the whole truth as he sees it

The physician called to the witness stand is well advised to be humble, careful and deliberate He may ask for restatements of complicated questions. He should give his attorney time to rescue him by objections when interrogation becomes too tense He cannot argue successfully with those who argue professionally He will find his cross examiners remarkably well informed, well prepared and able at their work opponents not to be underestimated capable of confusing and distorting what he says, best countered by courtesy an even temper careful patience and adherence to facts.

One may rightly assume that in a courtroom a good attorney can make a dupe of a good doctor One may remind a doctor that he has the right to decline or accept a case but that once he has accepted he is in it all the way

I formatiy articles on medicolegal aspects f occupational dermatoses re those by Downing (J 111 1518, 1938 ADS 39 12, 1939) Foerst (J 111 1842, 1938) Sulzberger (BullNYAcadM 18 665 1942), the M. D. and ross examination QMN (J 151 1052, 1952) answers on "spreading of llergic base, regard as whether occupational disease results in llergy to other substances Viscount Simon (BMJ 2 1 1953) the loctor on the witness stand Curphy (J 154 457 1954) preparation of medicolegal case Souder (Sci 119 819 1954) effectiv expert testimony techniq; Gilbert (J 156 1311 1954) courtroom comportment

INSECTICIDES AND REPELLENTS—*Pyrethrum and rotenone (from derris)* are substances valuable in insect control but they are sensitizers (Martin and Hester BJD 53 127 1941 Dorne and Friedman J 115 1268 1940) Sta Way caused not only a general rash but also nephrosis and edema in a case of Hoehn (J 128 513 1945) and Flit was the irritant containing oil of lemon, turpentine and pyrethrum in a report by Simons (abs J 114 95 1940) DDT with its valuable power of remaining insecticidal for a long time can continue for an equally long time to induce allergic dermatitis, as in a widespread case of eczema which lasted nine months after spraying (Leider JID 8 125 1947) and in one of exfoliative dermatitis (Higgins and Kindel JID 12 207 1949) The patient of Hollander (ADS 62 66 1950) allergic to DDT had not only an extensive severe rash but also areas of actual necrosis.

See Schwartz nd Warren (PHRpts 54 1426, 1939) on naphthyl isothiocyanate Simons (ActaD-V 28 601, 1948) on dermatitis, mucosal irritation, umbness, vomiting, even deaths among workers in derris mills Goldman (ADS 62 246, 1950) reviewing chemistry and dermatologic aspects of repellents Campbell (BMJ 2 415, 1952) neurologic langers of DDT See also Scabies and Pediculosis

MATCHBOX DERMATITIS.—Intolerance of the phosphorus compound on the striking surface of matchboxes is by no means rare. The lesions it produces are typically dry reddish scaly itchy ones, likely to be located underneath the pocket where matches are carried Conveyed by fingers, which are heavily contaminated in pipe smokers particularly it may cause dermatitis of the face, neck and hands sometimes, though the chest or the thighs and scrotum are the usual sites. Klaber (BJD 50 451 1938) reporting a case reviewed the literature and stated that P S is the active agent. He noted the abetting influence of moisture and warmth as well as allergy A patient of Wilson (NebrSMJ 18 183, 1933) acquired allergy to matches only after the head of a match burned

the finger tip beneath the nail The ears were principally affected in the patient of Templeton (ADS 44: 676 1941) the face in cases of Burgess (CanadMAJ 65 567 1951) Martin (abs BJD 63 39 1951) saw many instances in a matchbox factory While only dermatitis disturbed two patients, one had systemic poisoning of consequence as reported by Burgess (Canad MAJ 65 567 1951) When a lighter is substituted for matches one must think of the possibility of allergic response to lighter fluid.

Medicines are common causes of contact dermatitis. They include both primary irritants and sensitizers. A dermatologist must remain keenly alert to the possible ill effects of medication applied to skin or mucous membranes, for he sees daily in his patients the damage done by substances applied by the patient by other physicians, and even by himself.

Fig 113.—Dermatitis of eyelids from matches. (Dr D. E. H. Cleveland.)

Fig 114—Matchbox dermatitis. (Dr D E H Cleveland.)
Fig 115—Matchbox dermatitis. Close-up of Fig. 114

See medicinal irritation, the chapter on Treatment, also Prystowsky (SouthMJ 45 960 1952) Sulzberger and Wise (ADS 28 462, 1933), Gaul (J 127 430 1945); Underwood et al (J 130 249, 1946) Underwood and Gaul (J 138, 570 1948) overtreatment Bae et al (AD 71 19 1955) sensitivity index of various topical therapeutic agents Gaul (J 157 720, 1955) overtreatment, especially of contact dermatitis, worst offenders among medicines re mercurials, sulfonamides, local anesthetics, antihistamines

Adhesive Plaster.—At one time containing orris root a common sensitizer adhesive tape has been greatly improved. The mechanical effects should not be overlooked (Pinkus: JID 16: 383 1951) nor the possibility of confining pathogenic bacteria or molds and sweat under tape (Humphries JID 9 219 1947 Gaul and Underwood: JID 12: 173, 1949; Peck et al. ADS 63 280 1951) Composition of adhesive plaster and reactions thereto were reported on by Schwartz and Peck (PHRpts 50: 24, 851, 1935) See also Sheldon et al. (JID 4 295 1941); Franks (JAllergy 17 112, 1946); Kell and Bereston (ADS 45: 105, 1942) The irritating rosin often has come from abietic acid a turpentine derivative.

ANESTHETICS, TOPICAL.—Orthoform put into a tooth socket caused a generalized vesicular and urticarial rash (Hein and Feldman: UCutRev 38: 871 1934). Saline in leaking from gluteal m scle to skin of a patient given bismuth injections for syphilis produced contact dermatiti (Brunsting and Brs ting ADS 36: 118^ 1937 Nupercaine i a frequent ca se f dermatitis (Pantus: J 101: 30 1933) and few dermatologists prescribe it. Halley a d Halley (ADS 36: 1084 1937) were among the first to condemn it. Interesting studies of sensitization to the procaine group have been given by Goodman (JID

Fig. 116.—Cement dermatitis. (Dr Sam E. Sweitzer)

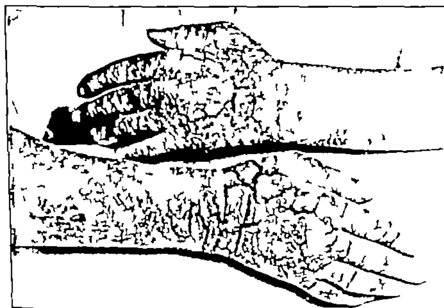

Fig. 117.—Severe dermatitis of the hands and forearms in grocer

53, 1939) Rein and Kanof (JID 11 311 1948) and Lane and Luikart (J 146: 717 1951.) Procaine Orthof rm, llutes Pi rat tetraca (Pontocai e) dibucaine (N per cai e) ethyl aminobenzoat (Benzocain) X lcain Apothesine Larocaine, nd Metcaine are members of the group. They are occupat o lly hazardou to dentist especially (Laden a d Wallace: JID 12 299 1949) although I see more dermatitis of th ha ds in denti ts caused by soap tha h llergy The eyel ds of patients nd fingers of ophthalmologists suffered Pontocaine dermat tis reported McAlpine and Berens (AmJOphth

25: 706, 194) and the use of local anesthetic substances in eye disease is being criticized nowadays. *Procaine accounts for some cases of seeming intolerance of penicillin* (Hitschmann et al.: JID 15 105 1950)

The antihistamine ointments are local anesthetics but generally do considerably more harm than good. See Treatment antihistamines. Sidi et al. (ActaAllerg 5: 292, 1953); Nomland (JIowaSMS Apr 1953)

ANTIBIOTICS.—Contact dermatitis evidently primary irritation was reported from bacitracin (Reisbea ADS 63 304, 1951) and from Chloromycetin (Robinson et al. JID 1 ?03 1951). Tyrothricin and other antibiotics irritated a patient of Goldman et al. (JID 11: 43 1949)

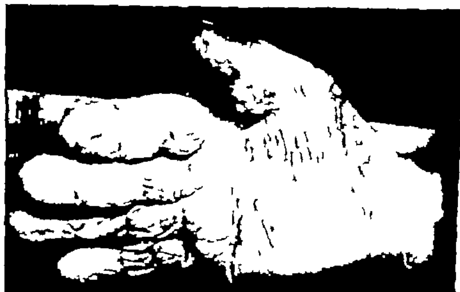

Fig 118.—Iodoform dermatitis

Fig 119.—Vesicular dermatitis caused by a fungicide

Penicillin ointment has been abandoned for it is often a primary irritant as well as a sensitizer and is especially likely to rouse intolerance if put on the skin and given parenterally at the same time. The dust on the hands of a man who dispensed penicillin caused facial and genital dermatitis, reported Pyle and Rattner (J 125: 903, 1944). Penicillin eye drops blistered the eyelids in Bedford's case (BMJ 1: 51, 1946). Epidermal sensitization appeared in 9 of 200 patients tested by Gottschalk and Weiss (ADS 53 863, 1946). Dermatitis among workers engaged in producing penicillin was reported on by Friedlaender et al (ADS 54 517 1946)

Streptomycin is an epidermal sensitizer affecting especially the nurses who handle the drug (Strauss and Warring JID 9 3, 90 1947; Berke and Obermayer: JID 11 253, 1949; Crofton and Foreman BMJ 71 1949; Touraine and Pichon PresseM 56 ?63 1949). About half the personnel frequently exposed to it develop contactant allergy. The eyelids and uncovered skin are principally affected.

Fig. 120.—Dermatitis venenata following application of belladonna plaster (Drs. John A. Fordyce and George M. MacKee.)

Fig. 121.—Medicinal contact dermatitis, from iodine. (Dr Howard Fox.)

Fig. 122.—Blistering from tincture of iodine applied as home remedy for "rheumatism." (Dr D. D. H. Cleveland.)

BUTESIN PICRATE is a notorious offender first reported as causing acute vesiculobullous dermatitis with erythema by Pusey and Rattner (ADS 10 917 1929); see Edit. (J 109: 902, 1937) for many cases with bibliography. The hypersensitivity is quite specific, being limited in the case of Laden and Rubin (JID 11 119 1949) to the alkyl esters of para aminobenzoic acid.

IODINE occasionally is intolerable, causing an acute violent, vesicular dermatitis. Its percutaneous absorption is rapid and topical application may be followed by the same rashes as follow sometimes its internal administration (Clifford BostonMSJ 193: 931 1920). Death ensuing from the application of iodine to the skin was reported by Alexander (BMJ : 100 1930). To remove iodine from the skin (or clothing) use a 1% aqueous solution of sodium thiosulfate the specific treatment for iodine burns (Sutton ADS 33: 100–, 1936). Patch tests on 5 persons sensitive to iodine evoked general reactions in 3 of them (Lelner: JLabClinM 7: 1151 194).

MERCURY.—Intolerance is common. Clinical experience suggests that about 1% of dermatologic patients cannot use it. Percutaneous absorption is a hazard: yellow oxide killed a psoriatic patient of Greuer (DWchr 111: 939 1940). Severe reactions in children concerned Gibel and Kramer (AmJDisChild 60 153 1943) for not only dermatitis but also fever albuminuria and lymphadenopathy may be produced (Samitz ADS 50 10 1944). See The Pink Disease. A severe case of intolerance of ammoniated mercury ointment was promptly alleviated by injection of BAL by William and Beach (J 14 1?90, 1950). Metaphen (Belote and Marshall: JMichSMS 34 1–, 1935) Merthiolate (Hill JAllergy 19: 1–, 1947) and Hydrophen, containing phenyl mercuric nitrate which is highly germicidal (Wilson: NebrSMJ ?4: 0, 1939) are all of them hazardous (Gall and Underwood J 140 ?90, 1949). Mercury amalgam fillings have been reported to cause perioral dermatitis (Traub and Holmes: ADS 38: 349 1938; Robinson and Bereston ADS 59: 116 1949). A sailor tattooed with cinnabar developed a severe allergic rash (Novy ADS 49 172 1944).

OINTMENT BASES, innocuous as they may seem, are not wholly to be trusted, by any means. Even petrolatum may irritate (Hollander ADS 39 49 1939). Vesiculation from contact with petrolatum was observed by Rosenbaum (ADS 48: 193, 1943) but patch tests with it are rarely positive (Levin and Moss: AnnAllergy 6: 5?9 1948). Sometimes when a bland ointment appears to irritate the fact is that it covers over pathogenic organisms and allows them to thrive. Among patients intolerant of Aquaphor cholesterol was the offending ingredient in 8 of the 9 (Ellis: ADS 56: 801 194). While lanolin is rarely irritating, the allergens in its composition seem to be the mixed alcohols rather than the fatty acids (Sulzberger and Lazar: JID 15 453, 1950). The specific excitant fraction of lanolin was shown in one allergic patient to be a yellow glassy solid which after acetylation was no longer irritant (Everall and Truter: JID 22: 493, 1954).

Olive oil is not a good vehicle for other ingredients of a topical application, probably because of the unsaturated fatty constituents which, when percutaneously absorbed, incite an inflammatory metabolic process (Sutton: J 122 34 1943).

OPIUM derivatives may cause contact dermatitis, especially on the hands of nurses and pharmacists (Jordan and Osborne: J 113: 1955 1939). Rashes on eyelids, neck and hands of workers in a morphine factory were observed by Dore and Thomas (BJD 56 177 1944) and Green (ib p. 18?). The once popular lead and opium lotion is honored only by time.

SULFONAMIDES are notorious for their capacity to sensitize when applied to the skin, especially in the presence of pathogenic staphylococci and when coincidentally given by mouth. See Fowlkes et al. (SouthMJ 35: 1018, 194–). Livengood and Pillsbury (J 121 400, 1943). Weiner (ib., p. 411). Park (BMJ 69 1943). Tait and Klorfain (Lancet I 39 1944). Sulfathiazole 5% ointment sensitized 1– of 18 patients of Darke (J 1 4 403 1944). Such sensitization introduces widely various hazards from sulfonamide derivatives, lacquers and plastics which the patient may subsequently meet nonmedicinally. There exists little excuse to use sulfonamides topically said Lane (SouthMJ 38 125, 1945) in describing 1– illustrative cases including one death; there exists not any excuse I would say now.

VITAMINS may irritate the skin: nicotinic acid caused redness and itching of some of the personnel engaged in its manufacture (Watrous J IL –13?, 1939); synthetic vitamin K in 1% concentration is a primary irritant and the crystals will ulcerate the skin (Page and Bercovitz AmJMSc ?03: 566 194–); and biotin concentrate irritated the hands and arms of a laboratory worker (Keller JAllergy 14 8? 194–).

MEDICINAL CONTACT DERMATITIS MISCELLANEOUS MEDICINES

Acriflavine dermatitis (Beare Lancet 1 410, 1947)
Antistine eye drops (Mosko and Peterson JID 14 1, 1950)

Coal tar (Simon and Brandt ADS 68 584, 1953)
Codeine (Palmer ADS 46 ?2, 1942) contact with cough syrup, case
Corticotropin from pork but not from beef (Zeligman J 149 262, 1952)
Emetine in persons who filled ampoules (Kile and Welsh ADS 45 ?30, 1942)
Ephedrine (Carpenter ADS 34 1038 1936. Lewis ADS 49 379, 1944. Spencer ADS 51 48, 1945) nose drops

Formaldehyde (Rostenberg et al.: JID 19 459 1952) quite specific, reaction sometimes delayed 72 hours.

Furacin (Richter and Mocchio: NYSJM 49 2325, 1949 Fox: ADS 63: 378, 1951; Morin: J 133: 942, 1947 George: J 156: 247 1954)

Hexylresorcinol (Templeton and Lunsford: ADS 25: 439 1932) in toothpaste; Cummer (J 100 384 1933), Walter (J 104: 1807 1935)

Iodoacetic acid, a violent corrosive (Marcus and Frerich J 14 : 895, 1950)

Isonicotinic acid (Jordon J 149 1316, 1952)

Lanolin (Lilingood et al. J 148: 334 1952) trouble with ointment bases (q.v.)

Phenol-camphor once popular treating tinea (Hubler J 123: 990, 1943; Ronchese: RhodeIslMJ 25: 176 1942)

Phenolphthalein (Skinner ADS 59 338 1949)

Physostigmine in eye drops (Alden and Jones: ADS 37 82, 1938)

Quotane (Daly ADS 66: 393, 1952)

Resorcinol (J 121: 985, 1943)

Salumiek (Sheard: ADS 70: 115, 1954)

Metals.—Many different metals are concerned with contact dermatitis in ordinary as well as occupational life.

Aluminum does not irritate but dermatitis attributed to it is generally caused by oils or cleansers. Arsenic from insecticide dust contaminating the clothing may cause erythema and vesiculation (Monahan JMoMS 41 54 1944) Cobalt, contacted by workers making cutting tools (carballoy) was recognized as a contactant irritant by Schwartz et al (JAllergy 16 51, 1945) It has induced rashes resembling pityriasis rosea and also asthma Conjunctivitis and upper respiratory irritation caused by vanadium was reported by Symanski (abs J 113 1080 1939) Selenium caused purpuric contact dermatitis according to Pringle (BJD 54 54 1942)

Antimony vapors induced itchy varicelliform eruptions in exposed workers (Fell PresseM 47 1133 1939)

Beryllium may produce severe papulovesicular and ulcerative dermatitides (Van Ordstrand et al. J 129 1084, 1945) and conjunctivitis (Edit BMJ 2 231 1946) Discrete papular lesions, papulovesicular lesions and ulcers were observed among workers in beryllium production plants by DeNardi et al (OhioSMJ 45 567 1949) A sarcoidal foreign body granuloma (q v) results from intracutaneous reaction to beryllium compounds such as the phosphores of fluorescent lamps, and pneumonitis resembling that from silica is caused by their inhalation (Grier et al. JIndustHyg 30 228 1948) Acute eczematous contact dermatitis is the usual type of intolerance, appearing in from 7 to 14 days after exposure and disappearing in a few days after removal from contact but chronic cases also occur often in the form of ulcers over the knuckles, sluggish unless curettage or excision is performed (Van Ordstrand AnnIntMed 35 1203 1951) A chronic beryllium ulcer may develop at the site of an injury from a broken fluorescent light bulb curable by excision. See Beerman (AmJMedSci 221 462, 1951) review

Chromium is at fault in many cases of persistent and rebellious allergic dermatitis. Chromate and dichromate may touch the population at large as well as industrial workers, being met with in tanning photoengraving the plating of various objects including automobile and kitchen trim, paint, antirust compounds and cement (J 119 851 1942 Pirila and Kilpio abs YBD 1949 p 152 Vaccaro IndustM 10 246 1941) Zinc chromate primer caused nummular eczema of hands and forearms of aircraft workers who did not harden, noted Hall (J 125 179 1944) A droplet of chromic acid produces painless dry gangrene which heals with scar The nasal septum is likely to suffer perforation in chrome workers. The caustic action is not associated with sensitization (Edmundson JID 17 17 1951) Diesel locomotive radiator fluid and fuel may contain antirust compounds and so incite chrome dermatitis (Winston and Walsh J 147 1133 1951) BAL used topically in 3% concentration was helpful in chrome dermatitis reported Cole (ADS 67 30 1953)

Lithium, like sodium produces alkali burns (QMN J 126 268 1944)

Nickel is a common cause of contact dermatitis. This metal may reach the skin by way of coins, spectacle frames, zippers, pins, garter fasteners, jewelry and the like (Foster and Ball ADS 31 461 1935 Downing ADS 41 568 1940) Plated articles as well as alloys may be the source. Although

the cutis appears to be the shock tissue passive transfer experiments in 11 cases were not successful (Cormia and Stewart CanadMAJ 32 270 1935) It seems that sweat serves to ionize the metal (Taylor et al. BMJ 2 40 1945) When 54 patients known to have been nickel sensitive were traced after various prolonged lapses of time by Morgan (BJD 65 84 1953) 43% of them had become negative to patch testing and some of these still had eczematoid dermatitis despite their negative tests to nickel *Many however remained* reactive one patient retaining nickel allergy for 11 years.

Platinum salts, dissolved in water and contacting laboratory and refinery workers via liquid sprays and splashes caused severe dermatitis and/or asthma reported Roberts (ArchIndustM 4 549 1951) The onset was sometimes gradual until an acute attack developed. The lesions were urticarial in acute stages, eczematous in chronic Scratch tests were positive in the asthmatic ones, and chest x rays sometimes showed low grade pulmonary fibrosis.

In a valuable and original study of 34 cases of nickel dermatitis, Epstein (Trans ADA, 1955) found 22 reactive to both patch and intradermal tests, 5 reactive to patch tests only 6 reactive to intradermal tests only and 1 negative to both types of tests. Cross sensitivity between Ni and Co *was present in 11 of 28 tested fewer showed Ni-CO or Ni-Cr cross sensi*tivity It was apparent that the epidermis is not exclusively the shock tissue in contact dermatitis, but that the dermis often is (see Contact dermatitis, pathology)

See Sully (Chromium, Academic Press, 1954) sources, alloys metallergy technology of chromium Walsh (J 153 1305 1953) chromat hazard l industry only the hexa valent compounds sensitize, Denton et al (JID 23 189 1954) Cr in cement, Hilt (*Dermatologica* 109 141, 1954), Cr found in surprising places, including laundry work Haxthausen (abs YBD *1954 p 420) Cr not specifically bound or retained but disappeared in 24 h in allergic and* normal animals, Gaul (AnnAllergy 121 429 1954) of 40 cases of dermatitis of hands, 18 reacted to metal, 12 of these to Cr

Oils used in lubrication and cutting with machine tools provoke folliculitis with acneic comedones pustules and scarring The parts affected are especially the hairy forearms and thighs. Prevention can be successful if efficient effort is made to minimize the exposure to oil if the skin is thoroughly *cleansed after exposure and if the clothing is* kept properly clean; no local therapy is necessary ordinarily (Schwartz PHRpts 56 1947 1941) The insoluble cutting oils are the worst offenders (Peck J 125 190 1944)

The addition of antiseptics to cutting oils is unnecessary and objectionable The bad odor oils develop is due to chemical changes induced by heat not by fermentation and an antiseptic is likely to be an irritant or a sensitizer itself *Low melting point and unsaturated oils are more irritating than high* melting point and saturated oils (Klauder and Brill *ADS 56 197 1947)* Oil acne of the forehead and face may be caused by hair oil such as Brilliantine (Garnier abs YBD 1946 p 277) Dermatitis of the face in certain workers near ventilator openings was found to be due to a petroleum solvent conveyed by air currents (Campbell and Schwartz OccupM 3 570 1947) See Council on Industrial Health Rpt. (J 157 1611 1955) industrial oils, composition of cutting oils, and dermatoses caused thereby

Chlorinated oils especially the dielectric chloronaphthalenes, may induce acne of extreme severity including comedones, milia, and sebaceous cysts, along with the inflammatory lesions subsequent to them Hot chlorine compounds and fumes are the active agents rather than cold wax (Jones JIndust Hyg 23 290 1941) Such acne has been named according to the product in the manufacture of which it was observed, as perna krankheit ' halowax acne, cable rash (Sulzberger et al. NYSJM 34 899 1934) All persons exposed to chloronaphthalenes chlorodiphenyls, or chlorodiphenyloxides will develop acne within a few months unless stringent precautions are used (Schwartz and Peck NYSJM 43 1711 1943) The face is exposed and the thigh, groin and umbilical regions are affected via soiled garments. Coal tar workers are subject to oil acne too but to a less degree than workers with

heavy tar distillates and pitch. A person with seborrhea prone to develop acne should not be hired for such work. Acute yellow atrophy as well as mere dermatitis may be caused by chlorinated naphthalenes (Collier Lancet 1 72, 1943) Good and Pensky (ADS 48 251 1943) described erythematous and vesicular dermatitis too and noted concomitant complaints of lassitude anorexia impotence headache alopecia, and loss of weight in their patients. Patch tests are negative Chlorophenate moth proofing in fabrics may cause oil acne

Almost every sebaceous gland had become a milium, sebaceous cyst or acne pustule in a man I saw who was exposed to a chlorinated refrigerant His disease did not yield until large doses of estrogenic substance were given. Premarin 1.25 mg daily appeared to exert a conspicuously beneficial influence on his sebaceous gland hypertrophy

See Leo Butler (ADS 36, 251 1937) Nakauchi (bs ADS 46 292, 1942) histology of lesions in rabbits Schwartz (J 122 158, 1943), Morri and Tabershaw (J 121 192, 1943) Meigs et al (J 154: 1417 1954) chloracne of face from prolonged exposure to low concentration of chlorinated diphenyl.

Tar acne is not different from the acneiform folliculitis caused by other oils and chlorinated waxes. It is seen in hemp workers, flax doffers and those who come in contact with the distillates of coal and residues of gas (Ormsby Dis. Skin, Lea & Febiger, 1937 p 1200); Jones and Alden ADS 33 1022, 1936) See also Photosensitization.

Fig. 121—Acneiform folliculitis from cutting oil. (Dr Clyde L. Cummer)

Keratosis follicularis epidemica appeared in patients handling wax covered tinfoil reported by Schenker (Dermatologica 97 35 1948)

PHOTOSENSITIZATION BY CONTACTANTS (BERLOCQUE DERMATITIS) —Pigmentation results from the application to the skin of toilet waters containing oil of bergamot (from the juice of Persian limes) or some other essential oils, followed by sunlight or quartz light. The lesions appear as dark red areas changing to brown slightly mottled with red. Certain grasses may by their oils so sensitize the skin that dermatitis and pigmentation of striking linear and crisscross configuration follow contact with them when sunshine is superadded. *Dermatitis bullosa striata pratensis* was the mellifluous name of Oppenheim (AnndeD 3 1 1932 ADS 46 541 1942 see Sandler J 112 2411 1939) Covered areas although contaminated with the essential oils are not affected. The furocoumarines of plant juices are responsible for this abnormal responsiveness to light of from 3100 to 3700 A While the furocoumarines vary in activity as photosensitizers, there is no known correlation between their chemical structures and their sensitizing powers (Kuske AfDuS 178 112, 1938 abs YBD 1939 p 568 1941 p 85) Parsnip (Jensen and Hansen ADS 40 566 1939) lime oil (Sams ADS 44 571 1941) and agrimony (O Donovan BJD 54 39 1942) have been carefully studied, but the photocatalysis of pigment remains ill understood. Tar and pitch handlers may develop melanosis as an occupational photosensitization phenomenon (Foerster and Schwartz ADS 39 955 1939)

Differing from the usual type of photosensitization a phenomenon was described by Sams (Trans ADA 19 ..) in which papular and papulo-urticarial lesions appeared diffusely in an area where a digallol trioleate sunscreen had been applied not in areas of unprotected sunburn Patch tests with this mixture of tannic acid derivatives was positive only after exposure to ultra violet light

Fig. 124—Contact photosensitization from a toilet water (Simons YBD 1939 p 125.)

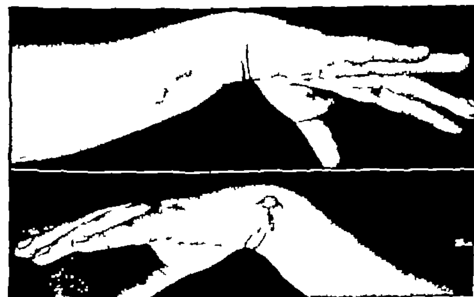

Fig 125—Contact photosensitization from Persian lime. (Gross ADS 63 370 1951)

Plant and Weed Dermatitis.—Plants are among the commonest causes of contact dermatitis. Poison ivy primrose and ragweed are noteworthy of

fenders The major skin sensitizers among the flowers and shrubs according to Shelmire (SouthMJ 33 337 1940) are primrose painted daisies (pyrethrums) and feverfew and other members of the chrysanthemum family

Woodworkers, carpenters, florists, farmers, agriculturists in various kinds of work and food handlers (q v) are obviously subject to exposure but products of vegetational life are handled by all people One cannot overlook such a seemingly obscure contactant as cocobolo wood which provides handles of knives and mouthpieces of musical instruments (Leider and Schwartzveld ADS 62 125 1950)—examples are endless.

Algae blue-green (Cohen and Reif: JAllergy 24: 452 1953)

Hops (Cookson and Lawton: BMJ _: 376 1953)
Krameria (Grolnick: JID 1: 179 1938)
Lemon grass oil, common in essential oils (Mendelsohn: ADS 33: 94 1946)
Mango from Anacardi ceae; can cause sores in and about mouth (Kirby-Smith: AmJTropM 19: 373, 1939; Zakon: J 113: 1509, 1939; Goldberg: J 156: 9 4 1954 perioral from peel not pulp)
Onion and garlic, in a cook (Burgess: CanadMAJ 66: 275, 195_)
Orris pollen, and root from hizome of iris, useful to hold perfumes (Prickman : PSMMC 9: 291 1934)
Parsnip, see Photosensitization
Primrose (Low: BJD 36: 292, 1924)
Tobacco, reagins a d vascular disease (Harkavy: JID 2: 247 1939); arsenic spray (Barksdale: J 115: 67 1940)
Tulips, paronychia in sorters and packers of bulbs (Overton: Lancet : 1003, 1970); barbs of testa traumatize, and sugar in juice ferments (Bertwhistle: BMJ 1: 1133, 1936); positive patch tests (Caulfeld CanadMAJ 34: 506, 1936)
Wood, cocobolo (Howell and Ballr: ADS 62: 400 1950); manzanillo or beach apple latex blisters may damage cornea (Snow and Harley ADS 49: 226, 1944); tropical wood (Piorkowski: EAfrMJ 21: 60, 1944); mesquite (Fox: ADS 44: 1009, 1941); walnut juice (Siegel: ADS 70 511 1954)

Articles containing lists of plants t which llergy has been observed include Harville (JAllergy 4 537 1933), Bonen (J 101: 1527, 1933) wood Shelmire and Black (J 108 719 1937) Shelmire (SouthMJ 33 337 1940) Allen (AmJTropM 23 3, 1943) Panama plants Weber (ADS 67: 388, 1953) sawdust.

See also Photosensitization by contactants

CASHEW —*Anacard um occidentale* a nut-bearing evergreen tree of a genus which includes poison ivy mango a d pist cia, i the source of an oil obtained from the nutshells which has many uses and i also a potent sensitizer if its irritant property is not destroyed by heat (Downing a d Gurney: JIndustHyg 22: 169 1940) Contact dermatitis does not follow from ingestion of cooked nuts. Th resins from cashew re of the phe ol-formaldehyde type, useful in mucilage, varnish, printer's ink and the like (Schwartz et al. IndustM 14: 500 1945) See Tulipan (Ind stM 5: 626, 1936) While some workers harden others do not Anacardol, a primary irritant in adequate concentration, i related to urushiol, so that cross sensitivity to poison ivy i common according to Schwartz.

DHOBIE MARK DERMATITIS i the contact dermatiti provoked by the laundry marking material derived from the ral or bella gutti in I dia (Livingood et al. J 123: 23 1943) This pote t sensitizing substa ce i not destroyed by boiling. The disease was long confused with dermatomycosis. The marking nut tree is a member of th Anacardiaceae and its tar or oil i a blistering primary irrit nt. A bottle of thi was broke in the mail and injured the ski s of several postal workers (Goldsmith J 123 27 1943) See Merrill (J 124: 222, 1944)

POISON IVY —Dermatitis results from contact with the oleoresin which may be conveyed indirectly as well as immediately Vesicle fluid and smoke from the burning plant are not noxious (Howell ADS 50 306 1944 Pratt and Corson ib 51 316 1945) Human beings are not born allergic to the oleoresin, but acquire sensitivity Guinea pigs can be sensitized by application or injection of the antigen (Ginsberg et al. ADS 36 1165 1937) The antigen is a primary irritant when it touches the skin in sufficient concentration, and it adheres strongly to the epidermis yet may be present in such quan

tity as to be spread about from the initial site of contact by way of the fingers or clothing. The initial attack of ivy dermatitis which sensitizes differs from subsequent attacks occurring after sensitization exists. The first attack is likely to manifest itself as an impetiginoid exudative painful lesion from primary irritation, a lesion sterile on culture which rebels at all kinds of treatment and remains practically unchanging for several days. Then sensitization, having developed, makes itself evident with swelling, spreading vesiculation and the appearance of distant lesions where relatively low concentrations of antigen reached the skin, low enough not to serve as primary irritants but

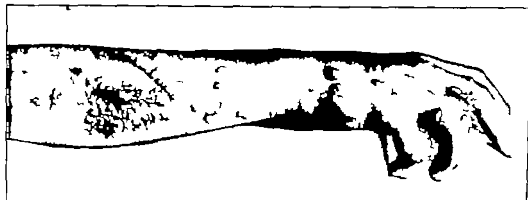

Fig. 126.—Dermatitis venenata, due to *Rhus toxicodendron*. (Dr. Howard Fox.)

Fig. 127.—Poison ivy dermatitis, not as yet vesicular. (Dr. J. P. Gueguierre.)
Fig. 128.—Poison ivy dermatitis at the height of reaction, the fifth day of the eruption.

ample to evoke reaction after allergy has incubated. Thereafter the individual is allergic and the next time even a little antigen reaches his skin, he reacts after a period of some 36 hours, with typical allergic vigor. From the time such a flare appears until it reaches its height is a period of about 5 days during which a patient may expect to get worse. More or less abruptly in the uncomplicated case improvement takes place, the disease "breaks," and the patient, miserable as he has been, knows that he is making the change for the better. About three weeks more are then required for the skin to revert to normal.

While the adherence of antigen to the epidermis is firm nevertheless some of it can be picked up by any oily topical application which will smear disease to previously unaffected parts. It is an error to apply any kind of ointment during the early stages of poison ivy dermatitis.

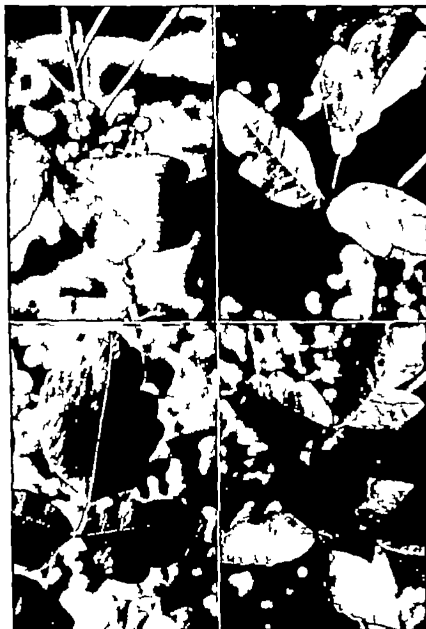

Fig 129 —Poison i y (From W T V ughan and J H Black Practice of Allergy Mosby ed 2, 1948)

Hydrourushiol, a stable crystalline substance to which all are sensitive who are sensitive to poison ivy was synthesized by Mason (JAmChemSoc 67 1538 1945) and quantitatively standardized patch tests were designed by Dunn et al (JID 6 323 1945) Not all human beings exposed to a strong extract of poison ivy develop sensitivity (Simon and Lotspeich JID 2 143 1939) and it is said that individuals with atopic dermatitis cannot be

sensitized If the skin is painted with the extract and then after 12 hours is extirpated, *generalized sensitivity nevertheless develops.* *To prevent systemic* absorption and reaction circumvallation of the painted island must be prompt and must go through to muscle so as to interrupt lymphatic absorption (Landsteiner and Chase JExpM 69 767 1939)

Poison ivy oak, and other variants represent a single polymorphic species with habitat variations (Shelmire JID 4 337 1941)

Many individuals are sensitive both to poison ivy and cashew nut shell liquid (Keil et al. Sc 102 279 1945)

Severe reactions may follow the use of poison ivy antigen, and large or frequent doses may prove dangerous, though French and Halpin (AnnAllergy 1 131 1943) were among those who believed that injections of an alcoholic extract helped their patients. The Council on Pharmacy (J 127 912, 1945) stated that treatment of the acute disease with ivy extract should be discouraged because many patients are made worse and no proof exists that any are helped. Many times I have observed the ill effects (see Goldman Ohio SMJ 38 146 1942) Prophylaxis by antigen injections is of extremely doubtful value (Sompayrac AmJMSc 195 361 1938), a statement true of all kinds of dermatitis venenata, and may cause a violent outbreak. Used in treatment injections caused two cases of acute glomerulonephritis, one of them fatal reported by Shaffer et al (J 146 1570 1951) Four patients with resultant exfoliative dermatitis were presented by Reyer (AnnAllergy 11 91 1953)

Oral desensitization may perhaps be partially successful but antigen must be given by mouth over a long period of time in doses large enough to cause gastrointestinal upset and pruritus ani (Shelmire ADS 44 983 1941) The oral tincture poisoned one patient, causing convulsions and yielding no hyposensitization (Lowenburg J 135 91 1947) Large doses by mouth have not damaged the kidneys in the human, and a rabbit killed with ivy extract showed no kidney damage, reported Howell et al (ADS 70 426 1954)

Hope of the future development of successful parenteral hyposensitization may be seen in the fact that some resistance to subsequent sensitization by hydrourushiol developed following injection into guinea pigs of a hydrourushiol albumin conjugate in experiments by Mason and Lada (JID 22 457 1954)

There is one way and one way only to keep from having ivy dermatitis, and that is to remain out of contact with the stuff

Patients poisoned severely enough by poison ivy to require hospital care were studied by Templeton et al. (JID 8 53 1947) Some developed a temperature of 101° Leukocytosis averaged about 10 000 to 12,000 but reached 16 000 in one case Eosinophilia averaged about 5 to 10% but reached as high as 20% The urine remained normal in these cases.

In the treatment of ivy poisoning the natural course of the disease should be kept in mind. Following contact, there is a latent period of about 36 hours in the allergic patient after which dermatitis starts. Erythema and local swelling of the initial lesions is followed by vesiculation and diffuse swelling with erythema, paroxysmal severe itching and more or less intoxication, reaching a peak on about the fifth day During the first day or two of the rash the patient tolerates his suffering as a rule. When he seeks help he has missed perhaps two nights of sleep and is within 48 hours of the acme of his disease He seeks help at a time when the practitioner needs only to temporize for 2 or 3 days to reach the breaking point of the disease The speed of recovery is not accelerated by any agent applied to the skin (Hoagland et al. J 146 612, 1951)

Treatment therefore is aimed at ameliorating symptoms. Cool showers are comforting and do not spread the antigen although of course the violently irritated skin will not tolerate soap Baths in aluminum acetate a tablespoon

to the tub of cool water are helpful, and soaks in potassium permanganate 5 grains to the gallon. Sedation with aspirin, chloral hydrate phenobarbital or opiates, if needed, should not be withheld. A child in the summertime suffering from not too much dermatitis will enjoy an air-conditioned movie and so pass away several hours of the time required for the skin reaction to complete itself Ointments of all kinds are wrong Antihistamines topically are worthless or injurious in my opinion by mouth they may reduce distress to some extent, Benadryl having a useful sedative effect as well as antiallergic. Phenolated calamine lotion and cold moist poultices are commendable. One may scrub the blisters with gauze wet with alcohol then apply 10% tannic acid for 20 to 30 minutes, repeating these measures as new blisters form with excellent relief though the face may not be so treated, according to Schwartz and Warren (PHRpts 56 1039 1941) although this is not my own recommendation.

For a small area the application of flexible collodion may give comfort (Woodward J 114 2587 1940) but it may also allow secondary infection to luxuriate A paint containing coal tar 10 benzine 20 and acetone 70 was favored by Tulipan. The only treatment appearing to promise actual neutralization of the poison on the skin utilizes the hydrous oxide or carbonate of zirconium which in vitro combines with the hydroxyl groups of urushiol to render it inactive (Cronk and Naumann JLabClinM 37 909 1951) Non toxic on topical application, the chemical in 5% concentration reduced the reaction to patch tests and effected apparently conspicuous benefit in 85% of the patients with ivy poisoning (Cronk ADS 66 282 1952 Strauss and Bruck JID 20 411 1953) The commercial preparation available in 1953 was worthless.

Cortisone and ACTH have been advocated and sometimes apparently help considerably (Falk et al. JID 18 307 1952 Gay and Murgatroid JAllergy 23 215 1952) Fuhrman (JMoMA 51 113 1954) obtained good palliative effects with ACTH and my experience is corroborative

Prevention by use of 10% sodium perborate in a protective ointment base is said to succeed (Schwartz et al.: PHRpts 57 578 1942) Soap will remove only some of the antigen if it is used within 5 minutes of exposure, and saturated aqueous $KMnO_4$ may partially neutralize within 15 minutes, but no effective prophylactic exists believed Howell (ADS 48 373 1943) A vanishing cream freshly prepared containing 2% potassium periodate may serve as a preventative (Schwartz Sci 92 6 1940) Control measures were studied by Goldman (OhioSMJ 40 629 1944) who recommended efforts to eliminate the plant itself, to prevent contact of people with the plant and to render the individuals less susceptible by means of oral hyposensitization.

Ragweed Dermatitis occurs in adults rarely in children. Its features are characteristic the seasonal incidence, annually repeated, during July and August and maximally in September disappearing with the first frost the redness, swelling and itching of the eyelids and inflammation of the exposed surfaces, especially the hands, wrists, ankles and face the exacerbations which occur after hunting weeding or otherwise contacting the plant and the local reaction with distant flare on patch testing The dust of ragweed in grain and flour may serve as an industrial hazard (Jordan et al. ADS 46 721 1942)

Hyposensitization by oral administration of the specific oleoresin is said to be practicable (see J 123 733 1943) It helped some of the patients of Fisher (JID 19 271 1952) all of whose 18 patients reacted positively also to pyrethrum. One may advise people who are severely afflicted to move to a location where ragweed does not grow (Slater et al. OccupatM 2 298 1946)

Eczematous reactivity is caused by the oil, which does not induce an urticarial reaction. Reactivity could not be passively transferred in experiments of Pascher and Sulzberger (ADS 28 223 1933) See Brunsting et

al (J 103 1285 1934 106 1533 1936) Oral desensitization was claimed to be curative in the case of Fisher (ADS 68 592 1953) the patch test reaction underwent reversal Cortisone and ACTH help very little

WEED DERMATITIS was reviewed by Shelmire (J 113 1085 1939) During the first few years the dermatitis is seasonal corresponding closely to the growing season of plants. At the onset the eruption is usually erythematous, scaling and pruritic Exacerbations caused by massive exposures are characterized by increase in erythema swelling and oozing and occasionally by fine vesiculation With seasonal recurrence dermatitis becomes more widespread, owing to increase in sensitivity and manual spread of antigenic oleoresins to areas of the body covered by clothing Thickening of affected areas follows trauma occasioned by protracted scratching and rubbing Seasonal attacks extend further into the winter before completely healing Sooner or later the eruption becomes perennial—extremely *severe during the growing season of* plants with remissions during the winter months. Erythema edema oozing and crusting disappear but pruritic lichenified areas often persist until the new spring weeds return. The sites affected are usually the exposed areas such as the face neck backs of the hands wrists and ankles. The eruption *gradually spreads to involve the forearms and legs. In men the penis and the* anterior surface of the scrotum are often erythematous and thickened. Occasionally patchy areas of dermatitis appear over the trunk and groins. In

Fig 136—Ragweed dermatitis (Sutton J 73 1433 1919)

the more widespread and long-standing cases those areas which are more easily irritated by external agents, such as the face the sides and front of the neck and the flexures, become markedly lichenified. Prolonged healing time is characteristic If patients with weed eczema are hospitalized and contact with vegetation is absolutely avoided disappearance of the eruption usually occurs within from 3 to 6 weeks. If these patients are ambulatory but avoid actual contact with weeds the healing time is frequently prolonged for from 6 weeks to several months, since they continue to come in contact with small amounts of the antigenic oleoresins through contaminated work clothes, tools, pets, udders of cows. Most of the affected persons are farmers and others whose occupations bring them into almost daily contact with vegetation. Each weed contains an ether-soluble, oleoresinous dermatitis-producing fraction and a water-soluble albuminous, hay fever producing fraction. This can be demonstrated by tests on a person in whom dermatitis develops from contact with a specific weed and hay fever or asthma from inhaling its pollen. Patch tests on this person with portions of the antigenic plant will evoke a delayed eczematous reaction If all the dermatitis-producing oleoresin is removed by repeated ether extraction the remaining de-oiled residue which still contains the atopic fraction will then evoke the typical immediate urticarial scratch or intradermal hay fever reaction. Eczema producing oleoresins appear on the leaves stems, and flowers of many weeds as tiny globules of oil,

readily seen with a hand lens. These oleoresins are sticky and adhere tenaciously to the skin or clothing. Contact of sensitized persons directly with the plant or with contaminated intermediary objects is followed by dermatitis. Previous contact is necessary for the development of sensitization to a plant. When weed-sensitive persons were tested on unbroken areas of the skin by the uncovered method many developed an apparent flare-up of the eruption. Focal flare-ups did *not* occur when the same persons were retested and the patch sites were completely covered to prevent manual transference of the oleoresin. All attempts to demonstrate antibodies in blood serums of weed sensitive persons by the Prausnitz Küstner method of passive transfer have failed.

Rubber Dermatitis is commonly due to sulfur monochloride used in the curing process. It can be rendered nonirritant by treatment with an alkali such as 4 per cent sodium hydroxide solution. An accelerator such as paranitrosodimethylaniline may be the irritant (QMN J 113 1245 1939). Mercaptobenzothiazol caused most of the trouble studied by Bonnevie and Marcussen (ActaD-V 25 163 1944). *Rubber and rubber cement are used in shoes,* and may cause dermatitis of the feet (Anderson CalWM 61 65 1944).

An antioxidant in rubber gloves caused depigmentation, but repigmentation eventually occurred when contact had been interrupted (Oliver et al. ADS 42 993 1940). The antioxidant was Agerite alba the monobenzyl ether *of hydroquinone. I saw a Negro physician with a startling white cross on* his back caused by his suspenders. See Zakon and Goldberg (ADS 64 441 1951) on occupational leukoderma; see also Melanotic hypopigmentation; Chloasma treatment.

Rubber gloves may cause troubles for surgeons or housewives. Beneath a *glove* the skin is moist and warm so that bacteria thrive while of course allergy to constituents of the gloves may produce dermatitis. Neoprene gloves (Stanzoil) big and loose using cornstarch on the hands to aid in getting the gloves on, are what I prescribe for protection of housewives. I do not consider the cloth lined gloves so satisfactory. The irritants in rubber gloves are usually sulfur accelerators, antioxidants, plasticizers or dyes (Sidi and Hincky PresseM 62 1305 1954).

See QMN (J 143 1298, 1950) Burgess (CanadMAJ 45 222, 1941). A review of 124 cases of rubber sensitivity was given by Leider et al. (ADS 65 557 1952). Miscellaneous rubber irritations have been reported: rubber adhesives (Blank and Miller J 149 1371 1952) condoms (Ratner J 104 1189 1935) and Clarke (JID 10 47, 1948), spongy powder puffs (Hollander J 113 2271, 1940) eyelash curlers (Curtis ADS 62 282, 1948) gas masks (Petro BMJ 1 631 1942); dress shield (Shepherd and Krall JIndustHyg 2 32, 1920) rubber bands (Morris J 152 1218 1953) a tourniquet of orange colored rubber containing thiobetanaphthol (Schamberg and Flesch JID 21 59 1953).

Irritants met in the manufacture of synthetic rubber and protective and preventive methods were described by Schwartz (J 127 389 1945).

Hair loss due to volatile intermediary polymers of chloroprene was studied by Flesch and Goldstone (Sci 113 126 1951). *Application of such compounds to the skin of experimental animals* produced complete hair loss, with disappearance of follicles and sebaceous glands, in 10 days, the changes disappearing spontaneously in 6 weeks. See Depilation, experimental.

Soaps are alkaline to a greater or lesser degree and are defatting agents, lacking which capacity they could not cleanse. Skins are variable with respect to the amount of soap usage they can withstand. Hands that may tolerate soap twenty times a day in the warm summertime may tolerate only half a dozen washings in winter when the air is dry the skin cool and the sweat and sebaceous secretions diminished. Soaps and detergents are frequently the inciting cause of dermatitis of the hands, the disrupted epidermis then allowing bacterial invasion (Jordon et al J 115 1001 1940).

A technic for comparing the effect of soaps and detergents on the hands of housewives was elaborated by Johnson et al (ADS 68 643, 1953). A skin already inflamed tolerates soap poorly (Goldman J 109 1317 1937). Any soap contains many ingredients, each one of which embodies the modicum of irritant or sensitizing hazard. Tests of the mildness of soaps were discussed by Jordon et al (NYSJM 36 791, 1936) and Kooyman and Snyder (ADS 46 846 194). Many a patient imagines that water alone is the cause of her soap troubles. I counter the argument with a statement of the fact that about three-quarters of a human body is water and a person intolerant of water would indeed be in trouble.

Synthetic Resins were described by Schwartz (JID 6 279 1945) with respect to their manufacture and use hazards and dermatologic connotations. They are irritating in inverse proportion with the completeness of their polymerization. Fully polymerized they are glasslike and inert but in that stage lack the flexibility and adhesive qualities for which they are likely to be designed. The monomers are usually primary irritants.

The principal types are: (1) phenol formaldehyde (furfural phenol formaldehyde, lignin formaldehyde, cashew nut shell liquid formaldehyde; (2) urea aldehyde; (3) an aldehyde condensation series using of simpler chemicals, urea and formaldehyde including sulfonamide resin and melamine; (4) ester gum made of glycerols or glycol with natural resin; (5) alkyd resins, made of glycerols or glycol with polybasic acid or anhydrides such as phthalic or maleic usually used as coatings, the cure completed by drying; (6) modified alkyd combining alkyd resins with Styrene vinyl chloride allyl alcohol or another resin; ( ) polyvinyl resins; (8) acrylate and methacrylates; (9) polystyrene; (10) allyl alcohol and allyl modified alkyd (11) cumarone and indene, made from tar residue; (1) cellulose nitrate and acetate; (13) mixed resins, combining two or more of the preceding; (14) polymerized hexamethylene adipate (Nylon); (15) chlorinated resins, from chlorination of oil balsams and waxes, (16) rubber hydrochloride (Pliofilm). The solid resins are used for making plastic panels knobs, buttons, ornaments bottle caps, dishes, vessels, dentures, garments, gears rubber compounds, adhesive plaster etc. The semisolid resins are used for glues, fillings, adhesives, etc. Solutions of the resins are used for lacquers, varnishes, floor finishes fabric finishes, hair lacquers, etc.

See Lockey (JAllergy 15 198, 1944) Sulzberger (ADS 41 216, 1940) lacquer on bracelet Schwartz et al. (J 115 440 1940) resin lining of cans, Nelson and Fletcher (ADS 44 213, 1941) underwear fabric finish Markuson et al. (IndM 12 383, 1943) resin formol dermatitis QMN (J 131 563 1946) straw hat sizing id (J 132 894 1946) playing card sizing, Peterkin (ADS 58 249 1948) textile dermatitis, Gaul and Underwood (JID 13 1 1949) phenol Formol resin in a medicine Jordon (ADS 62 671 1950) shoe linings containing resins, Hitschmann (ADS 61, 679 1950) vinyl plastic tablecloth Pirila (ActaAllergol 6 82, 1953) resin cellulose worker sensitivity to phenol-formaldehyde resins Smith (AD 1 212, 1955) epoxy resins and amine hardeners, used particularly in aircraft industry.

War Materials.—The occupational hazards in war industries include those of cutting oils rust preventatives (chromates) electroplating welding and soldering defatting agents cleansing agents, explosives and poison gases (Schwartz IndustM 11 457 1942 Downing NEngJM 227 539 1942)

While TNT can cause acute yellow atrophy its principal hazard is a dermatitis which resembles pompholyx. It induces sago-grain vesiculation of the hands and erythema of flexures and sites of friction with clothing (Eddy and Tomb TriStateMJ 14 2751 1942) to which hardening often takes place.

Tetryl (trinitrophenylmethylnitramine) is an explosive in the manufacture of which workers routinely develop dermatitis with itching burning erythema edema epistaxis, sneezing and coughing and a typical yellow staining of the skin and redness of the hair. Most workers undergo hardening and may persist with their work (Schwartz J 125 186 1944) Fulminate causes discrete erythema of hands, forearms and face (Swanson BJD 56 44 1944)

Ammonium nitrate irritates wounds even leading to ulceration and slows healing. Smokeless powder may cause mild conjunctivitis and has been known to provoke urticaria. A clean shop protective clothing and adequate rinsing are useful control measures. Schwartz's protective cream, containing ferrous oxide 1 to 2% in a water miscible base, is helpful to tetryl workers (Witkowski et al J 119 1406 1942) A special soap incorporating 10% potassium sulfite takes off TNT and tetryl, with which it reacts to make a brown stain (Norwood IndustM 12 206 1943)

War chemicals are designed for various purposes and include signaling and obscuring smokes incendiary agents such as magnesium thermite and phosphorus and agents primarily injurious to enemy personnel, such as lachrymators, sternutators, vesicants, pulmonary irritants and systemic toxic substances (Cole et al ADS 39 45 1939) See Norris (J 71 1822 1918 Goldman and Cullen J 114 2200 1940 Sulzberger et al JID 8 365 1947 Prentiss Chemicals in War McGraw Hill 1937)

Mustard gas $(CH_2CH_2Cl)_2S$ is a vesicant, a primary irritant and a sensitizer. The effects are delayed 2 or 3 hours in onset, then there appear

nausea and vomiting burning of the eyes pain in the throat, and hoarse cough, intense conjunctivitis temporarily blinding the victim redness of the skin followed by blistering and brownish staining of the exposed skin and the flexures, and inflammation and necrosis of pulmonic mucosae leading to septic bronchitis and bronchopneumonia. Death results ordinarily only as a result of septic complications and later than the first day Intense exposure may produce gangrene Moist skin is more susceptible than dry skin (Renshaw JID 9 75 1947) Prompt washing with green soap greatly reduces the severity of the lesions. If the chemical is allowed to remain on the skin the burns are deep and severe although comparatively painless at first One may immerse the injured parts in Dakin s solution, the strength being about 0.5 per cent hypochlorous acid or weaker or use applications of wet dressings saturated with the same solution Dichloramine T in chlorozone or chloramine-T in sodium stearate may be used. Greasy dressings are not good. With extensive bulla formation protein loss is consequential and the case is fundamentally like an extensive burn to be managed with regard for plasma replacement shock and secondary infection

Lewisite an arsenical mustardlike poison of great potency produces erythema and bulla formation along with arsenical intoxication. British Anti Lewisite (BAL) is 2,3 dimercaptopropanol which given intramuscularly in an oil solution is an effective antidote

See Lymphoblastomas, nitrogen musta d t eatment; also Davis (J 126 209 1944) Cullumbine and Liddell (JID 68 291, 294, 1946) penetration of a tissue ointment containing chlorine Alexander (Milsurg 101 1 1947), casualties from accidental explosion Sinclair (BMJ 2 290 1948 1 476 1949 1 346, 1950; JID 61 113, 1949) clinical features, treatment, experimental exposure, Cox n (J 122 438, 1943), lewisite eye injuries instantly painful, different from mustard, Sulzberger et al. (ADS 56 10, 1947) BAL vehicle and protective efficacy Keumand (be YBD 1950 p. 391) experimental nitrogen mustard sensitization.

Tear gas (CN) may cause vesicular dermatitis and is a sensitizer (Ingram BJD 54 319 1942) Tear gas burns are treated with weak alkali washes.

Diphenylchlorarsine (DA) is detoxified by chlorine water or KMnO

Radiation injuries of all degrees of severity and of local or general extent may result from atomic fission (see Atomic Energy Injuries)

Prognosis of Dermatitis Venenata.—Elimination of the cause is usually followed by recovery within a few days or weeks. Clinical *restitutio ad integrum* is only apparent hypersensitivity generally remains. Repeated attacks or continued persistence of disease is expected until the cause is successfully escaped from although it is certainly not necessary always to identify the cause in order to escape from it (Sutton ADS 59 30 1949) A known and carefully avoided irritant may be met accidentally or inadvertently

The effort to hyposensitize is not likely to be practicable or helpful. It is seldom the line of attack. But sensitization may disappear if contact is avoided for many months, or the degree of sensitivity may diminish greatly Despite persistent contact with an irritant some persons become hardened to some allergens. This fact surely accounts for a proportion of the practitioner s tedious cures of difficult cases

Allergic react v t sometimes disappears spontaneously When the skin w re tested afte a int rval of 1 t 3 ears duri g whi h an irritant had been avo ded and the ki had remained healthy reactivity t th original rritant wa found to have been lost in some 67% of the patient reported Gomez Orbaneja and Barrientos (abs BMJ 59 1939) Repeating patch test patient known to have been reacti e 20 years previously, Nielsen and Bang (Act D V 34 110 1954) fou d that allergy had been lost by 90% f those previous rritated by perborate washing powde , but by only 18% of those previous reactive t iek L About 25% of those wh voided substances to which they reacted positively neverth less had ee mateu relapses No patient showed an increase of hypersensitivity

Prognosis is materially influenced by treatment for patients and even doctors commonly a l l t the injury by their therapeutic efforts. The insistent urge to put something n a rash is an impulse hard to resist (Gaul J 127: 439 1945)

The outcome in dermatitis venenata is influenced by the nature of the irritant and the social economic and intellectual status of the patient. The aged farmer attached to his land and unable to learn a new way of earning a living and unwilling as well as too poor to move is going to continue to have his ragweed dermatitis, for he and his allergen cannot be separated. Many a patient is so lacking in resourcefulness that he is repeatedly *damaged by the same* irritant even when he knows what it is. A *patient's stupidity if it* exists is a great handicap to himself and to his medical adviser for there is no way to force a repetitiously injured skin to heal.

Complications.—The principal complications of contact dermatitis are (1) secondary medicinal chemical irritation (2) secondary extrinsic bacterial fungous or mixed parasitism (3) dermatitis medicamentosa from antigens given with the hope of hyposensitizing and such drugs as penicillin to combat secondary infection (4) focal infections, which maintain a supply of pathogens residing within the body and so impossible to eliminate by means of topical medication (5) imperfections of nutritional and endocrine balance such that the patient fails to heal himself as a normal person would and (6) combinations of these. All of these complications are commonly not rarely at work. When a dermatologist knows contact dermatitis and its complications, and is adept at unraveling them and dealing with them effectively he has become a master of his work. See Dermatitis of the hands.

The wise choice of external and internal medication is requisite remaining alert to intolerance. Patch tests with proposed medicines may be worth doing (Goodman and Sulzberger ADS 35 944 1937) although I and my patients seldom have the leisure for this and discover our mistakes, when they occur the hard way.

Relative to secondary parasitism, it is to be recognized that once the corneum is disrupted and especially when it is anointed with greases, bacteria which would be transient on normal skin are able to produce disease. This explains the commonplace development of vesicular and spreading staphylococcic dermatitis under the housewife's rings, where detergent accumulated in an unrinsed film, damaged her skin and abetted parasitic invasion. Contact dermatitis of the feet is likely to become infected with fungi already present but of previously trivial pathogenicity. Contact dermatitis of the face and neck is often complicated by the spread of seborrheic dermatitis from the scalp. Contact dermatitis often exacerbates lichen chronicus simplex (q v).

The effect of focal infection is obvious in many cases of occupational or housewives dermatitis of the hands. The worker's skin is irritated by cutting oil or cleansing agent and does not heal when contactants are eliminated. Until the infection of pyorrheic gums or abscessed teeth is eradicated, or the erosion of the cervix uteri is cauterized, dermatitis persists.

Chronic dermatitis in which contactants are an initiating factor are frequently not responsive to therapeutic effort until the overingestion of caffeine is corrected or the underingestion of protein or the inadequacy of the body's own production of thyroxine or estrogenic hormone or until iron, vitamin B (especially B) and liver extract or cortisone or ACTH are given in adequate and effective doses. see Sutton and Ayres (ADS 68 260 1953).

A complication rarer than it used to be yet requiring a word of warning is injury from unwise x ray therapy. For contact dermatitis may under x ray treatment temporarily recede to the delight of the patient only to relapse and receive more treatment repeatedly until disaster has come about.

Chronic dermatitis presumably initially contactant may undergo lichenification and manifest the features of Lichen chronicus simplex (q v) including autoeczematization phenomena. The best explanation seems to lie in the nature of the soil the patient's peculiarities with especial reference to imperfections of nutritional and hormonal balance. Lichenification may occur as one form of response to chronic irritation.

Treatment of Dermatitis Venenata.—The basic principle is to eliminate contact with the irritant. One must give the patient symptomatic relief while the skin heals. *Primary effort is directed at keeping something off the skin, not at putting something on it.* No medicine can force an injured tissue to heal. There need be no haste to identify the cause. Remove all likely causes, relieve the patient, then seek the cause. In selecting palliative medicines, remember that "what you don't put on don't give no trouble" (Davies, BJD 65 388 1953)

If contact has occurred within a few hours but reaction has not as yet set in, then the removal of the irritant from the skin may be possible. Soap and water or alcohol at this time may be urgently needed and successful, whereas, a few hours later this same treatment would do harm. In ivy poisoning allergen may be present even after reaction has set in.

Chemical neutralization of many dermal irritants can be accomplished. Sodium thiosulfate is the antidote for iodine and chromates, sodium bicarbonate for formaldehyde and potassium sulfite soap for TNT for example (Anderson ADS 49 176 1944)

Prevention of contact may be achieved by discarding objects, such as shoes or furs. Often it is difficult to convince a patient that one solitary momentary contact is sufficient to undo the benefits of two weeks of isolation. Sometimes mechanical means (gloves, petrolatum, boots) or chemical means (baths, soaks, detoxifying agents) may be used to interrupt the contact or the sufferer may learn what not to touch, or where not to spread the contact or a workman may be shifted to a different job so that his contacts are different. Chemicals nonirritant to a given worker may be substituted for irritants. Protective ointments are a last choice not a first one in industrial dermatitis, though they encourage the worker to wash. Better measures are a clean tidy shop with equipment designed and processes planned to prevent contact with hazardous chemicals, and ample facilities for use of clean clothing and selected cleansing agents so as to minimize the workman's contacts (Schwartz)

Such solutions are easy comparatively if the allergen is known. But some allergens are so widely disseminated or of such ubiquitous occurrence that avoidance may be difficult. Nitrocellulose wax and sulfonamides are such agents. One may apply talc to keep the skin dry rather than grease which would simply cause particulate irritants to adhere the more. It may be impossible to move the individual from his occupation or to protect him or to desensitize him as in some cases of ragweed dermatitis.

When the allergen is not known, the avoidance of every likely agent is desirable. Unless the patient is considerably distressed by his disease he will not ordinarily be willing to be hospitalized, but hospitalization, with complete control of the environment, separating the patient from his home clothing hair tonic toothpaste, garden, potted plants, sofa cushions and insect powder is an effective way to bring irritation under control.

When the Injurious Agent Is Unknown but the diagnosis of chemical injury by contact is presumed, the technic of cure may be put in algebraic form (Sutton JIlo SMA 44 431 194) Let chemical items a, b, c be all the chemicals capable of injuring the skin; then

$$a \quad b + c \quad = \text{disease}$$

Let no item touch the skin unless it is extremely likely to be harmless. Then

$$a \quad b + c \qquad a - b - c \qquad = 0$$

If all contacts except trustworthy ones are in fact removed, disease will disappear within one or two weeks; rarely is a longer time required. If disease does not steadily fade but does flare after the effort has begun, the implication must be accepted that, while the theory is right, the practice has failed, so that effort must be redoubled to make certain that an unidentified injurious agent or an irritating medicine will be eliminated.

After elimination has succeeded, as attested by the fact of uninterrupted improvement, then, of a, b, c at least one item is injurious. The status of the patient at this moment perhaps one or two weeks after the initial instruction in the avoidance of "everything," is a relieved but disaccommodated status of freedom from disease and isolation from all contacts. The task is half finished, and the patient's skin is now ready

to serve as the testing ground for the item previously eliminated. If contact with all were replaced at once no information would be gained from the subsequent flare. But if a is replaced, and 24 hours later b is applied, and later c according to a written tabulation of items to be tested by schedule, then identification of the poisonous item is straightforward. For on contact with that item the disease flares, usually first evidenced by itching which starts within 4 to 8 hours. If a, b, c are so replaced in their usual form of contact at 24 hour intervals, then classification of a and b and c into sheep and wolves is a matter requiring rarely more than one week of purposeful effort. It is common to relieve the patient in one week and to identify the cause in another two weeks of endeavor accomplishing complete cure in a month or less.

When the patient is first seen, the fact is that patient and doctor cannot know what chemical caused the disease. One does know however that the causative chemical must touch the skin, be it constantly or infrequently. One therefore orders the patient to let nothing touch the skin except those chemicals which are most trustworthy and least open to suspicion. These are the safest and most trustworthy chemicals:

(1) air if it is not contaminated with soap particles, perfume or such
(2) water
(3) petrolatum (not invariably "safe")
(4) cellulose, such as cleansing tissues, cotton or linen uncontaminated with detergent, dye, laundry starch or fabric finish
(5) hands (*which are going to touch an itchy skin, one may be sure*) if they are not contaminated with nail lacquer, cold cream, soap or the like
(6) selected textiles: a textile including garments for day and night wear may be judged "safe" if it was touched repeatedly without harmful effect during a six-month period prior to the onset of dermatitis. Request the patient to sort his garments by this criterion, item by item, into two groups. He wears and touches the "safe" ones only and sets aside the doubtful ones until the time comes for testing items later. A seemingly "safe" garment may be contaminated by cleaning fluid, insect repellent, cologne, etc.

Technic of Elimination of Irritants According to Location of Disease
(Sutton, AD&S 59: 36, 1949)

Instructions vary in cases affecting various parts of the body. If contact dermatitis is limited to the scalp, for example, it would be silly to advise the patient to wear predermatitis shoes. One has also to take into account the ecologic situation. The patient must eat, sleep, be clothed and do certain unavoidable tasks. A wealthy unemployed single woman presents a different problem from the housewife who is economically incapable of hiring help and is responsible for several small children and an ailing mother. One must give instructions which can be carried out. The patient is asked for a maximum of two weeks of intensive effort at eliminating contactants, for this is long enough to do the work and short enough to get cooperation. The patient is caused to understand that elimination means 100 per cent and that 99 per cent is not good enough. Even obtuse patients, if not hopelessly stupid, can be induced to comprehend.

Dermatitis Limited to the Scalp.—Omit medication, shampoo, lacquer, hair tonic, brush, hat, hair pins, perfume, *barber shop or beauty parlor*. See that hands do not convey an irritant, such as nail lacquer. Cleanse scalp and hair by prolonged spraying or showering with tap water (the "fire hose treatment").

Dermatitis Limited to the Face.—Omit medication, every toilet article and cosmetic, soap, dentifrice, mouthwash and eyewash. See that hands do not convey an irritant to the face. Cleanse with water and petrolatum. Brush teeth with baking soda. Shave with electric shaver. Wash dishes with a selected cleanser so as not to contaminate the hands. Eliminate textile, scalp and neck contactants.

Dermatitis Limited to the Neck.—Omit medication, every toilet article and cosmetic, soap, perfume, and jewelry which may touch the neck. Eliminate textile and face contactants. See that hands do not convey an irritant to the neck. Cleanse with water and liquid petrolatum.

Dermatitis Limited to the Region of the Trunk.—Omit medication, every toilet article, soap and cosmetic which touches the trunk. Control textile and neck contactants and those conveyed by hands. Check metal fasteners, menstrual accouterments, contraceptives, mat hes, dress shields, bust pads, cleansing or antiseptic agents applied to the bathtub, rubber pad and hot water bottles, insecticides and cleaning fluid or laundry starch (which contains borax) in textiles which might explain exceptions if safety of the

garment were judged solely by its age. Cleanse with water. Prohibit use of water softening agents. Use corn starch for powder and baking soda for underarm deodorant. Use petrolatum on babies, not olive oil or antiseptic oils.

DERMATITIS LIMITED TO FEET AND LEGS.—Omit medication, soap, depilatory and leg makeup. Control textile contactants and those conveyed by hands. Judge shoes and slippers by the same criteria as textiles. Check for weeds, irritant dusts, floor waxes, paints and cleansers. Women rarely possess safe old stockings; they may risk the purchase of silk or cotton hose, wear bobby sox or go bare-legged. Soap splashed from the washing machine may irritate legs. Nail lacquer is sometimes applied to runs in stockings. Presumably safe, old shoes may be contaminated with medication. One may buy a pair of new shoes and wear them exclusively; either they are harmless and the foot disease fades, or they are not and the feet get steadily worse so that security of the foot gear may be judged positively. Launder hose with mild toilet soap.

DERMATITIS LIMITED TO DISTAL UPPER EXTREMITY.—Omit medication and all cosmetic and toilet articles which may touch the hands. Control face and scalp contactants, for these are applied with the hands and hair tonic, cold cream or dentifrice may irritate hands without irritating the head. Cleanse hands and body (hands must hold the soap to wash other parts) only with water and petrolatum. Wash dishes with hot water only or delegate the job without drying dishes which have been washed by others. The patient should wash her babies only with water for the two-week period. Avoid baby oil. Stop baking (see Food handlers). Omit every household cleansing and polishing agent and gloves, including rubber gloves. Judge purses by criteria of safe textiles. The usual irritant of hand are bleaching agent and toilet and cosmetic articles. However paints, paint remover, plants, sprays, materials for all sorts of needlework, chrome nickel and lacquered fasteners, glue, cement, gewgaws and gadgets, chemicals met in hobby, business or recreation—all are open to suspicion. Employees may have to be taken off the job in order to eliminate the unknown contactant.

Cases of dermatitis of the hand (q.v.) are harder to solve than others, but the reason for this proves usually to be that the dermatitis is not purely contactant. Few cases of dermatitis of the hand of two or more months duration are of uncomplicated contact dermatitis. Occlusive dressings may be used, of course, and, if improvement is not obtained in a week, complicating factors may be assumed to exist.

DERMATITIS AFFECTING THE SKIN IN MORE THAN ONE OF THE LISTED LIMITED REGIONS.—Since any distribution is a sum of some combination of the limited distributions already considered separately, add together the elimination efforts for each region involved.

ILLUSTRATIVE HYPOTHETICAL CASE PRESENTATION.—June 1. Mrs. X, 30-year old white woman, requests medical service because of itchy eyelids. The skin of the lid is wrinkled, leathery, flaky, excoriated, but not exudative. Disease has existed with no great change in intensity and no conspicuous flares for 3 years. There is no other disease or area of dermatitis. The interview:

Madam, your skin disease is caused by some chemical which touches your eyelids. Germs are not concerned, and your interior food or function, is not pertinent. No medicine exists which will make your eyelids heal. You will be cured, and you can be cured only by avoiding that which on touching your skin poisons it. You and I, as we sit here at this moment, do not know what poisons you.

Then, doctor, how can I escape the poison?

If nothing touches your face except chemicals which are harmless, then surely your disease must fade and disappear. In order to eliminate all contacts except the probably harmless ones, you will be put to the trouble of eliminating many chemicals you didn't need to—we shall eventually know which chemicals are which—but for the next week, I want nothing to touch your face except (1) air (you can't avoid it, but you don't need to contaminate it by scattering soap powders indiscriminately); (2) water (it is harmless—things in water are often harmful, but water is not); (3) petrolatum (I have seen only people in 25 years of dermatologic practice whose skin would not tolerate petrolatum); (4) old cotton or linen garments, towels, sheets, and pillowslips (do not allow residual soap, starch, bluing or bleach to remain in these please; but the cell loose of which they are composed is trustworthy); (5) hands (which must be free from lotions, creams, nail lacquer, etc.); and finally (6) the utensils and foods you use in eating (silver and china are harmless, and you've got to eat).

My face may be touched by nothing but air, water, petrolatum, cotton or linen, and uncontaminated hands? I may eat and drink what I wish? All right, doctor, but how do I wash, or clean my teeth or relieve my itching?

I have listed the things you may touch, a short positive list. I have not tried to list the multitudinous things you may not touch for the negative list is not short and is not determinate. If I don't say touch it, don't. Wash with water and dry with a towel. You won't be as clean as you like, but you'll be as clean as you need to be. Cleanse your teeth with table salt or baking soda—I can trust them—after all, you'll only have to live this way for a week or so. Wash your hair with Prell (I have seldom caught it doing harm) and do this right away, because cosmetic articles on hair especially lacquer often cause dermatitis. Use Marcelle lipstick and powder if you must,

for they are designed to be hypoallergenic; you may use the lipstick for rouge and do not need to buy a lot of things. Do not throw away your old cosmetics, which are expensive, for we do not know a yet what you will have to discard or avoid—we shall find that out later Instead of a y kind of cold cream use mineral oil (not baby oil or olive oil) and petrolatum. These are not so ba l a lubricants, you will fin l

As for relief of itching use just enough petrolatum to keep the skin from feeling as if it would crack, and lay on your itchy lids a towel wrung out in cold water Petrolatum would *not* be suitable if your trouble were poison ivy; it would spread the irritant around. Apply the cold compresses for as long as you desire any time you desire. They will relieve you a well a any medication we could choose and cannot harm you. Among the many things you may *not* touch are soaps of any kind, rouge creams, perfumes, shampoo medicines hand lotion, and nail lacquer I think it was Balzac who said A woman smells best when she doesn t smell at all. Do not put any medicine in your ears, eyes, nose or mouth or on your skin unless I know what it is and approve of it

What makes me get well, doctor if I do nothing but avoid a poison?

An injured ski i analogou to an injured bone In treating a broken bone, the physician basically puts its ends together and leaves it alone It heals itself *Th ski will heal when nothi g interferes with its heali g* In the case of the fracture the patient requires morphine perhaps or aspirin, but medicines do not cure him. They enable him to live more or less comfortably through the period of time that healing requires. The cold compresses and petrolatum will do for you what the sedatives do for the patient with the broken bone

June 8 Mrs X returns, stating that her eyelid did not change much for the first 3 days, then improved steadily There wa no flare itching became less and the cold compresses a d petrolatum proved comforting Impro ement is visible

We may j dge the doctor say that you have successfully avoided the poison, although this has inconvenienced you to some extent. We must now arrange for you to live normally instead of livi g in chemical isolation. Of the many things you have been de ied what would you like to put on your face first?

Soap then my rouge powder a d cold cream. If I could use these I d be satisfied.

We must plan these contacts so that if any one of them flares your disease we will recognize it. Write down a list of items to test and test one each day designating of course the particula brand of t let article you propose to try Apply one item each day in the manner i which you ordinarily apply it Let me see you when your disease flares. Do you understand you instructions?

Perfectly doctor This seems almost too easy Other physicians gave me x ray treatments, intravenous and other shot , a cabi etful of expensive prescriptions the alphabet of vitamins and quite a series of food allergy tests. Why for two years, before I met you I ate no eggplant o kohlrabi whatever and nevertheless itched furiously

The therapeutic technic of othe physician is not a proper subject for comment but it may be said that not all human beings are guided exclusively by crystalline in tellectual function. I myself have prescribed a blood purifier; I was weary at the time and the patient asked for it Follow your instructions, and let me hear from you.

June 1.. Mrs X returns, he lids swollen, red and itchy She says, Doctor I used my favorite soap the day of ou last i terview rouge the ext day a d powd the e t without trouble But last n ght I ppl ed cold cream a I retired. This morning my lids were again swollen and itchy

You and I now know that thi bra d of cold cream poisons you the physicia explains. You will get ove this flare in a few days. Use the cold water compresses as you did before. When you have cleared up try Bla k s brand of cold cream. The Journal accepts this firm advertizing which claims that few people are allergic to its p oducts. Seldom indeed do I find a person being poisoned by more than one chemical, although it i not rare for an indi idual to meet his poison i several different guises. T ke for example Mrs Z whose poison wa n trocellulose. A few years ago, he spectacle frames, th handles of her bru h a d comb and her patent leathe slippers and handbag each poisoned her She and I finally worked that problem out, but she late flared after handling p g pong balls A f you, howev I surmise that your troubles are over

Doctor my appreciation knows no bounds.

You cure was accompl hed, madam by prescribing nothing fo you, with meticlous care

Difficulties occur when contacts believed to have been eliminated never theless are made A woman with itchy eyelids, who cooperated intelligently experienced a flare-up after playing cards the sizing of the washable cards was carried to the face by the fingers, previously imagined to be not con taminated A patient with dermatitis of the face from menthol experienced a flare up when she sucked certain cough drops. A man with dermatitis of the dorsum of the left hand was intolerant of the dentifrice with which he cleansed his dentures which he held in the left hand and rinsed with the right

before returning them to his mouth. One must be alert to chemicals put into ears, eyes, nose mouth rectum or vagina The expert is cognizant of all the things that persons of various ages and both sexes do and touch

Difficulties occur when the contactant is an occupational one for the patient if he is to be on the job at all must make contact with many possibly harmful chemicals. The disease in such patients can be proved occupational by (1) excluding all contactants except occupational, (2) observing that the disease continues and then (3) removing the patient from the job and finding that the disease disappears. *Prior to returning the patient to his job patch tests with chemicals met occupationally are necessary*

I do not say that patch testing may be wholly dispensed with but a great deal of patch testing may be neglected and the practice of dermatology may thereby be improved in efficiency

SKIN TESTS are discussed in the pages devoted to diagnosis. One use of them is to pass the time required for the patient to heal (Gaul: J 1*7: 439 1945) I do not emphatically decry the use of skin tests for investigational purposes. While patch tests would have to be used to determine the particular noxious ingredient of a face cream, another cream can be substituted successfully in all probability so that neither the patient nor the physician ever learns what chemical substance was in fact harmful, for it was neither necessary nor expedient to find out Indeed I am willing to cure a patient without ever knowing what was the matter with him, exactly

FAILURES occur when the disease is not pure contact dermatitis. Secondary infection must be recognized and dealt with by means of nonirritating antiseptics. Primary infections may simulate contact dermatitis. Foci of infection may profoundly influence what starts as contact disease In chronic dermatitis of hands or feet especially the elimination of contactants combined with the elimination of focal infection comprises an attack which is often curative Atopic dermatitis does not yield to elimination of contactants, although such elimination contributes to the patient s welfare

Allergic dermatitis may persist for days or even weeks after the cause has been removed. It is during such a refractory period that a physician, impatient for benefit in a case of distressing dermatitis of unknown external cause changes from one medicine to another in the futile expectation of finding something that will bring about healing In shifting from one application to another great risk is run of applying a medicine to which the patient is sensitive One does best by prescribing the simplest and blandest of agents and adhering to their use if one is sure that they do no harm The evils of overtreatment have been stressed by many authors, notably Gaul and Underwood (IndianaSMAJ 40 17 1935) Exfoliative dermatitis has resulted from the application of ammoniated mercury ointment to some minor inflammation with the development of spreading mercurial dermatitis not recognized as such and treated with more mercury

Explanations of why occupational cases may fail to clear include according to Morris (ArchIndustHyg 10 43 1954) failure to follow advice overtreatment, failure of hardening incorrect diagnosis, bacterial infection dermatitis medicamentosa tinea of the feet inadvertent contact with the irritant nervous upset physical trauma stupidity in following treatment advised, *preference of patient for compensation rather than cure* flares incited by patch testing atopic background, accentuation of pre-existing disease focus of infection avitaminosis Morris called attention to the cures achieved by the lump sum settlement, the monetary pay-off constituting a magic green salve

OTHER THERAPEUTIC MEASURES.—X ray therapy desensitizes locally This is, hypothetically due to destruction of fixed cellular elements responsible for sessile antibodies. Reactivity generally returns within from 1 to 3 weeks after this nonspecific desensitization. If the same dermatitis is treated time after time with x rays, the eventual result is an x ray burn. The dermatitis produced by dinitrochlorobenzene was not influenced by x ray therapy in the experiments of Kemp and Kligman (JID 23 423 1954)

Benadryl and other antihistamines are helpful when an urticarial element is prominent in the reaction of the patient to the poison, but in fairly pure epidermitis these do not allay (Blumenthal and Bostenberg MAnnDC 16 86 1947) Topically they are hazardous often irritating

ACTH and cortisone may be helpful in the palliation of severe cases especially if the dermal reaction is considerable (see Poison Ivy)

Sodium thiosulfate intravenously 0.5 Gm the first day and 1 0 Gm the second third fifth and seventh days, was said by Ormsby (MichSMSJ 37 135 1938) to aid in overcoming hypersensitivity I doubt its efficacy

The simplest of medicines are satisfactory In acute dermatitis of contact origin, the skin may be freed of previously applied greases by means of benzine White petroleum jelly is put on to protect denuded nerve endings, and soft clean towels, wet with plain cool water are superimposed This is comforting and it is bland The patient is denied coffee and may be given aspirin 5 grains every three hours unless intolerance occurs. What the tired itching patient wants is respite from bedevilment by his skin then he will sleep Compresses should be moist not dripping and cool and should act like a blotter in absorbing exudate rather than rendering the skin soggy and macerated They should be left in place not longer than half an hour but may be repeated as frequently as the patient desires. If they are medicated they should not be allowed to dry on the skin, for as the water evaporates the concentration of solute increases until it may irritate They should not be covered with an impervious wrapping Aluminum acetate half a level teaspoonful to a quart of water made up in a milk bottle and poured from that onto the towel is convenient and satisfactory

Barrier creams may be of water repellent or oil repellent types. Several commercial preparations of elegance and excellence are readily obtainable Such an innunction can serve as an invisible glove which is applied prior to exposure of the skin to the irritant and which washes off readily after exposure Of greasy agents for repelling water solutions petrolatum is the best Mason in 1946 showed me his technic for testing barrier effectiveness of ointments and proved that lanolin and petrolatum are both impenetrable in a layer 1/5000th inch thick while the particles in zinc paste render it more pervious than simple petrolatum. See Sadler and Marriott (BMJ 2 769 1946) Schwartz et al (Occupational Diseases, Lea & Febiger 1947 p 100) complete with formulas. A silicone preparation with nitrocellulose in it to prevents its washing off has evinced some value (Smith et al. JID 21 111 1953 Covicone) Silicone protective creams tried by Morris (ArchIndustHyg 9 104 1954) proved unsatisfactory

Treatment of Complications obviously presupposes the recognition of them When a patient gets worse instead of better the first thoughts are concerned with failure to escape from injurious agents and possible irritation by medicines. Bacterial secondary infection (see Infectious Eczematoid Dermatitis) should be fairly evident The usual invaders are hemolytic *Staph aureus* or hemolytic streptococci or both When *B proteus* or *Ps aeruginosa* enter in, difficulties may be considerable for these are sometimes hard to get rid of. While in my practice the mainstays of treatment of bacterial infection are potassium permanganate soaks, tetracycline ointment or Vioform Cream incorporating Chloromycetin 200 mg per ounce I also often use antibiotics by mouth seldom by injection. It is highly advantageous to have available reliable laboratory assistance for antibiotic sensitivity tests.

When topical and internal antibiotics fail, then especially is one suspicious of the presence of significant systemic derangement It is typical in a case of focal infection for injections of penicillin to help the patient only temporarily Common foci are pyorrhea, dead teeth cervical erosion and cystocele I am dependent on competent dental gynecologic and urologic consultants when I am responsible for the care of a difficult patient See Chronic Dermatitis of Undetermined Cause (p 879)

The errors of metabolism which most often interfere with a patient's ability to heal are excess of caffeine and inadequacy of protein. Many a patient slow to respond to medical effort is anemic and one likes to know the red cell count hemoglobin, color index and blood serum total protein. Daily in managing chronic dermatitis of which contactant irritation comprises an etiologic factor but not the whole explanation I endeavor to correct metabolic deficiencies using high protein diet iron and vitamin preparations, injections of liver concentrate or of vitamin B_{12} (presently I am of the notion that 600 micrograms of B_{12} intramuscularly helps almost anything!) and thyroid, estrogen or cortisone when indicated. Any individual deficient in thyroid or estrogen is better off for receiving a correct dose of it. Cortisone is often extremely helpful in palliating difficult stages of dermatitis of mixed etiology particularly when lichenification and autoeczematization are factors.

Seborrheic dermatitis (q v) can be attacked successfully by treating the scalp improving the patient's nutritional and hormonal balance and using topically a ½ or 1% coal tar ointment.

Secondary infection with fungi is due usually to a trichophyton from the feet or toenails, or to monilia. The combination of fungus infection secondary infection with bacteria and injury by chemicals is by no means a rare one. Potassium permanganate tetracycline 2% sulfur in Vioform Cream the control of contactants gentle débridement rest elevation drying in air attention to foci and perhaps cortisone are the usual therapy.

Fatigue exerts a deleterious influence and nothing is so exhausting as nervous tension and anxiety. Patients with extensive dermatitis need sedation, sympathy and psychotherapy. Hospitalization is not a last resort but should be used without hesitation for the benefits are likely to be economical, in the long run. A patient in hospital is not only segregated from unknown contactants but obtains respite from responsibility and pressure and generally does well.

POMPHOLYX

Symptoms.—Pompholyx is a variously caused syndrome manifested by vesiculation of the thick epidermis of hands and feet. Vesicles characteristically *appear in crops, are deeply seated and symmetrically located and* usually affect the fingers and palms. At a given time the vesicles are of more or less the same size. Representative of epidermitis (q v) and minute in their early development, they may progress in severity even to an extreme degree. The disease usually involutes without exudation after a few days, and exfoliation follows, often taking the form of tiny expanding circular scaling lesions. Itching is intense during the active stage. Secondary infection may occur especially when salves are used in treatment. Recurrent attacks are typical.

Whatever the chemical may be that causes vesiculation of the thickest epidermis and the clinical syndrome of pompholyx its prolonged and extreme effect, when this occurs, is to damage thin epidermis also so that there develop macular and edematous erythema and eczematous dermatitis which spreads symmetrically on the arms, the sides of the neck and face and the eyelids. The clinician would then give the disease a different name.

Etiology.—Pompholyx is a cutaneous reaction representing epithelial damage. Many cases are straightforward dermatitis venenata while others are dermatophytids, responsive to suitable treatment. Dermatophytosis of the feet, *onychomycosis* and *vaginal moniliasis* are causes easy to discover. Muende (BJD 46 479 1934) estimated that half the cases are secondary to dermatophytosis elsewhere. The lesions of pompholyx are free from ordinary parasites unless secondarily infected. They seem to depend for their existence on deleterious chemicals either directly contacted or absorbed from the metabolism of parasites located at a distance.

B endoperasiticus was identified in cultures from unbroken vesicles and named by Benedek, who undertook to prove its etiologic relation to pompholyx (UCutRev 60: 467 1946) and prepared from it a vaccine which he believed therapeutically valuable a view confirmed by Schuster (NoWM 46 298 1947). See Sutton and Ayres (ADS 69: 208, 1953)

Fig 131 —Pompholyx. Note fine vesiculation of dorsa and sides of distal digital skin.
Fig 132—Pompholyx secondary to vesicular dermatomycosis of feet

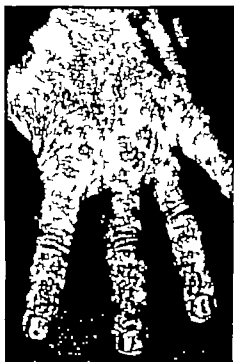

Fig. 133 —Pompholyx. Compare epidermophytid of Peck (ADS 22 40 1930)
Fig 134 —Pompholyx, histopathology intra-epithelial vesiculation of palmar skin.

Trichophytin or ragweed injections in overdosage may provoke attacks in sensitive persons. Hyperhidrotic individuals with psychosomatic difficulties are especially subject to pompholyx, of which not all cases are fully understood. In ʺ selected psychoneurotic patients (Goldman: MBullUCincinnati 8: 79 1941) mecholyl injections provoked exacerbations, while various other agents that act on the vegetative nervous system did not influence the disease.

Histologically the vesicular lesions are not related to the sweat ducts or pores saving by coincidence. Sutton (J 61: 40 1913) showed, confirmed by Shelley (ADS 65: 314 1953) among others, neither pilocarpin nor atropine influenced the quantity of vesicle fluid, which did not contain iodine after iodide was given by mouth. The sweat ducts in f et long withstand the processes which affect adjacent prickle cells (Devine: BJD 64: 393, 1952). Sweat retention is not the explanation (Robinson: ArchDerm 3: 59 1877; Wilson and Thackray: BJD 64 402, 1952. Ascher: BJD 67: 9 1955)

Fig. 136.—Pompholyx, showing superficial intraepithelial vesiculation. (Miller ADS 56 678, 1947.)

Pompholyx-like eruptions may be classified (Callaway and Barefoot NCarolMJ 1 547 1940) as (1) mycotic, (2) allergic from contact fungi, or bacteria, (3) idiopathic, (4) toxic from food or drug, (5) chronic infectious dermatitis, and (6) associated with general skin diseases. Becker (NebrSMJ 26 419 1941) attributed many cases to functional perversion of the sense of fatigue. Davidson and Birt (CanadMAJ 49 97 1943) limited Hutchinson's name cheiropompholyx to those cases which are not contactant or dermatophytid, and stressed the fact that the rash is more common in hot weather. I think the disease is sometimes atopic (see p. 884).

Diagnosis.—The deep-seated vesicular character of the lesions, their symmetric distribution and their occurrence in crops are distinctive. Demonstrable parasites are absent.

Treatment.—Rest, elimination of contactants, and symptomatic relief are essential. Mild, soothing astringents, such as cold compresses of 1:500 aqueous aluminum acetate or 1:5000 potassium permanganate may be prescribed. Some patients obtain temporary relief by running extremely hot water over their hands. The lesions may be incised and drained. Suitable treatment must be directed against focal infection, mycotic or bacterial. Roentgen therapy is effective in fractional doses but must be prescribed with caution against overdosage. Drugs which inhibit hyperhidrosis, such as Banthine and Prantal, have considerable value in some cases. Cortisone 25 mg. b.i.d. by mouth, is likely to be effectively palliative.

DRUG ERUPTIONS

Dermatitis Medicamentosa is applicable to any eruption due to absorption of medicinal chemicals, differentiating contact dermatitis caused by medicinal agents (q v) One must distinguish intoxication from intolerance The latter comprises symptoms not normally produced by mere overdosage Drug eruptions may simulate almost any dermatosis, and careful investigation is likely to be necessary to identify puzzling cases. The lesions are likely to be *widely and symmetrically distributed and sudden* in onset and recurrence Drug eruptions result from administration of chemicals by ingestion injection, inhalation or inunction, or from absorption of them from their application to nasal vaginal anal, vesical or conjunctival mucosae or wounds, or through the pulmonary system milk, or placenta Sulzberger (Dermatologic Allergy) noted Clinical manifestations include eruptions which are erythematous, morbilliform scarlatiniform eczematous, exfoliative urticarial, purpuric gangrenous, keratotic vegetative acneiform furunculoid, dyshidrotic hyperpigmentary or depigmentary nodular or sclerodermatous, or which simulate erythema multiforme pityriasis rosea lichen planus herpes zoster erysipelas, or lupus erythematosus. They may even include alopecia or pruritus without a rush Aplastic anemia and death are sometimes caused by medicines.

Etiology.—The disease is usually accredited to idiosyncrasy which may persist indefinitely See classification of allergic phenomena drug allergy Abramowitz (NYSJM 37 128 1937) observed that passive transfer is sometimes possible Arsenical dermatitis may commence as Stokes and Kulchar (BJD 46 134 1934) noted at a dermatophytic focus.

The disease is not common. It occurred in about 1 of 2,000 patients seen at the University of Kansas Hospital (JKansMS 38 365 1937) The large majority and by far the most serious cases, were those due to the arsenical antisyphilitic remedies, and the fatalities which occurred were among these

Eruptions may be produced by minute amounts of a drug though in most persons the drug provokes no rash even in *large* doses. Drug eruptions recur when the same or perhaps when a chemically related substance is given. Identical eruptions may be provoked by dissimilar drugs. One drug may induce different manifestations in different persons. Specificity of drug sensitivity may be demonstrable Some drugs experimentally sensitize human and other animal skins. Drugs act like allergens in inducing diseases which exhibit incubation periods and subsequently altered reactivity to reexposure and variations in host susceptibility are notable Tuberculoid structure is rarely if ever produced however *Reagins usually* cannot be demonstrated Eczematous eruption may appear following internal administration of a drug after contact dermatitis has been produced by it Drugs may produce photosensitization, vasomotor disturbances nervous and visceral manifestations.

Mechanism product e f drug reactions were carefully considered by Hostenberg and Webster (J 154 221 1954) who listed (1) pharmacologic reactions to overdosage, exemplified by erythema *from* nicoti e acid or argyria from silver salts; ( ) enzymatic terference as acrodynia from mercury or light sensitivity from sulfonamide (3) idiosyncrasy as fungating lesions from iodide; (4) allergy exemplified by acute urti ria from penicillin chronic polyarteritis from sulfonamide or eczema from arsphenam e (5) Shwartzman phenomenon i ba Ht rate purpura (6) Herxheim phenomenon (7) ecologi effects a when monil asis follows Aureomycin and (8) biotropic ffects, f erythema nodosum from sulfathiazole These authors co sidered allergy o ly one mech nism of se ral ca sing d rmatitis medicamentosa, which by th ir semantics mean any derm tosis ca sed by pharmaceutical i ternally admi istered.

Arterial embolism when an oil emulsion i injected erroneously prod ces a typical syndrome of marmoraceous lividity soo *followed* by gangrene (Sulzberger nd Baer AmJS 4 60 1940) Intravenous inject on of such a medicine as bismuth subsalicylate in oil result in pulmo ary embolism and death. *Embolism followi g the se of sclerosing* agents n treatment of varicose veins is rare (Shelley J 112 1792, 1939)

Diagnosis is established if the eruption disappears when the drug is discontinued and reappears if a small dose is given experimentally Recognition

is facilitated by suspicion history and knowledge of the various potentialities of drugs for producing disease

Treatment.—Recognition of the cause and its elimination are essential. When one of several drugs might be the agent stop all of them The wider the assortment of drugs a patient receives, the less the likelihood of catastrophe resulting from their withdrawal. If gastric lavage or catharsis will remove unabsorbed chemicals, it is indicated BAL has utility in the metal poisonings, especially the arsenical ones. Silver pigmentation arsenical keratoses, and severe arsenical dermatitis became less common as wisdom in the use of medicines became more widespread and as the usefulness of these now old fashioned remedies diminished when better ones were devised.

Individual idiosyncrasies are to a considerable extent individually treated. The antihistaminics are palliative in urticarial cases. ACTH and cortisone are frequently of great value Calcium intravenously helps the painful erythema nodosum sometimes caused by penicillin but it rarely helps any other drug eruption. From the standpoint of the patient there is not much difference between drug allergy and poisoning

Overenthusiastic treatment of comparatively innocuous infections, so that dermatitis results, has no justification. Permanent relief lies in complete avoidance of the provocative agent

See Sulzberger and Wise (ADS 8: 441, 1933) eczematous drug rashes, allergen reaching skin from without or within; Wise and Sulzberger (PaMJ 37 973, 1934), dermatophytid and drug eruptions; Cipollaro (N YMonth 63 477 1936) dermatitis from drugs Sherman (J 140 447 1949) generalities; Stokes et al. (AmJMSci 218 440, 1949) survey and bibliography; Goldman (ConnSMJ 13 4 0, 1949) antibiotics Hermann (AmJMSci 218 446, 1949), recent literature; Carr (NEngJM 245 892, 935, 1951) review Flaxman (J 147 377, 1951) drug fatalities, 107 found in period 1947 1950, not all allergic; Percival (BMJ 1 809 1951), refresher review Peterkin (EdinMJ 58 41 1951), common examples Berkowitz et al (AnnAllergy 11: 561 1953) in pediatrics; Alexander (Reactions With Drug Therapy Saunders, 1955); Brown (J 157 814 1955) problems of drug allergy

TABULATION OF ILL EFFECTS OF VARIOUS MEDICINES

Acetanilide.—Generalized erythema. Methemoglobinemia.

Acetarsone.—See Arsphenamines.

ACTH.—Cushing's syndrome; hyperpigmentation acneiform eruptions, hirsutism, moon face striae atrophicae (Behrman and Goodman: J 144: 18 1950) Androgenic effects, including acne, seborrhea and seborrheic dermatitis (Brunner et al.: JID 16: 201 1951) Sodium retention. Urticaria (Feinberg et al.: J 147: 40 1951) ACTH acne lesions are small papules and pustules, erythematous and sore, monomorphous on skin that is not greasy disappear without scarring on withdrawal of drug (Sullivan: Trans ADA 1955) Anaphylactic death case (Hill and Swinburn Lancet 1: 1 1 1954)

Acetazolamide (Diamox).—Agranulocytosis (Pearson et al.: J 157: 339 1955)

Adrenalin.—Urticaria, possibly from chlorbutanol (Rubin: J 138: 626, 1948)

Alfalfa Seed Infusion.—Itching of forearms and face (Kaufman: J 155: 1059 1954)

Alpha Methopterin.—Exfoliative dermatitis, oral hemorrhages and ulcers (Meyer et al.: CaRes 9: 606, 1949)

Amidopyrine.—Neutropenia, urticaria, fixed eruption, bullae, agranulocytosis. See Unger (JAllergy 8 76, 1931); Bott et al. (AIntM 64: 26 1939) Ritchie and Spille (ADS 59: 437 1949); Discombe (BMJ 1 1270 1953)

Aminopterin.—Oral hemorrhage and ulceration alopecia leukopenia, folic acid antagonism, countered by administration of citrovorum factor (Schoenbach et al.: J 144 1558 1950)

Amphetamine (Benzedrine).—Rash resembling atopic dermatitis (Kanvar et al.: J 122: 1078, 1943) denied by Epstein (J 123: 54 1943) Causes coldness, blanching of extremities, erythema of neck and shoulders, perspiration (Wand: J 110 206 1938) It promotes stoeczematization in lichen chronicus simplex

Androgenic Substances.—Acneiform eruptions, hirsutism, enlargement of clitoris, and diminution in size of breast are physiologic effects of overdosage The acne is itchy and more common in women. See Greenhill and Freed (J 112: 1573, 1939); Geist and Salmon (J 117: 2207 1941) Acne from androgens is itchy; compare that from ACTH

Antabuse.—Tetraethylthiuram disulfide causes redness and burning of face and conjunctivae, rapid pulse pounding heart headache anxiety vomiting (Carver: BMJ 2 406, 1949) Acne (Barefoot J 147 1653 1951)

Antibiotics.—See individual antibiotics by name also moniliasis, etiology

Antihistamine Drugs.—Side reactions involving various systems including cutaneous have been reported, and rare fatal reactions were stressed by Wyngaarden and Seevers (J 145: 277 1951) Hemolytic anemia (Crumbley: J 143: 726, 1950) Common reactions: drowsiness, dizziness, headache insomnia, nervousness, nausea, impaired mental reaction. Fever cerebral edema, convulsions and nephritis are rarer Benadryl has caused urticaria

and eczema (Epstein: JID 1 : 161 1949); purpura (Deanie pers. comm.); dry mouth, ataxia, facial edema, sore tongue tinnitus (Geiger et al. J 133 392, 1947) Thephorin caused urinary retention (Uhle and Knoch: J 146 1319 1951) Diatrin and other anti histamines with benzamine linkage structure have caused agranulocytosis (Drake: J 14 4 1950) Pyribenzamine caused agranulocytosis (Blanton and Owens J 134: 454 194) urticaria (London and Moody: JID 13: 17 1949; Pratt: ADS 61: 667, 1950) rashes resembling pityriasis rosea and lichenoid dermatitis (Epstein: J 134: 782, 1947)

Antilepro1.—Chaulmoogra oil caused seborrheic dermatitis, fever and papular eruption (Brinkhaus: abs ADS 40 81, 1939)

Antimony.—Thiomalate for bladder schistosomiasis caused exfoliative dermatitis responsive to BAL (Ritter: La cet 1: 55, 1950) Neostam caused urticaria (Mathieson and Watson: J 11 209 1930)

Fig. 136.—Antipyrene-fixed eruption on dorsum f hand and knee region (Dr Robert V Andrade.)

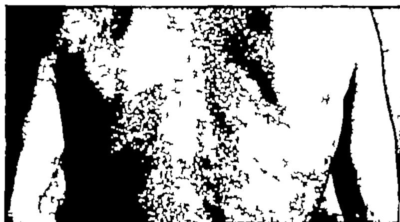

Fig. 137.—Arsenical pigmentation. (Drs. Fordyce and Ma Kee)

Antipyrine.—Usually morbilliform may be urticarial, scarlatiniform, or even bullous. Ma vol e muc membranes. Moderate itching Fixed eruption.

Antitoxin.—Immediate reactions sweating erythema, pruritus, urticaria, cough. Delayed reaction ccelerated serum disease n from 6 hours to 5 days. Serum sickness: urt caria, erythema, joint pains, malaise feve purpura lymphadenitis, albuminuria, leukope a. A ph lactic gangrene

Apiol.—Erythema, gingivitis buccal mucosal gangrene feve vomiting, n phritis (Lowenberg J 110 672, 1938)

Apresoline.—C used syst mic lupus erythematosus (q v) or syndrome much like it (Perry d Schroed J 154 670 1954; Muller et al J 157: 894 1955) Th drug gi to logy produced L.E. l ke disease and L.E cells (Wevs and Swift JAD 7 103, 1955)

Arsenic.—Erythematous, scarlatiniform, papula vesicula herpetic urticarial, keratotic pigmentary ulcerative even carcinomatous lesions. Palmar and plantar arsenical keratoses begin round the sweat follicles. Arsenical keratoses may improve unde large

Fig. 138.—Arsenical keratosis of palm. (Dr Louis P. Hamburger.)

Fig. 139.—Depigmentation and hyperpigmentation resulting from neoarsphenamine intoxication. (Dr Sam E. Sweitzer.)

Fig. 140.—Arsenical keratoses of soles. (Dr Sam E. Sweitzer.)

doses of vitamin A (Hall ADS 53: 154 1946) Arsenic trioxide produces an escharotic effect locally as well as erythema, weeping and scaling. Sensitivity to both trivalent and pentavalent arsenic may exist in one person. It is dangerous to give arsenic in any form to a patient sensitive to any arsenical. BAL yields remarkable improvement in all kind of arsenical intoxication (Eagle and Magnuson AMJS 30: 470 1946)

See Cancer etiology arsenic; also Hutchinson (TransPathSocLondon 39 352, 188) keratoses and cancer Osborne (AJDS 12 72, 193 16 3 1925) microchemical studies in arsenical dermatitis Harkwlale (A MMonth 6 392, 1946) arsenic in tobacco Pascher and Wolf (J 148 734 1952) pigmentation.

ARSPHENAMINES.—Erythematous, sea latiniform, morbilliform, and eczematous lesions followed by desquamation. Exfoliative dermatitis beginning in the flexures of the extremities, then on trunk and chest. *Sudden erythema 9 days after injection. Purpura*, hemorrhagic encephalitis, jaundice hepatitis. Ulcerative colitis, perforation. Acute yellow atrophy Agranulocytosis. Arsenical reactions of considerable severity may be expected perhaps once in 1 000 injections. Mapharsen is less toxic than other arsenicals and may be given to some patients even when previous intolerance has manifested itself; but if previously provoked dermatitis was severe no arsenical can be used without risking *disaster (Levin and Keddie J 115: 369 194_)*

The value of the patch test in determining sensitivity to arsphenamine is controversial, but a positive test before its administration is a contraindication. Recognition of earliest lesions or other evidence of intolerance is fundamentally important. Beerman and Stokes (AmJMedSci 201: 611 ...; 006, 1941) reviewed reactions and gave bibliography

Acetarsone causes the same troubles as other arsenicals, including dermatitis, jaundice, nephritis, fever and anemia (Epstein J 106 69, 1936) Myelitis, peripheral neuritis and fatalities were reported by Glaser (AmJDis Child 48 124 1934) Acetarsone pessaries caused exfoliative dermatitis, case (Peck BMJ 650 1951)

Acidic Arsphenamine—Unneutralized arsphenamine given intravenously kills within a few minutes, as a rule.

Nitritoid Reaction occurs at once or within 10 minutes, and is characterized by *suffusion of the face, sensations of asphyxia, even loss of consciousness. Epinephrine is the antidote.* Serious reaction may be prevented by cautious injection. It is rarely fatal.

Arsphenamine Collapse occurs at once. It is rare. Abruptly the patient becomes pale, pulseless, and breathless, and experiences agonizing pain in the kidney region. Atropine is protective, 1/150 grain being given by hypodermic 5 minutes before injection.

Shock is rare following the administration of arsenicals. Weakness, cyanosis, cold sweat, nausea, vomiting, collapse, syncope, fall in blood pressure, weakness and rapidity of the pulse, diminution of blood volume, rapid dehydration, increase in blood nitrogen, oliguria or even anuria occurring in progression. Not relieved by epinephrine, it may last for hours or days, and is dangerous but unpredictable. See Weinberg (AmJSyph 1 3 6, 1938)

Lichen Planus-Like and Pityriasis Rosea-Like Eruptions may occur (Goodman and Sullivan SouthMJ 36 491 1943)

Nausea and *Headache* frequently follow the injections. They are not contraindications to continuation of necessary treatment. Psychic influences are important in their cause and correction. At the time of injection, which should be given skillfully, the patient should not be hot, *hasty or exhausted, and he should have eaten a light carbohydrate meal perhaps two* hours previously

Herxheimer Reaction and *Therapeutic Paradox* see p. 448.

Arsphenamine Dermatitis is an absolute contraindication to the further administration of arsenic. I retain the remainder of these paragraphs with present tense and obsolete treatment (antibiotics and cortisone became available after they were written) because they illustrate what happened to medical science in the brief span of 15 years. Arsphenamine dermatitis presaged by itching and is characterized by macules or blotches sometimes confluent eczematous dermatitis on the face trunk and extremities. The patient should be questioned and examined before each injection. Arsphenamine dermatitis is treated with BAL and by complete rest soothing local applications, such as oatmeal baths *or aluminum acetate (1 500)* wet dressings, calamine lotion or Lassar's paste and sedatives such as aspirin. In the early stage sodium thiosulfate 1 gm. in 10 c.c. of water given each day intravenously may or may not be beneficial (Abramowitz et al. ADS 47 1 5, 1943) Epstein (*J 109 11 1937*) reported that all his patients with exfoliative dermatitis gave positive patch test reactions to neoarsphenamine. A course of heavy metal preceding arsenic seems to protect against the development of dermatitis, but if *given concurrently dermatitis is more likely to be severe*. In 80% the onset precedes the twelfth injection of arsenic. The recognition of itching palms, faint morbilliform rash in the antecubital areas, or itching or rash on the trunk, will prevent violent reactions or fatalities which would certainly follow the administration of more poison when mild symptom of poisoning already exist. The occurrence of coincidental allergic dermatitis is indication that arsenical should be temporarily discontinued. Furunculosis complicates many cases of *arsenical dermatitis this would not be so common if grease-free lotions* instead of ointments were applied for topical relief particularly in axillary and pubic regions. In treatment, Epstein gave (1) 1,000 c.c. 10% dextrose with 25 units of insulin intravenously daily (2) one gram sodium thiosulfate intravenously on alternate days *to 7 doses* (3) one gram calcium gluconate by mouth between meals t.i.d. (4) four grams sodium bicarbonate by mouth t.i.d.; (5) colloid baths; and (6) a high protein diet. Symptomatic therapy including the *administration of opiates when necessary* may be desired for each case. Glucose and saline intravenously help combat severe toxicity. Liver extract for intramuscular administration seems helpful, especially if hepatic damage is in evidence. Atropine and vitamin C have been recommended.

Erythema of the Ninth Day.—Morbilliform erythema of sudden onset but generally innocuous nature sometimes appears about the ninth day after a dose of arsphenamine. The rash appears on the trunk and limbs, spreads to involve the whole body, reaches its height in 24 to 48 hours, disappears usually within 3 or 4 days; it is accompanied by general lymphadenopathy and variable constitutional symptoms, including fever which falls when the rash fades (Epstein and Levin: AmJSyph 23: 490, 1939). While considered by some to be not a contraindication to further treatment, 14 cases of ninth day erythema in which arsenical treatment was promptly resumed suffered severe parenchymatous injury reported Leifer (AmJMSc 10: 458, 1945). See also Keim (ADS 31: 291, 1935), Peters (AmJSyph 25: 587, 1941); Beymann (AmJSyph 34: 468, 1950); Berlin (ADS 56: 771, 1947).

Hematopoietic Damage.—Neutropenia is the first detectable evidence of agranulocytosis due to arsenicals. Hemorrhagic purpura followed in cases which experienced varying degrees of shock following test doses (Falconer and Epstein: AIntM 63: 413, 1940), a fact suggesting that allergy was concerned. Thrombopenia, granulopenia and aplastic anemia occur (McCarthy and Wilson: J 99: 1557, 1932). Cases of bone marrow damage were reported by Kadin (ADS 37: 787, 1938), Schwartz and Von derHeide (J 128: 657, 1945); Fisher et al. (ADS 55: 57, 1947); Nelson (BMJ 1: 300, 1952). BAL may or may not prove helpful, but transfusion and penicillin are indicated.

Hemorrhagic Encephalitis occurs perhaps once in 5,000 patients on routine therapy usually after the second dose; the onset is within 1 to 144 hours after the dose with headache, vomiting, chills, fever, cyanosis, convulsions, coma, loss of sphincter control, mental changes, stiff neck, neurologic sign of encephalomyelitis. Death is the usual outcome. Pregnant women comprised 70% of 158 cases collected by Paley and Plewett (AmJS 23: 69, 1939). Massive dose and intensive methods have in the past carried a mortality approximating 1%, from this dread complication, wherein congestion, edema, focal necrosis, and capillary hemorrhages damage the central nervous system sometimes irreversibly (Boyd and Nie: ANeurP 49: 863, 1943). If recognized early by alert personnel, however, BAL successfully detoxifies (Eagle and Magnuson: AmJS 30: 420, 1946). Other therapy includes posture (the sitting position), administration of fluid and plasma, decompression by repeated lumbar puncture, control of hyperpyrexia, and sedation with paraldehyde (Ransome et al.: BMJ 1: 639, 1945).

Jaundice.—Impairment of liver function and significant drop in prothrombin indicate arsenical intoxication, yet discontinuation of treatment when these occur may not succeed in preventing serious complications, and vitamins B, C or K or liver extract neither prevent nor protect, so that massive arsen therapy should be abolished, according to Hinds and Kalz (AmJSyph 30: 70, 1946). The incidence and severity of hepatitis are not related to the total amount of arsenic given and histologic distinction cannot be made from epidemic or postarsam hepatitis, wrote Dibble and McMichael (BJVD 19: 102, 1943). Jaundice in syphilis thought due to arsenicals probably actually is infectious jaundice transmitted by faulty aseptic technic in treatment, in many instances (Marshall: BJVD 19: 52, 1943), although arsenical toxic hepatitis of course does occur and may be fatal. Syringe transmission of jaundice accounted for half of the cases reported by Willcox (BJVD 23: 121, 1947).

BAL.—See Treatment, BAL. Dramatic improvement in cases of arsenical dermatitis may be expected when the antidote is given early (Reeve: BMJ 2: 182, 1947) for urinary excretion of arsenic follows. Sometimes the patient fails to respond favorably (Peters et al.: Lancet 2: 497, 1947; Charleton et al.: QJM 17: 49, 1948). Thrombocytopenic purpura may respond (Schrampf: J 135: 1163, 1947).

Miscellaneous Arsphenamine Effects.—Gangrene from extravascular injection (Newman and Giles: OhioSMJ 36: 961, 1940). Myocarditis (Brown and McNamara: ADS 42: 312, 1940). Anuria from Mapharsen (Simon and Inlauer: AmJSyph 22: 612, 1938). Paralytic ileus with intestinal perforation (Dennie and Miller: ADS 35: 591, 1937). Keloidal bands and reticular atrophy of skin of neck (Epstein: ADS 37: 967, 1938). Rhinitis and asthma from inhalation of powder (Saunders: JAllergy 14: 70, 1942).

TRYPARSAMIDE.—Optic atrophy (135 cases studied by Mayer: J 109: 1793, 1937). Urticarial, eczematoid and fixed eruptions. Exfoliative dermatitis (Bragman: AmJSyph 18: 308, 1934). Delusions (Hoverson: AmJSyph 19: 217, 1935). Fixed eruption (Pillsbury: ADS 34: 163, 1936). General pruritus (Robinson: ADS 34: 231, 1936). Nitritoid reaction (Miller and O'Donnell: ADS 36: 304, 1937). Itchy papules on large trophic scar (Ellis: AmJSyph 22: 316, 1938). Erythema and crusting (Epstein: in YBD 1940, p. 159). Relapse of previous arsenical dermatitis (Franks and Fisher: ADS 42: 808, 1940). Visual and neural damage (Sloan and Woods: AmJSyph 30: 633, 1936; Kopp and Soloman: AmJSyph 24: 268, 1940; Bremman and Shaffer: BJVD 16: 148, 1940). Optic neuritis treated with BAL recovered (Friedenberg: J 135: 1072, 1947).

Arterenol.—Local venospasm and phlebitis; superficial vesicular eruptions and ulceration; ergotlike gangrene (Urlecchio et al.: J 152: 607, 1953). Necrosis of skin and vein arteriospasm and ischemic gangrene (Bufalco: J 152: 1654, 1953).

Aspidium.—Exfoliative dermatitis, vomiting, bloody diarrhea (Neumark: DWehn 106: 331, 1938).

Aspirin and Salicylates.—Urticaria, asthma, purpura, angioneurotic edema, laryngeal edema necessitating tracheotomy (Prickman and Buchstein: J 108: 445, 1937). Deaths (J 115: 1199, 1940). Allergy to aspirin is not frequent (Gordon and Blanton: AmJMSc 200: 390, 1940). Fatal thrombocytopenia (Rappoport et al.: JLabClinM 30: 916, 1945).

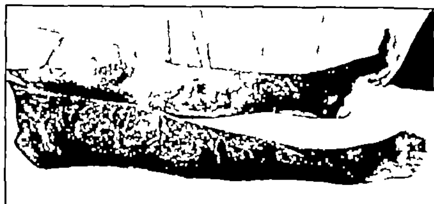

Fig. 141 —Arsenical dermatiti with gangrene, lue t neoarsphenamine. (Ronchese Am J Syph 15 348 1931)

Fig 142 —Barbiturate dermatitis due to Luminal. Miliary morbilliform, generalized (Drs Fordyce and MacKee)

Fig. 143 —Barbiturate caused this fixed eruption (Dr J Lama Callow y)

Asthma may develop after years of aspirin tolerance (Friedlaender and Feinberg: AnnIntM 26: 734 1947) Consider aspirin poisoning in presence of blotchy erythema of face profuse perspiration rapid breathing and tachycardia without distress cyanosis or pathologic signs in heart and lungs (Leveson BMJ 2: 628 1949) Urinary test for aspirin: boil to remove aceto acetic acid, add 10% ferric chloride drop by drop to 5 cc. urine white ferric phosphate turns purple if salicylates are present Treat by gastric lavage warmth, intravenous fluid, ACTH prevention of infection. See Walton and Bottomley (CanadMAJ 64: 187 1951)

Asterol.—Toxic encephalopathy convulsions (Wilson Hitch Featherston: J 150: 1002, 1004, 1006 1952)

Atabrine.—See Quinacrine

Atropine.—Erythema, scarlatiniform patchy or general rash, usually itchy; pyrexia, delirium, convulsions. May be hard to distinguish from scarlet fever See Scally (BMJ 1: 311 1936); Welbourn and Buxton (Lancet 2 11 1949) Dilated pupils, dry mouth, hot dry skin low white blood cell count helpful in diagnosis.

Aureomycin.—Mucosal and gastrointestinal irritation exfoliation of oral and anal epithelium, angular stomatitis, cheilitis, stomatitis, diarrhea pruritus ani, scroti or vulvae vaginitis, black hairy tongue, encouragement of monilial overgrowth, generalized erythema, vesiculopapular eruption urticarial erythema multiforme-like eruptions. See Behrman (J 144: 993 1950) Pareta (J 143: 652, 1950); Peck and Feldman (J 14 : 1137, 1950); Edit. (BMJ 1: 1104 1950); Gittell (J 14 1141 1951), shock Rlebes and Webb (ADS 64: 63, 1951), genital pruritus; Tomaszewski (BMJ 1: 888 1951) oral lesions resembling vitamin B deficiency Bedford (BMJ 1: 1429, 1951), asthma; Welsh and Goldberg (ADS 64: 256, 1951) fixed eruption; Kutscher et al. (JAllergy 4: 164 1953) stomatitis from troches.

Avertin.—Contains bromide See Bromides.

Aurothioglycanide (Lauron)—See Gold. Toxic in a fourth of patients treated erythema, pruritus, exfoliative dermatitis (Batterman: J 13 : 1013, 1953)

BAL may cause intoxication cramps tetany nausea lachrymation, salivation, burning sensations of mucous membranes, headache (Sulzberger et al.: JClinInv 25: 474 1946) These symptoms are considerably relieved by giving ephedrine 3 mg orally half an hour before an injection (Tye and Siegel: J 134: 1477, 1947) Abscess formation at the site of injection is common (Lancet : 497 1947) BAL has caused vesicular and bullous dermatitis in an arthritic woman intoxicated by gold (Hageman and Baghy: JMoMA 46 776, 1949) When given along with an arsenical it protects the spirochete as well as the patient from arsenical damage (DeOreo ADS 56: 605 1947) See Treatment BAL; Arsphenamine.

Banthine.—Exfoliative dermatitis (Clark and McNaughton ADS 66: 101 1953)

Barbiturates.—Exanthema with fever Urticarial, erythematous, bullous, ulcerous, eczematous or fixed eruptions. Pruritus, purpura, leukopenia, photosensitization. Exfoliative dermatitis (Winer and Baer: ADS 43 473, 1941) stomatitis and conjunctivitis (Mees and Long: ADS 46: 386, 1942); see Novy (CalifWM 43 324 1935) Light sensitivity leukopenia, purpura and death (Sweitzer and Lawson MinnM 20 92, 1937) Fatal exfoliative dermatitis (Wile and Benson: AnnIntM 13: 1243, 1940) Photosensitization (Stryker JMoMA 36: 484 1939) Bullous erythema and stricture of esophagus (Feldman ADS 46: 433, 1942) Purpura from Pentothal (Peterkin: BMJ 6 1946) from phenobarbital (McGehy and Bloomer AmJMed 14 600 1953)

Benadryl.—See Antihistamine Drugs.

Benzedrine.—See Amphetamine.

Bismuth.—Pigmentation of gums, ulcerative stomatitis, erythroderma papulosquamous erythema, scarlatinoid erythema, urticaria and pruritus Embolism nephritis, agranulocytosis, ulcerative colitis, argyria like pigmentation, arthralgia, jaundice. Brittingham (JMAGa 22 322, 1933) showed that stomatitis is of high incidence in persons with caries or pyorrhea. Salivation pain and swelling of tongue gastric upset with watery diarrhea and griping renal irritation with frequency weakness, malaise, albuminuria (even anuria) headache backache and malaise similar to influenzal symptoms except the lower fever — all these occur bismuth poisoning Ninth day erythema (Grand ADS 41: 1076 1940) Arterial embolism (Sulzberger and Baer AMJSyph 24: 50, 1940; Underwood ib. 29 656, 1945) Oral manifestations (McCarthy and Dexter NEngJM 213: 345, 1935 not in edentulous mouths; Felsher and Jones: JID 4 135, 1941 keep mouth clean with 15% sodium hexamet phosphate in tal when on bismuth therapy) Stomatitus and albuminuria like lead poisoning (I ters: AmJSyph 26 84, 1942) Response to BAL (Reekie: BMJ 2: 1218, 1949) Hepatitis (Kolchar and Reynolds: J 120: 848, 1942) Arthralgia (Gonner ADS 34 233 1936) Renal damage (Keith and Osterberg AIntM 60 416, 1937) Pityriasis roseaike eruption (Dobes and Allen: SouthMJ 4 672, 1949)

Bistrimat stomatitis and dermatitis (Wirth: ADS 60 1206, 1949) sore face, bleeding gums, vesicular stomatitis (Noun and Greenhill ADS 59 347 1949)

Bismarsen has caused arsenical dermatitis and purpura (Swartz et al.: ADS 33 874 1936)

Boric Acid.—Accidentally given by mouth, this is poison, causing gastroenteritis, hepatitis, nephrosis, cerebral edema, and exfoliative dermatitis (Young et al.: CanadMAJ

61 447 1949) Percutaneous absorption can cause fatal poisoning (Watson: J 1*0: 332 1945) Dusting powder has caused toxicity by transcutaneous absorption (Brooke: GP 7: 43, 1953; Maxson: KyMJ 5_ 4*3 1954 Ducey and Williams JPediat 43: 644 1953)

Figs 144 145, and 146 —Art rial embolism following accidental intra-arterial injection of bismuth in oil into i ferior gluteal vessel. Fig. 144 show dry gangrene and beginning separation of slough on fifteenth day Fig 145 shows spontaneou separation of slough, granulation and partial healing seen on the ixty-ninth day footdrop present from destruction f sciatic nerve. Fig 146 hows sca many months later (DeWolf UCutRev 37 423 1932)

Fig. 14 —Bromide eruption. (Dr F Ronchese)
Fig 148 —Bromid eruption. (Dr Sam E Sweitzer)
Fig 149 —Vegetative bromide eruption f leg.

Bromides.—Fairly common from sedatives and headache remedies. Lesions develop slowly and re persistent. Erythem tous, urticarial pustul r f runcul r condylom form bullous, and squamous. Eruption localized or ge ral. Hemorrhagic, fungating lesions, erythema odosumlike, toxic psychosis common. Treat by rging qua t ties f sodium

chloride and water and sodium chloride solution intravenously; or by intravenous sodium chloride solution, continuously by drip, with continuous suction of gastric juice from the stomach (Furniss BGO 63: 118, 1939) No relation is found between blood bromide level and skin lesions (Kimberly: JID _: 331, 1939) Serum bromide is reduced by mercurial diuresis (Hussar and Holley: AmJMedSci 223 202, 1952) Ammonium chloride is a better diuretic than sodium (Cornbleet: J 146: 1110, 1951)

Bromoderma limited to sites of insulin injections (Abramowitz ADS 40: 478, 1939) Mental symptoms (Skoog: JMoMA 36 339 1939 Cunningham: BMJ 2 226 1946, 3 rashes among 88 intoxications) From B.C. Headache Powder (Krack and Platt J 126 107 1944); from Asertis (Robinson: Practical Dermatology Blakiston, 1939) Fixed eruption, erythematovesicular (Tolmach and Frank: JID 12 41 1949) Infant with rash from mother's milk (Young BMJ 1: 769, 1930) Nicotinamide appears to prevent and to cure bromism (Feinblatt and Ferguson: NYSJM 52: 2017 1952)

Bromsulfalein.—Urticaria, and fixed eruption at site of accidental intradermal injection (Sievers et al.: JAllergy 20: 167 1949)

Carbarsone.—See Arsphenamines, acetarsone.

Carbromal.—Bromi e-containing drug resembli g Sedormid, causing purpura, 6 cases (Borrie: BMJ 1: 645 1953)

Chloral Hydrate.—Papular lichenoid, urticarial, purpuric, erythematous, and scarlatiniform. Bullous, exceptionally

Fig 150.—Dilantin hypertrophic gingivitis (Dr J Lamar Calloway)

Chlorpromazine (Thorazine)—Agranulocytosis (Prokopowycz J 157 1041 1955) jaundice, agranulocytosis, L.E. like rash and symptoms (Hodges and LaZerte J 158 114, 1955) Maculopapular rash, nonrecurring (Margoli et al. AD : 72, 1953)

Chloroform.—Erythematous or purpuric.

Chloromycetin.—Angioneurotic edema and shock (Patterson: NoWM 40: 352, 1950) Glossitis, cheilitis, pharyngitis, burning mouth, maculopapular rashes (Altemeis and Culbertson J 145: 449 1951; Ursdek et al. ADS 64: 217 1951) Bone marrow hypoplasia, aplastic anemia (Rich et al.: AnnIntM 33 1459 1950 see J 149 231, 912, 1293, 1801 1952) Review of 639 blood dyscrasias, 55 on this drug only 23 deaths (Lewis t al. Antibiot&Chemother 2: 601, 1952)

Chloroquin.—Pruritus toxicity rare (Loeb et al. J 130 1069, 1946) nausea, loss of weight, lichenoid dermatitis (Alving et l JClinInv 27 66 1948 Goldman et al.: J 153: 1428 1953) Restlessness, confusion, diplopia, cumulati e toxicity Pruriti burni g eruptions, erythematous, discrete and conflue t, xt sive (Ayres and Ayres J 157 186 1955)

Cinchophen.—Angioneurotic ed ma, erysipelatous swelling of face, pruritus, scarlatiniform rashes, jaundice, death (Palmer and Woodall J 107 760, 1936)

Cod Liver Oil.—Acneif rm.

Codeine.—Erythema with pruritus, sometimes follicular or perifollicular and scarlatiniform (Seldmann ADS 47 654, 1943) Exfoliative derm titis (Moyer: NEngJM 238 409 1948); desquamation (MacK nzie BMJ 766, 1949; 2 231, 1951)

Cortisone.—See ACTH, but cortison is a safe drug from the standpoint of cutaneous changes. While it causes sod um retention, t seldom, in my experience causes acne hirsutism, pigmentation etc. See Boland and Headley (CalifM 74 416, 1951); T ylor et al. (J 144: 1059 1950); Smith et al. (ADS 67: 620 1953) acne in infant.

Cyvarine.—Exfoliative dermatitis; alopecia (Levin and Bahrman: J 115: 41 1942).

DDT.—Dependent and flexural erythema, papules and purpura (Stryker and Godfrey: JMoMA 43: 384 1946) See Dermatitis Venenata, insecticides occupational hazards (Gordon BJIndustM 3: 245 1946); toxicology (Council Rpt. J 145 728 1950)

Diasone.—Blood dyscrasia Red, maculopapular rash with enanthem, becoming vesicular (Pfuetze and Pyle: J 125: 354, 1944) Dermatitis, lepra reaction, erythema nodosum (Reyes et al.: ADS 59 118 1949; Combes and Scott ADS 66: 748 1952)

Dicumarol.—Alopecia in 11 of 87 patients on anticoagulant therapy for 6- 4 months (Fisher et al. SchweizMWehn 83: 509 1953) I saw a ra h resembli g purpura annularis telangiectodes Local hemorrhage and necrosis of skin (Verhagen ActaMScand 148 453, 1954) ACTH dimini hes anticoagulant effect.

Digitalis.—Erythematous and papular followed by desquamation. Digitoxin caused thrombocytopenic purpura (Berger J 148 282, 195_)

Dilantin.—Oral changes resembling scurvy (Kimball: J 11_: 1_44 1939) Hemorrhagic erythema multiforme (Ritchl and Kolb: ADS 46: 856 194_) Pruritus, scarlatiniform rash, bullous mucositis at body orifices (Ellis: SouthMJ 36: 575 1943) Hypertrophy a d overgrowth of gums (McCarthy: ADS 45: 4*7 194_) Fixed eruption (Barton and O'Leary: ADS 48: 413, 1943)

Figs 151 and 152.—Gold sodium thiosulfat caused this case of exfoliativ dermatitis (Dr Robert Andrade)

Dinitro-orthocresol.—Weed kille with cumulative toxicity from inhalation, causing yellow pigmentat on of kin hyperhidrosis, weakness, loss of weight, hemorrhage l lungs (Bidstrup and Payne BMJ 16 1951)

Dinitrophenol.—Urt aria, purpura, pruritu , acroerythema (Koun ADS 33 288, 1935) Exfoliati e dermat t s, cataract, polyneuritis (Hitch a d Schwartz: J 106 130 1936) Leukopenia and purpura (Imerman and Imerman J 106: 108_ 1936) See Simkins (J 108 117 193, 193)

Diodrast.—Urt caria and wheezing from intravenous pyelography (N terman and Robins J 119 491 194_)

Diphenylhydantoin Sodium.—See Dilantin.

Epinephrine.—Gangrene (Cohen and Waterstone JAllergy 11 393, 1940)

Ergot.—Po soni g from ergoted grain (Gabl et al. BMJ 2 630 1951) symptoms in 6 to 48 hours, depression, nguish, nausea, bell pain, sense of pharyngeal tightness paroxysmal h pe hidrosis, pallo low pulse cold ext emit es, burning pains in intestines and some col pat ent pale limp, n ble to focus eyes f reading paresthesia, cramps, fainting spells death with muscle spasms and cardiovascular coll pse. Ergotamine used medicinally m cause gangrene relief with papaverine (Perlow and Bloch: J 109; 27

1937) See v Storch (J 111: 291, 1938); safe in 0.5 mg dose twice in 1 day in 1 week, if obliterative vascular disease is absent. Flexural urticaria and follicular dermatitis resembling lichen spinulosus (Lindsay ADS 48: 134, 1943)

Estrogenic Substances.—Purpura (Watson et al. JLabClinM 3?: 600, 1947) See Stilbestrol.

Fixed Eruptions.—Erythematous, swollen and bullous plaques followed by pigmentation suddenly recurrent in the same places with each dose of the drug have resulted from antipyrine phenolphthalein barbiturates, cinchophen, mercury quinine acriflavine acetyl arsan, Mapharsen, Tryparsamide. Early the eruption is urticarial, eczematous, and pruritic (Abramowitz ADS 43: 07? 1941) Phenolphthalein (Abramowitz: ADS 40 436, 1939) Arsphenamine (Chargin and Leifer: JID 3: 443, 1940) Magnesium hydroxide (Abramowitz and Russo: ADS 41: 707 1940) Sulfonamide (Meltzer: JID 13: 13, 1949) All drugs known to cause fixed eruptions listed by Cornbleet et al: (AD 71: 507 1955); phenolphthalein cases rare; alleged cases should be given test doses.

Fluoride.—Follicular pustules mottled teeth (Gaul: ADS 36: ?6 1937)

Fig. 161—Atrophy of fat, following injections of insulin in a diabetic. (From Clendening and Hashinger Methods of Treatment, Mosby ed. 7 1941.)

Frei Antigen.—Papular eruptions. Fever Flaccid paraplegia ranging from mild to fatal (Keim and Wakefield: ADS 40 709 1939) Erythema nodosum (Sonck; abs YBD 1940, p. 180)

Gold.—Gold sodium thiosulfate, succinimide, Sanocrysin, may produce erythema, morbilliform eruptions, leukopenia stomatitis exfoliative dermatitis, urticaria, ephritis, jaundice, purpura. Argyria-like pigmentation (chrysocyanosis) especially about eyes. Pityriasis rosea-like (Wile and Courville ADS 42: 1105, 1940) Pigmentation (Schmidt ADS 44 446 1941; Sezary et al. BSocfrançD 40 1613, 1933) Dermatitis frequently associated with positive patch test, test sometimes positive before dermatitis appears (Lichtenstein: JAllergy 6 460 1935) See Phillips (NEngJM 214 114 1936) Treatment with BAL effective (Cohen J 133 749 1947; Simpson BMJ 1 545, 1948; Sulzberger ADS 60: 807 1949) ACTH more effective than BAL (Stenberg and Roodenburg J 146 1225, 1951) Cortisone is effective. Thrombopenic purpura responds better to BAL than to ACTH (Thompson BMJ 1 899 1954)

Heparin.—Urticaria, erythema, fever; itchy eyes, nose and mouth controlled by ephedrine (H ck et L PSEBMC ?? 165, 195_)

Hexamethonium Bromide.—Rosacea from bromide (Sommerville and Allen: BMJ 1 864, 1951)

Hexamethylenamine.—Urticaria, erythema.

Hydralazine.—See *Apresoline (lupus erythematosus)*

Insulin.—Urticaria, symptoms like serum sickness (Baver: J 102: 23 1934) Lipoma told lesions (Adlersberg: MedKlin 31: 779 1935; Bader and Vero: JPediat 10 184 1937) Local atrophy of fat at sites of injections (Rosenberg and Berliner: WienKlinWchn 49: 1.53 1936; Yohalem and Pollack: JMtSinaiH 15: 320 1949) Desensitization of urticarial case (Weitz: JAllergy 14: 220 1943) See Gouldner and Ricketts (JClinEndocrin *: 505 194.) Local urticaria with passive transfer (Musso and Golay: Dermatologica 109: *74 1934)

Iodides.—Erythematous purpuric urticarial acneiform, papular nodular pustular bullous, carbuncular and vegetating Fatal hemorrhagic vegetative and ulcerative dermatitis. Lachrymation salivation red nose Sites of predilection are areas richest in sebaceous glands—face shoulders and back—although no region is exempt. The lesions

Fig. 184 —Purpuric iodide eruption in a nursing infant whose mother took iodide. (Dr D Wood Ruggles.)

Fig 185 —Iodism following diagnostic use of Lipiodol (Dr D. E. H. Cleveland)

Fig 186 —Iododerma, a fatal case showing vegetating and hemorrhagic lesions (Goldstein J 106 1469 1936)

may be discrete or confluent, and there may occur suppuration and ulceration, eventually scarring The eruption generally appears promptly, within 24 48 hours, but it is usually persistent. Intravenous sodium thiosulfate checks reaction from potassium iodide given orally to an iodine sensitive person. Persons with cardiac or renal embarrassment are susceptible (Wartzk MJAustral : 38 1933) Purpura (Davis and Saunders ADS 53: 645, 1946) Bullous (Adamson BJD 50 167 1938) Fungating (Cleveland Canad MAJ 30: 131 1934 Hollander and Fetterman ADS 34 228 1936 Pi kus et L JMich SMS 43: 709 1943) Fever (Katzenst n AmJSyph 22 348, 1938) Absorption from vagina (Schoch J 104 85., 1935) Iodized salt and odism (Bechet JID 8: 400 1947) Lipiodol (Belot J 89 892, 1927 Readding BMJ 114 1934) Diagnostic radiologic iodized chemicals (Irwin AnnOtol 61 403 1952) Rash coryza and fever in hyper

thyroid patients treated with iodide (Barker and Wood: J 114: 1029 1940) Response to ACTH in vegetative case with extreme eosinophilia which followed pyelography and post operative iodide in asthmatic undergoing prostatectomy (Cape: BMJ 1: 255 1954) Nicotinic acid, 25 mg s.c., counteracts iodide aggravation of acne (Barefoot: AD 1: 529, 1955)

Iodoform.—Macular purpuric papular vesicular

Isoniazid.—Pruritus legs and head, desquamation of hands and body (Connell Rpt.: BMJ 1: 737 1952) Pellagra (McConnell and Cheetham: Lancet 2: 959 1952) Burning formication sensations of smothering, lancinating pains in hand and feet (Pickroth: abs J 153: 771 1953)

Karaya Gum.—In some hand and hair lotions, laxatives, gumdrops, this has caused atopic dermatitis, asthma, urticaria (Bullen: JAllergy 5: 484 1934; Figley: J 114: 74 1940); pigmentation like phenolphthalein (Bowen: ADS 39: 506 1939)

Khellin.—Urticaria, dermatitis, nausea, dizziness insomnia from Visammin (Roseman et al.: J 143 160 1950)

Lipiodol.—Iodism; see Iodides.

Liquorice.—Plaques of fixed eruption tending to bulla formation (Korting and Unselt DermWchr 123: 29 1951)

Liver Extracts.—Urticaria, erythema, asthma, pruritus, nausea, weakness (Crisp: J 110: 506 1938; Krantz: ibid p 807; Feinberg et al.: AnnIntM 18 311 1943) Local histamine-like reaction, erythema and swelling (Englehardt and Derbes: SouthMJ 37: 31 1944) Allergy to pork not beef liver (Bauer et al. NEngJM 236 622, 1947)

Mandelic Acid.—Violent punctate erythema with swelling of face and extensor skin and ebemosis (James: BMJ 1: 1455 1937)

Mercuprin.—Urticaria, mercurial rashes, fever asthma; reaction more likely when kidneys are severely impaired already (Gottlieb: AnnAllergy 6: 519 1948) BAL effective antidote (Long and Farah: Sci 104: 220 1946)

Mercury.—Erythema pruritus, scarlatiniform with exfoliation; salivation, stomatitis, gastroenterocolitis. See Pink Disease Review of fatalities (Wolfenstein: BerlKlinWchr 1004 1913) Arterial embolism (Carley: VDI 17: 281, 1936) Dermographia, hyperhidrosis, weight loss, insomnia, tremor in hatters fur cutting industry (Neal and Jones J 110: 337 1938) Cinnabar tattoo caused general erythema (Novy: ADS 49: 172, 1944)

Mesantoin.—Macular rash, fever eosinophilia, stupor granulocytopenia; fatal bullous exfoliative dermatitis (Ruskin: J 137: 1031 1948) Pancytopenia (Frank and Holland: J 139: 1148, 1949) Pigmentation (?) (Hunter and Jenkins: J 147: 744 1951) See Bercel et al. (J 143 1460 1950) Compare Dilantin.

Methimazole.—Rashes, agranulocytosis, arthritis, toxic hepatitis, peripheral neuritis (Acetta et al.: J 155: 253, 1954)

Morphine.—Erythematous, maculopapular vesicular urticarial. Pruritus.

Nalorphine (Nalline).—Sweating and other symptoms of abstinence from opiates in addicts, not in normal persons (Edit.: J 154 414, 1954)

Nicotinic Acid.—See Vitamins.

Paludrine.—Erythema, swelling of hands and feet followed by exfoliation; urticaria pruritus (Findley quoted by Loewenthal: BJD 64: 106, 1952)

Para-amino Salicylic Acid.—Scarlatiniform or morbilliform rash, fixed eruption, fever; nausea, diarrhea, lymphadenitis, hepatitis, nephrosis (Kierland and Carr: PSMMC 24: 539 1949 Steel: BMJ 1: 415 1952) Lichen planus-like eruption after several months (Shatin et al. JID 21 135 1953) Thrombocytopenia (Wurzel and Mayock: J 153: 1094, 1953)

Penicillin.—Reaction resembling serum sickness (Gordon: J 131: 727 1946) Vesiculation with or without spreading scarlatiniform eruption of toes, feet, crotch (Lamb: ADS 52: 93, 1945) Pompholyx. Herxheimer-like phenomena, and aggravation of bacterid (Heinlein et al.: USNMBull, April, 1946) Oral administration frequently provokes urticaria. Universal erythema perhaps with dependent petechiae. Erythema multiforme-like eruption, spreading from the dermatosis for which penicillin was administered Erythema nodosum with superimposed bullae Dermographia without urticaria (Kalz: ADS 54: 66 1946) Exfoliative dermatitis (Nolan and Pedigo: AnnIntM 25: 725 1936) Pityriasis rosea-like (Epstein: J 134 782, 1947) Agranulocytosis (Spain and Clark: AnnIntM 25: 732, 1946) Topical application eczematous dermatitis; flares of this may occur if subsequently penicillin is given parenterally (Templeton et al. ADS 56 325 1947); urticaria (Kalb J 145 1004 1951); see Black tongue.

Sensitization related to T. gypseum infection (Cormia and Lewis JID 7 375 1946), not related (Peck and Siegel ib. 9: 165, 1947)

Passive transfer test negative in penicillin urticaria (Callaway and Barefoot: JID 7 43 1946) Reaction rate about 9% commonest urticaria epidermal sensitization easy to induce (Gottschalk and Weiss ADS 53: 4, 1946) Classification of reactions see Farrington et al. (BMJ 41 614 1948) Exfoliative dermatitis (Shaffer: NEngJM 238 660 1948) Spontaneous sensitivity in 5%; 10% of those receiving penicillin got reactions, mostly males probably due to previous time (Peck et al. J 138: 631 1948) Stomatitis and glossitis from oral tablet (Goldman and Farrington: ADS 57: 399 1948; Crowe BMJ 1 171 1949)

Intramuscular injection of beeswax and oil (Bondy et al.: AmJM 3: 34, 1947) Injection damaging peripheral nerve (Broadbent et al.: J 140: 1008 1949) Purulent abscesses at sites of injection (Call and Gilbert J 134: 1476, 1947) Eczematous reaction

to procaine fraction (Peck and Feldman: JID 13: 109 1949) Beeswax allergy (Watson: BMJ 1 601 1945) Sensitization to instillation in maxillary sinuses (Everett: J 146: 1314 1951) Vesicular dermatitis of hand showi g only tuberculin type reactivity (Epstein and Pinku : AnnAllergy 4: 136, 1946) Fixed eruptions (Canizares: ADS 63: 500 1951) Reviews: Farrington (SouthMJ 48 637 1955); Strauch et al. (TexasSJM 50 699, 1954)

Serum sickness type of reactions showed marked depression of hemoglobin (Riley: ADS 65: *7 1952) Fatal exfoliative dermatitis not necessarily due to penicillin (Hase lck: J 143: 116, 1949) Acceleration of blood clotting (Macht: J 143: 205, 195_). Granulomatous visceral lesions, fatal (Waugh AmJPath 28: 437 1953) Hazards (Gilman: USArmedForcesMJ 1: 1153 1950) Allergic hydroarthrosis, serum sickness, anaphylactic shock (Suchecki: BMJ 2 938 1946) Anaphylactic shock (Sterling: JAllergy *4 54_, 1953) Skin test are unreliable in predicting penicillin allergy (Berger and Eisen J 150: 191 1953)

Anaphylactic death (Higgins and Rothschild: NEngJM 4 : 644 1952; Felsberg et al.: J 15_: 114 1953 Pick and Patterson BJD _ 605 1953; Prior and Burrell South MJ 46 11 1 1953; Edit BMJ : 0 1953)

Desensitization (O Donovan and Klorfajn: Lancet : 444, 1946 Peck et al.: J 134: 1546 1947; Alexander: ADS 63: 333, 1953)

Treatme t antihistamine drugs intravenous procaine (Dressler and Dworki J 133: 849 1947) *ACTH (Lichtenstein and Friedman: J 147: 1633 1951)* cortisone; intravenous calcium in erythema nodosum type Aluminum acetate or permanganate baths.

Pertussis Toxin.—Thrombopenic purpura (Kugelmann: J 10? _120, 1936)

Phenacemide (Phenurone).—Rashes, exfoliative dermatitis (Tyler and King: J 147: *17 1951*)

Phenacetin.—Urtic ria, erythema.

Phenergan.—Photosensitization followed topical application (Tzanck et al.: AnndeD 8: 433, 1951)

Phenindione.—Rash, jaundice anemia (Makous and Vander Veer: J 155: 739 1954)

Phenolphthalein.—Persistent spots pink, dusky red, itchy sometimes bullous during flare fading to leave persistent brownish purple stains; fixed eruption. Stomatitis, catarrhal col t Common ingredient of laxatives. Pigment is melanin (Wise and Abramowitz ADS 5 297 192_) Urticarial lesions, co junctival ecchemoses, mucosal ulcers, scaly erythroderma, erythema multiforme-like eruptions, nephrosis, visceral hemorrhage ul erati e lti (Newman J 101 61 1933) (?) blu stain of nail bed (Campbell: BJD 43 186, 1931) Tra splantation experiments: normal skin moved to affected site reacted (Wise and Sulzberger: *7 549 1933) Bibliography and review (Abramowitz: ADS 31: 7", 1935) Toxicity (Knowles et al.: ADS 33 2?7 1936); drugs containing phenolphthalein (Belote and Whitney ADS 36 *70 1937); effects on kidneys (Fantus and Dyniew ex J 108 439 1937); on intestines (Soper: AmJDigestDis 5: 297 1938)

Phenylbutazone.—Macular erythema morbilliform, vesicular papular, purpuric and rt carial eruptions (Kuzell et al. J 149: 29 195 ; Stephen et al.: J 150: 1084, 1952; Ste brocker et al.: ib. p. 1087) Exfoliative dermatitis (Cheret and Siegel J 151: 556 1953 Fishman and Reynolds J 153: 64_, 1953) Fatal bullous erythema multiforme (Cone et al. ADS 69: 674 1954) Agranulocytosis (Stifel and Burnheimer: J 151: 555, 1953 see p. 53) agranulocytosis helped by ACTH (Werblow and Neber: J 151 1256, 1953)

Phenytoin Sodium.—See Dilantin.

Photodynamic Effects of Internally Absorbed Drugs.—See Hydroa; Phenergan; also Mathews (APath 23 399 1937)

Pituitary Extracts.—Angio eurotic edema (Simon and Ryder J 106 515 1936) Urti aria from posterio pituitary (McMann J 113 1488, 1939) Collapse (Seligman: J 114 344 1940) See also ACTH.

Presidon (Pyrithyldione).—Ulcerative stomatitis, proctitis, vul itis; agranulocytosis (Co er and Halpern NEngJM 4_ 49 1950)

Promin.—See Sulfonamides.

Pyribenzamine.—See Antihistamine drugs.

Quinacrine (Atabrine).—See also Lichen planus; lupus erythematosus; Chloroquin. Y llow pigmentat universal but more intense on exposed parts (Sugar and Waddell BMJ ?9 _34 1946) Blue macules o face, nose nd mucosae. Blue nails (Sugar and Waddell BullUSAMD 4 370 1945) Rarely hepatitis, exfoliative dermatitis (Agress J 131 14 1946) Fluoresce greenish yellow of all hair and skin (Glasberg and Shallenberger J 131 80* 1946 Kierla d et al.: ib. p. 809) Color plates of blue pigme tation (Lutterloh nd Shallenberger: ADS 53: 349 1946) Fatal aplastic anemia, from 0 1 Gm. B.I.D (Parm and Sawitsky: J 153 1172, 1953); from 8 0 Gm. in 55 days (Vilanova d d M raga A d D 80 360 1953)

Quinidine.—Edem scarlatiniform, pruritic, general o scattered rashes, often located on dependent part Purpura, thrombocytopenia (Nudelman et al. J 137: 1219 1948; Moodie BMJ 563 1950); mechanism of cause of purpura, allergi interference with clot retraction in presence of sensitive serum and the drug (Larson Blood 8: 16, 1953) Fe e (Be ley and Saland J 148 1131, 1952) Exfoliative dermatitis (Taylor and Pota hnick: J 145 641 1951) eruption resembling lichen planus (Wechsler ADS 69: 41 1954)

Quinine.—Erythematous, scarlatiniform, purpuric, urticarial vesicular bullous and ulcerative attended with severe itching Acuminate follicular papular pruritic eruption. Bullae on hands and tongue (Settle: J 106: 1801, 1936) Coppery rash fatal anuria (Vartan and Discombe: BMJ 1: 625, 1940) Thrombocytopenic purpura (Bolton and Young: JClinPath 6: 320, 1953; Steinkamp et al.: JLabCli M 45 18, 1955) Anacin contains quinine (Lamb: ADS 40: 803 1939) and Bromoquinine does also.

Fig. 157.—Phenolphthalein eruption in a young man, who had been taking the drug over a period of many months.

Figs 158 and 159.—Phenolphthalein stomatitis in 2 patients. Fig. 158 shows glossitis in the form of a fixed eruption. Fig 159 shows exudative cheilitis. (Dr Belford Shelmire.)

Radium.—Mandibula destruction; sarcoma (Evans and Aub AIntM 11: 1443, 1938)

Reserpine.—Depression, arthralgia, stuffy nose. I have seen several cases of diffuse alopecia from it.

Rutin.—See Vitamins.

Fig. 160 —Bullous erythema multiforme from phenolphthalein

Fig. 161 —Phenolphthalein intolerance. (Dr J Lamar Callaway)

Salicylates.—See Aspirin. Erythema; scarlatiniform, morbilliform, urticarial, vesicular bullous, rarely ulcerative eruptions. Thrombocytopenia, purpura. Percutaneous fatal intoxication (Young: SouthMJ 45: 1073 195.)

Sclerosing Agents.—Emboli are less common since coagu ants are less used. Sodium salicylate may cause urticaria. Quinine (q.v.) Sodium morrhuate (q.v.) See Shelley (J 112: 1792, 1939)

Sedormid.—Allyl isopropyl acetyl carbamide causes thrombocytopenic purpura (Boas and Erf: NYSJM 36: 491, 1936; Hoffman et al.: J 110: 725 1935; Moody: ib. p. 726; Hill: J 111: 1450 1938; Huber: J 113: 674, 1939; Falconer and Schumacher: AIntM 65: 122 1940) Thrombocytolysis in vitro (Ackroyd: ClinSci 7: 231 40; 8: 235, 269 1949) Temporary intolerance (Grant: BMJ 2 128 1953)

Selenium.—Erythema and edema of exposed parts, porphyria and leukocytosis with relative lymphocytosis (Halter: abs YBD 1939, p. 546)

Silver.—*Argyria* is permanent discoloration of the skin which sometimes follows prolonged administration of silver salts, particularly silver nitrate May result from use of Argyrol or silver arsphenamine. Earliest signs of pigmentation are noted on the edges of the gums. The hue of the affected skin ranges from a bluish or bl ish gray to a slate or bronze color and may be generalized or localized to treated area. Color simulates that of cyanosis from heart disease (Smith and Watson GlasgowMJ 35: .5 1954) The deposit of silve or rather the silver combination is limited to the margin of the connective tissue and affects particularly the elastic fibers and the sheaths of the membranes (Hill and Mo tgomery: ADS 44: 588 1941) Many elastic fibers are sheathed with the metal. Stillians and Lawless (J 9?: ?0, 1929) successfully bleached the pigmentation by injecting locally a mixture of 1% potassium ferricyanide with 6% sodi m thiosulf te.

See Gaul and Staud (ADS 30 433 1934 J 104: 1387 1935) spectrometric nalysis Harker and Hunter (BJD 47: 441, 1935) occupational rgyria in silversmiths; Stillians (ADS 35 67, 1937), review; Hill and Pillsbury (Argyria The Pharmacology f Sil er Williams nd Wilkins, 1939); Levin and Smith (NEngJM 226: 482, 1942) confusion with heart disease Olcott and Riker (Sci 105: 67 1947) DAL futile in rats Rosenthal and Ollswang (ADS 57 742, 1948) DAL futile in human beings.

Sodium Morrhuate.—Pruritus, erythema, edema, flare at sites of previous injections. Urticaria, collapse. Embolism. (Shelley: J 112: 1792 1939)

Stilbamidine.—See Blastomycosis, treatment.

Stilbestrol.—Edema of legs, erythema progressing to exfoliati e dermatiti (Keyser: ValMMonth 69: 544, 1942; Kasselberg: J 120 117 1942) Hypertrophy of breasts (Dunn: J 115: 2263, 1940)

Stovarsol.—See Arsphenamines, acetarso e.

Stramonium.—Contains atropine, scopolamine, hyoscyamine; flushing, dry erythema, scarlatiniform rash dilation of pupils (Hughes and Clark: J 11.: .500, 1939)

Streptomycin.—Histamine-like flushing headache, fever myalgia, and arthralgia. Maculopapular and erythema nodosum-like exanthems (Hettig and Adcock: Sc 103: 355 1946) Rashes resembling erythema of ninth day not a contra dication to furthe dosage (Steiner and Fishborn: ADS 56 511, 1947) Contact dermatitis (Strauss and Warring: JID 9 3 90 1947) Severe membranous stomatitis (Beham nd Perr J 135 493 1948) Deafness, dizziness, leukopenia, anemia, renal irritation (Davis et al.: AnnWest M&S 2: 45 1948) Erythema nd stomatitis, fatal (Pallister BMJ ?: 1?71, 1949) Exfoliative dermatitis (Lindars and others: Lancet 1: 110, 112, 233, 234 1950) Hypertrichosis n children (Rouques PresseMéd. 58 1230 1950) Purpura (R densky and Fisher: J 147 311 1951)

Sulfisoxazole.—Agranulocytosis responsive to ACTH (McCluskey: J 152: 232 1953)

Sulfocyanate.—Erythema, papular rash, exfoliative dermatitis (Baker and Brunsting J 108 549, 1937) Toxic alopecia, perineal pru t s mucosal petechiae (Holla d et al.: ADS 59: 112, 1949)

Sulfonamides.—Erythema with edema, urticarial followed by desquamation. Scarlatiniform. Tends to localize on parts exposed to sunlight; photosensitization. Erythroderma. Pruritus, granulopenia purpura. Cyanosis. Methemoglobinemia. Porphyrinuria. Acute yellow atrophy Headache, nausea, insomnia; worse with sulfapyridi e. Erythema nodosum like eruptions. Eczem tous flare of exudative derm titis for which drug was given, with development f widespread eruption more or less resembl ng the original disease (Livingood and Pillsbury: J 121 406 1943) Conjunctivitis and f ver Pemphigoid eruption (Joh son J 1 4: 979 1944) Fixed eruption (Dostrovski and Sagher: ADS 49 418 1944) G neral erythema, conjunctivitis and purpura, fatal (Gessler BMJ 37 465 1944) Peripheral neuritis. An ria. Topical use often sen itizes, so that subsequent i ternal administration causes sensitization phenomen of a y ki d, especially local flare (T lloch BMJ 2 318, 1943; Shaffer et al.: J 1.3 17 1943) Percutaneous absorption can cause a y toxic phenomenon that ral administration can (Pete kin: BMJ : 1 1945) Sensitization from sulfonamide medication is flared by contact with sulfonamide ren m h as nail lacquer may ontain. Treatment of sulfonamide intoxication: para-aminobenzoic cid, o hemically related procaine 1% 5 c.c., subcutaneously each 4 hours (Dixon: Pers. comm. 1945) If patch test is positive, oral testing is hazardous (Phillips: BJD 58 212, 1946) Cont ct sensitization is more likely to develop if kin is inflamed: ex perime t l sensitizat on b Gottschalk and Weiss (ADS 56 775 1947) Varieties of reactions (Erski e: BMJ 2: 104 1930; Dowling and Lepper: J 121: 1190 1943) Sensitization f om topical use (Shaffer et al. J 123 17 1943 Sulzberger et al. JAllergy 15:

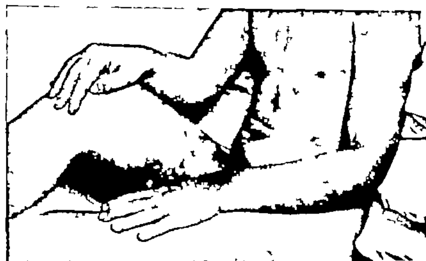

Fig. 182.—Sulfonamid eruption which ppeared on 9th day of administration f drug. Photograph on 10th day (Thompson BMJ 2: 13 1939)

Fig. 183.—Pemphigoid sulfonamide eruption (Bloom NYSJM 43 1499 1943)

Fig. 184.—Bullous sulfathiazole eruption seen on rm and forearm. (Dr J Lamar Calloway)

92, 1947) Fixed eruptions (Loveman and Simon: ADS 40: 99, 1939 McGuire and Shaffer: ADS 5.: 343, 1945; Leifer: ADS 53: 125 1940; Philpott: ADS 63: 776 1951) Photosensitization (Epstein: JID .: 43, 1939; Blum: JID 4 159 1941; Park and Platts: BMJ : 308 194.; Clark: J 123 968 1943; Watkinson and Hillis: BMJ *: 609, 1947; Sidi and Dobkevitch: abs YBD 1949 p. 1 ; related chemicals with amino group in para position on benzene ring) Initiation of psoriasis (Philpott: ADS 55: 825, 1947) Acquired epidermolysis bullosa, 3 cases (Bloom: NYSJM 53: 1077 1953) Fixed eruption of male genitalia, simulating secondary syphilid (Doyle BMJ *: 1530 1934)

Sulfur, Colloidal.—Urticaria, erythema, fever vomiting, diarrhea, cramps (QMN: J 110: 458 1938)

Tapazole.—See Methimazole

Terramycin.—Diarrhea, anal soreness (Willcox: Lancet : 154, 1951); see Moniliasis, etiology Scarlatiniform rash (Hay and McKenzie: Lancet 1: 045, 1954)

Testosterone.—See Androgen.

Tetanus Toxoid.—Urticaria (Cooke et al.: J 114: 1854 1940)

Tetracycline.—Diarrhea, pruritus ani; intolerance less frequent than from Aureomycin (q v) or T rramycin (q.v)

Thallium.—Alopecia, nephritis, formication in hands and feet, encephalitis, arthralgia, gastrointestinal pain, anorexia, insomnia, thirst, depression. Transverse bands of nails (Philadelphy: DWehn 93: 78 1934) Rat paste poisoning, treatment with sodium thiosulfate and vitamin B (Bromm: MünchMWehn 85: 1084 1938) Criminal Th poisoning (Steidle: MWelt 13: 1557 1939) Chemical detection in tissues (Gettler and Weiss: Am JChemPath 13: 322, 1943) No scientific basis for use of BAL in poisoning (Flesch and Goldstone: JID 15: 345, 1950) BAL cured rat poison case (Mazzei and Schaposnik: BMJ *: 791, 1949) See Tinea capitis, epilation with Thallium; also Prick et al. (abs J 141: 877 1949) Frank and Hirsch (J 150: 586, 1952); Lapiere and Demey Pousart (Annde D 79: 137 1952) BAL increased excretion fivefold.

Thiamin.—See Vitamins.

Thiocyanate.—Macular maculopapular dermatitis; itching and scaling exfoliative dermatitis (Watkinson and E anst BMJ 1: 595 194) Urticaria (Wald et al.: J 11 : 1120, 1939) Nondescript faint erythema resembling contact dermatitis (Green a d Snow: AIntM 64: 579 1939) Exfoliative dermatitis and necrosis of liver (Kessler and Hines: J 138: 549 1948)

Thiouracil and Thiourea.—Morbilliform eruption fever; erythematous macular, papular acneiform ra hes; pruritus; edema of legs (VanWinkle et l. J 130 343, 1946) Urticaria, neuritis, arthritis, mal ise (Williams: JClEndocr 6: 23, 1946) Thrombocytopenic purpura (Newcomb and Deane: La cet 1 179 1944); f tal agranulocytosis (Julian and H rris: J 139: 646, 1949) Alopecia (Clarke: J 147: 1711 1951)

Thorazine.—See Chlorpromazine Agra locytosis.

Tin.—Di-ethyl tin oxide with linoleic eid popular in France in 1953, poisoned several, killed some patients treat d fo furunculosis (Edit BMJ 602, 1954)

Tibione.—Agran locytosis (Da is et al.: SouthMJ 45 861 195)

Tragacanth.—Urticaria and atopy (Gelfand JAllergy 14 203 1943)

Tridione.—Purpura, aplastic a emia (H rrison et al. J 132: 11 1946)

Triethylene Melamine (TEM).—Maculopapular itchy rash spreading from arms to trunk and wrists (Fromin and Rubenstone: J 152: 915 1953) See Lymphosarcoma, treatment.

Trihexyphenidyl.—Numerous pulsating spider angiomas developed on face, neck and chest of 3 patients taking the drug for Parkinson's disease and disappeared when it was withdrawn (Holt: NEngJM 249: 318, 1953)

Tryparsamide.—See Arsphenamines.

Tuberculin.—Erythema, urticaria, erythema nodosum. Local reaction mild or severe, even sloughing Tuberculid.

Undecylenic Acid.—Morbilliform generalized rash (Reiches: ADS 62: 706 1950) Exfoliative dermatitis (Schiff: J 144 620 1950)

Vaccines and Bacterins.—Erythematous, papular and urticarial toxic rashes fever; erythema multiforme; herpes simplex exacerbations. See Antitoxins; Tet nus toxoid Frei ntigen; Tuberculin.

Vitamins.—See Hypervitaminoses A and D Lupus vulgaris vitamin D treatm t (Calciferol, etc.); Cod liver oil; Liver extracts. Vitamin A has caused erythema, exfoliative dermatitis, lopecia. Thiamin has caused angioneurotic edema (Eisenstadt MinnM .5 861 194.) macula itchy erythema disappearing after hyposensitization (Mitrani: JAllergy 15 150 1944) Nicotin c acid causes transient vasodilation, flushing itching, rticaria, dizziness, nausea, om ting (Sebrell and Butler: J 111: 2286, 1938) Vitamin B_{12} impu e, caused reactions (Young et al.: J 143 893, 1950); pure, gave tuberculin type reactions on ntradermal test in patient sensitive to Ni and Co (Rostenberg and Perkins: JAllergy 22: 466 1951) The B complex can cause urticaria, anaphylactic shock (Chitwood and Moore J 148 461 195 dangerous intravenously) Haliver oil with Viosterol caused fine papula rash resembling dry eczema (Pfister J 102: 633, 1934) Vitamin D intoxication exudative conjunctivitis, nausea, weakness, coma, peripheral and optic neuritis (M cree BJD 59 33, 1947) Wheat germ caused rash lik lichen planus (Newman CanadMAJ 43 175 1941) Rutin ca sed conjunctival petechiae (Wolffe and Daniels: J 134 602, 1947)

URTICARIA

Symptoms.—Urticaria (nettle rash or hives) is an inflammatory affection characterized by the eruption of whitish pinkish or reddish wheals caused by transudation of fluid from vessels into tissue spaces in allergic response to the local release of a histamine like substance The lesions are evanescent and give rise to burning itching and stinging sensations. Wheals vary greatly in size and considerably in shape They usually appear suddenly They are elevations, pinhead to fingernail sized at first but frequently they coalesce to form irregular patches. Rarely they become purpuric and are followed by temporary pigmentation Any or all parts of the body may be affected, but the sites of predilection are the lower trunk buttocks, and outer surfaces of the thighs. In ordinary cases the lesions persist for several hours and then disappear spontaneously leaving no trace Rubbing usually renders the lesions worse instead of better and may provoke a new outbreak in regions previously unaffected The mucous membranes notably those of the larynx, may also be involved.

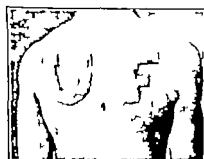
Visceral lesions (see also Angioneurotic edema) have been demonstrated with the gastroscope by Chevallier (AnndeD 7 113 1936) Transitory myocardial changes shown by EKG have been reported by Foster and Laymon (J 148 203 1952)

Acute Urticaria is the most common clinical type an attack extending over a period of 3 or 4 days. During this time crops of new lesions are constantly appearing after older ones have subsided. The disease may then disappear permanently or it may recur

Chronic Urticaria may consist simply of repeated attacks of acute urticaria extending over a period of months or even years. Or the individual may have lesions continuously with or without exacerbations.

Serum Sickness presents urticaria as one of its major symptoms. Its phenomena are thought to be due to release of the H-substance from the union of serum protein antigens and antibodies. Histaminase (Best and McHenry JPhys 70 349 1930) has helped many patients (Foshay and Hagebusch J 112 2398 1939) and failed in others. The antihistaminic substances are effective in palliating the urticarial element but influence the arthralgia little Cortisone and ACTH usually help this.

Angioneurotic Edema is a form of urticaria characterized by large single or multiple circumscribed evanescent edematous swellings. The lesions differ from urticaria only in size The regions commonly involved are the lips the eyelids, and the lobes of the ears, although the extremities trunk larynx and genitals occasionally are involved The lesions are somewhat more persistent than those seen in urticaria. The disease is sometimes familial (Fineman AnnIntM 14 916 1940) Of 73 cases in which the cause was determined 38 resulted from drugs and of these 15 were due to aspirin and 9 to codeine preparations, reported Bruun (JAllergy 24 97 1953) Inhalants or contactants accounted for 11 and allergic etiology was presumed in 24 more In 35 cases of the total of 132 the cause was not determined In treatment Kafka (MRec 246 441 1937) recommended ephedrine sulfate gr ¾ by mouth and starch water baths. In edema of the glottis, he found effective the repeated administration of adrenalin at intervals of ½, 1 2, 4 and 8 hours It is in these cases that a tracheal catheter or as a last resort tracheotomy may be required Antihistamine drugs are effective



Urticaria From Heat and Cold— Physical allergy received brief consideration under Allergy (q v) Descriptions of heat sensitive cold sensitive light-sensitive and trauma-sensitive (dermographic) cases were collated by Duke (J 84 736 1925) there is an extensive literature to which reference is made in Edit (J 103 996 1934 see p. 1325) Reaction to the physical stimulus may remain local or become diffuse. A tourniquet proximal to cold induced whealing prevents the spread of wheals, which may become generalized when the tourniquet is loosened (Levine AIntM 56 498 1935)

Fig 165.—Urticaria, acute severe

Fig 166.—Urticaria with both ordinary and an [illegible] lesion

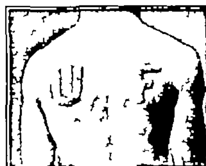


Fig. 167.—Dermographism urticaria elicited by mechanical irritation. Edema does not extend beyond the skin area directly irritated. (Dr W W Duke.)

Fig. 168.—Urticaria solaris, elicited by irritation by light. The area of edema does not extend beyond the area directly exposed to light. (Dr W W Duke.)

Reaction may involve tissues other than the skin, giving rise to coryza, asthma even abdominal pain, sometimes eczema. The application of cold in some individuals provoking redness, warmth and swelling locally is followed in a few minutes by a systemic histamine-like reaction of half an hour s duration with fall in blood pressure rapid pulse flushed face and faintness (Horton and Brown Am JMSc 178 191 1929) Collapse during swimming is a dangerous hazard in such persons (Horton et al J 107 1263 1936) Desensitization by graded exposures to cold has been accomplished.

Purpura associated with cold sensitivity was studied by Peters and Horton (PSMMC 16 631 1941) Familial cold urticaria has been reported by Urbach et al (ADS 43 366 1941) and Witherspoon et al. (ADS 58 52, 1948)

The release of acetylcholine by heat, physical exertion and emotion was the subject of interesting experiments by Grant et al (ClinSci 2 253 1936) Cholinogenic urticaria from heat and urticaria due to cold apparently are based on different mechanisms, concluded Hopkins et al. (ADS 38 679 1938) The classic abnormalities of response to choline esters given systemically and intradermally were observed by Morgan (JID 21 173 1953) who found

Fig 169 —Angioneurotic edema

Fig. 170.—Dermographism

somewhat reduced blood cholesterase in his 3 patients. When he experimentally exhausted the histamine content of a local region by using histamine-releasing compounds, the region no longer responded with urticaria.

Light Urticaria —See Urticaria solare (p 718)

Dermographism is characterized by the provokability of linear wheals by one s simply rubbing or stroking the skin with some pointed instrument Walzer (ADS 17 659 1928) demonstrated passive transfer of dermographia inducing factors in 7 of 12 persons tested. While Pyribenzamine will diminish the dermographic response it does not completely inhibit it (Baer JID 7 201 1946) Antihistamines can be used to inhibit the phenomenon more or less effectively so that for example a girl can attend a formal party without welts, but one does not know how to cure the condition. Dermographism is rarely seen in chronic urticaria and the two conditions should not be confused, noted Fisher and Schwartz (ADS 68 553 1953) In their 20 cases of dermographism without urticaria they were not able to find food or drug allergy

Black Dermographism is a physical phenomenon dependent on powder present on the skin When the skin is stroked with certain metals, particles scraped off leave their mark. The same reaction may be obtained on paper cloth and wood, reported Urbach and Pillsbury (J 121 485 1943) This has nothing to do with urticaria or dermographia See QMN (J 112 1749 1939)

PAPULAR URTICARIA (LICHEN URTICATUS)—The lesions are papular and yet possess some of the characteristics of wheals They are pinhead to pea sized, flat sharply defined and intensely itchy and are usually comparatively few in number This type is observed most frequently in poorly nourished children although adults are not immune The loins and buttocks are the sites of predilection. Diagnostically noted Laymon (J Lancet 52 29 1937) *papular urticaria shows wheals, only minor secondary changes, an even distribution* on the extremities and no constitutional symptoms, while in prurigo mitis there are lichenification, excoriation and scarring a heavy distribution on forearms and thighs and anemia and nervousness. Histologically the lesions of papular urticaria were of tuberculoid structure resembling positive skin reactions to insect bites reported Shaffer et al. (ADS 70 437 1954)

A Negro patient was cured with cod liver oil by Cole (ADS 33 657 1936) Patients generally improve in hospital even when their food is brought from home Pillsbury and Sternberg (AmJDisChild 53 1209 1937) reported good results in 85 per cent of their cases which were treated with calcium and parathyroid extract and similar results in 38% of those treated by calcium alone. Clinical improvement seemed chiefly concerned with the elevation of the level of the calcium content of the blood. They thought that evidence supporting a view of allergy as the cause of papular urticaria is meager Ellis (BMJ 2 118 1942) recommended potassium citrate, 10 grams t i.d. by mouth It is possible that the cause is external and that bedbugs or fleas may play a part Of 60 cases of Shaffer et al. (JID 11 293 1948) the majority were cured by using DDT locally and as a household spray and comparable experience was reported by Blank et al. (Ped 3 406 1950) Antihistamine agents failed to help cases studied by Cornbleet (ADS 60 1167 1949)

Etiology—The urticarial reaction consists essentially of three local changes in the skin, Lewis triple response a red area which within a few seconds becomes surrounded by a flare or flush, after which a wheal begins to appear (Ivy et al. ADS 58: 659 1948)

The triple response may be produced experimentally in man and some animals in response to mechanical injury heat cold and the intracutaneous introduction of many subst ces: allergens, histamine morphine, codeine, physostigmine, pilocarpine nd atropine. Wheaing is a specific response to these substances. The red spot at the site of introduction f the drug is pparently due to direct action on the blood vessels and occurs in denervated skin but the flare requires integrity of the axon ref x. The wheal, which will occur after n rve degeneration, is due to increased capillary permeability as proved by its discoloration by dyes give intravenously shortly before o d ri g the f rmation of the wheal. It does not occur if the dye is injected after the wheal has blanched. Protein in the wheal fluid approximates the concentration of protein in the blood plasma. A cuff which increases capillary pressure does not increase the size of wheals experimentally produced, but such wheals are of progressively smaller size as systolic pressure is approached, and wheating does not occur while blood flow is occluded. The wheal and flare are evidently due to the release of a substance by the cells of the skin when they are injured.

See Physiology Vascular Activity and Treatment, Antihistamine Agents. The different manifestations of urticaria, purpura, angioneurotic edema nd erythema nodosum merely represent differences in degree of allergic reaction and site of shock tissue, argued Lowe that (BJD 61 403, 1949)

Etiologic grouping of 170 cases of urticaria by Fink and Gay (BullJHH 55 280 1934) was as follows

1 Foci of infection 30% Of these 74% were cured by elimination of the focus.
2 Allergy to food, drug, ext rnal agent, scabies, 20%
3. Psychogenic, 18%
4. Endocrine, 6% All were females.
5. Unknown 25%

Hopkins and Kesten (ADS 29 358 1934) were able to demonstrate the etiologic factor in many cases, although some could not be ascribed to a known cause. They classified proved causative agents as follows

Acute Urticaria (single or repeated attacks)
A. Localized
1. Plant sect, jellyfish poisons

2. Nontoxic substances to which skin is sensitized
3. Heat, cold, light, mechanical irritation (many agents producing generalized urticaria may produce it locally)

B. Generalized
4. *Serum sickness, anaphylactic shock*
5. Food
6. Foreign substances absorbed through conjunctiva or respiratory tract
7. Drugs
8. Heat (exertion, excitement, fever)
9. Infections
10. Menstruation

Chronic Urticaria
11. Food (rarely)
12. Focal infection (frequently)
13. Animal parasites

An attack of urticaria occasionally follows the ingestion of a particular food or drug Allergy may be of obscure origin in some instances multiple factors being involved In some cases urticaria can be brought on by the specific action of physical agents such as light, heat cold, scratching and in heat sensitiveness by either mental or physical exertion Attacks may be precipitated by the ingestion or parenteral introduction of foreign proteins, especially serums and bacterial products.

Penicillin has been the commonest cause of urticaria in recent years in my experience and the high incidence attributable to it was noted too by Steinhardt (AnnAllergy 12 659 1954) although among his 500 cases were far more cases thought due to food allergy and psychologic factors than I should readily accredit.

Serum calcium estimations, studied by Greenbaum (ADS 16 553, 1927) in 63 patients representing all forms of urticaria, showed a normal or increased calcium level. He concluded that the administration of calcium salts to patients with urticaria generally lacks scientific basis. Increase of serum potassium during activity and diminution thereof during decline of urticaria, as is true also in asthma, was described by Rusk et al. (J 11 : *395 1939) Patients with urticaria who had low prothrombin levels were often relieved by vitamin K, 2 mg t.i.d. before meals (Black JAllergy 16: 83 1945) Cases associated with disease of the biliary tract and favorably influenced by cholagogues and biliary drainage were reported by Menagh (J 90 668 19**) The lack of vitamin C must be considered Chronic cases are usually due to foods, according to Kahn and Grothaus (SouthMJ 33 1086 1940) Women are more often affected than men. Inhalants, such as ragweed pollen, may cause urticaria as they cause asthma (Derbes and Engleshardt SouthMJ 37 7*9 1944) Perfume acted as an inhalant allergen in a case of Zakon and Kah (ADS 53: 11 1945)

Contact with some chemicals can ca se wheals in some perso s, a formald hyde (Rappaport and Hoffman: J 116 *656, 1941) and TNT (Preston and Watkins: ADS 53 134 1946) See Epstein (1955) on p. 146.

Of mal parasitoses inciting urticaria, scabies is the most l k l i testinal worms, *Schistosoma japonicum* and pediculosis of the scalp have etiologic potentialities. A patient who once had malaria, and whose chro ic rt caria wa puzzling, wa cured by At bri (Fineberg UCutRev 53: 100 1949) and this drug eliminated *Giardia lamblia*, diarrhea and urticaria, all of them, in a patient of Harris and Mitchell (ADS 59: 587 1949) Of 27 patients with amebiasis due to *E histolytica* 5 had urticaria and were cured with emetine by Giordano (abs YBD 1944, p. 175) Amebae accounted f r 19 of 33 chronic cases of obscure cause seen by Cohen and Criep (AmPractit 1: 246 1950) who cured many of them with carbarsone 0.25 Gm. t.i.d. for 10 days, although some equired emetine, 0.065 Gm. daily for 10 days. *Several patients when given ameb cides flared as with a Herxheimer* reaction.

Tinea of the feet can gi e rise to urticarial dermatophytids (Sulzberger and Kerr: JAllergy 2 11 1930)

Sweat, when injected intradermally into the skin of the subject from whom it was obtained, prod ced wheals observed Sulzberger t al. (JID 21: 293, 1933) The hypothesis was interestingly pursued that when sweat ducts are obstructed and sweat secretion occurs, intradermal dsorption of sweat ca produce discomfort, itching, wheals and aggravation of a coexistent dermatosis. See Anhidrosis.

Psychogenic factors causing urticaria were reviewed by Stokes et al. (ADS 31 470 1935) Emotional strain is more fatiguing than digging ditches. Urticaria when due to nervous exhaustion may respond to thyroid or ACTH. Frustration is *especially provocative (Saul and Bernstein* PsychosomM 3 349 1941) See Blitz (NYSJM 39 1309 1939) Kaywin

(PsychosomM 9: 131 1947) Attacks of urticaria in chronic cases were highly correlated with traumatic life situations, especially of resentment according to Graham and Wolf (J 143: 1396 1950)

Endocrine imbalance especially hypothyroidism, is by no means a rare cause of chronic urticaria Premenstrual exacerbations may respond to estrogenic substances, and endocrine balance should be established in any vexing case When endocrine medication is needed it is usually thyroid that helps the patient (Ravitch JCutDis 25 612 1907) If estrogenic substances are given to a patient with chronic urticaria and the patient becomes worse thyroid can be expected to prove helpful. The dose must of course be a correct one (see Acne treatment) Sensitization to the patient s own corpus luteum hormone was reported by Guy et al. (ADS 63 377 1951) and benefit was obtained by hyposensitizing injections of corpus luteum extract. See Geber (BJD 51 265 1939) Zondek and Bromberg (JAllergy 16 1 1945) Phillips (AnnIntM 30 2 364 1949)

Blood transfusion from a donor with urticaria resulted in a rash in the recipient whereas a later transfusion when the donor was not urticarial, did not (Tedstrom: JAllergy 5 303 1934)

Pathology —A wheal is a reversible acute inflammatory edematous lesion due to the action of a toxic agent which may reach the dermis from within or from without. Changes occur in papillary and subpapillary regions of the dermis and consist in vascular dilation with profuse outpouring of serum and white cells. The dilated vessels are filled with leukocytes. Throughout the area perivascular infiltration is prominent.

Diagnosis.—The wheal is a distinctive lesion A patient seen when wheals are absent shows perhaps macular erythema where lesions have faded and excoriations. The history of evanescent lesions, often called blisters by the patient is acceptable When urticaria has been identified, the diagnostic problem has commenced, not ended. A little scabies with much urticaria used to be a relatively common confusing picture.

Fluorescein given intravenously during an attack of urticaria is concentrated in the lesions, as demonstrated in ultraviolet light (Herrmann JID 7 210 1946) Concentration of bile pigment was noted in the urticarial lesions in a jaundiced patient by Derbes and Engelhardt (ADS 48 310 1943)

Prognosis.—An ordinary attack of acute urticaria is self limited and the lesions shortly disappear spontaneously or respond promptly to palliative antihistamine administration. Chronic urticaria usually proves to be a vexing tedious problem.

Treatment.—In acute cases occurring in persons who have not had hives before or have had attacks only a time or two one is not especially concerned with the cause which might be an unusual or contaminated food or a recently taken allergenic drug Palliation is generally simple using a light diet perhaps a saline laxative, tepid or cool baths with a cupful of baking soda to the tub of water phenolated calamine lotion, interdiction of any medicine not prescribed by the physician and an antihistamine drug of which my favorite is Chlor Trimeton, the dose for an adult being 4 mg every 4 to 6 hours, q s. to obtain relief. Capsules containing ephedrine 3/8 grain with Amytal 3/4 grain t.i.d. may be quite helpful. Excessive ingestion of caffeine is to be condemned, for patients who have not slept are likely to drink too much coffee which further interferes with the possibility of their obtaining rest See Forman (SouthMJ 44 11 1951) Subcutaneous injections of 0.5 cc 1 1000 epinephrine given as often as each 30 minutes may yield excellent relief Seldom indeed have I recommended intravenous injections of Benadryl though it can be so given (Goldman RockyMtMJ 44 1007 1947) or aminophylline (Turner JAllergy 20 307 1949) or procaine the dangers of which were pointed out by Waldbott (J 133 1301 1947)

Cerebral edema complicating skin allergy was relieved by intravenous hypertonic glucose by Murrell and Murrell (SouthMJ 43 950 1950) Laryngeal edema can force an emergency tracheotomy on the patient and the physician, who is obliged to respect urticaria as a dangerous disease

Chronic cases tax one's resourcefulness, sometimes considerably. While initial orders given to the patient are practically the same as in acute cases, the further steps in my practice include meticulous elimination of the possible etiologic influence of drugs (aspirin often enough), parasites (scabies, vesicular tinea, pediculosis, stool examinations), focal infections (teeth especially), endocrine imbalance (hypothyroidism especially), consequential anemia (iron and B_1 cure some cases), food allergy (not too common in fact, determined by elimination dieting), contactants and inhalants (soap, fabric finish, perfume, cosmetics occasionally) and psychologic stress.

The patient should receive a painstaking physical examination. The history must be adequate with respect to drugs (suspect vitamin pills, even contraceptive vaginal instillations, but penicillin is more likely), endocrine function, eating habits, the circumstances of exacerbations if urticaria comes occasionally rather than daily, and the possibility of emotional factors. Purposeful laboratory study must be undertaken. I like to have early in the case the red blood cell count, hemoglobin, serum total protein, blood sugar, urinalysis and stool examination. The white cell count and the proportion of eosinophilia are worth learning. More than once a gastric analysis showing no free HCl has provided the solution to the problem, in my experience. Since recognizing the importance of external parasites, drugs, foci of infection, endocrine factors and emotional influences, I have not failed, thanks to palliation with antihistamine drugs and sometimes cortisone, to manage successfully the large majority of my patients.

The detection of food allergens can be accomplished by the method of Winston and Sutton (Pract 160: 347, 1948). A single simple food, not a mixture of foods, is tested by eating it and waiting until the following meal to see if it has caused urticaria. Water, cane sugar, and noniodized salt are permitted freely, and rice, oatmeal, beef, beets, milk, and bread are tested at successive meals. A food that has been tested and is not followed by urticaria may thereafter be eaten right along. Thus, the number of foods which may be selected for the next meal rapidly increases. When urticaria follows the eating of a food, that food is tentatively considered to be an allergen and is not eaten again for one week. If urticaria follows a food upon retesting, it is considered proved to be an allergen. No new food is tested until the urticaria subsides. An antihistaminic of the tripelennamine hydrochloride type may be given to suppress the urticaria that may develop. The patient is given daily a list of the foods tolerated, those suspected upon initial testing, those proved causative upon retesting, and the new foods to be tested. This method, in contrast to skin testing, tests foods by eating them in the manner in which they are normally encountered. The specific ingested allergen is identified with precision, avoiding the uncertainty of the multiple choice elimination diets. The use of undiluted food extracts for skin testing and the elimination of all positively reacting food items was recommended by Kahn and Grothaus (SouthMJ 33: 1066, 1940). Food allergy is an unusual cause of urticaria, I believe. Manipulations of the menu were disappointing therapeutically to Sheldon et al. (JAllergy 25: 525, 1954).

Among various internal remedies Sutton Sr. found a cascara and bile salt preparation valuable. A pancreatic extract lacking insulin (Depancol, for example) may relieve at least while it is being given (Markel: ADS 39: 992, 1939). Calcium is commended by some but not by me. Epinephrine is best given in small doses frequently repeated until relief is obtained. Ephedrine often proves helpful. Wise (YBD 1936, p. 6) recommended pilocarpine in 1% aqueous solution, giving 3 drops first and increasing to 20 drops t.i.d., trying atropine later if this fails. The injection of a foreign protein, such as typhoid bacterin, sometimes proves beneficial (Traub: ADS 40: 368, 1939). Dilute hydrochloric acid, 30 drops t.i.d. with water, may help. Nicotinic acid was claimed to have cured some cases and to have caused others (Chambers and Bernton: JAllergy 15: 141, 1944). Vitamin K, 5 mg. q.i.d. the first day and t.i.d. on the second and third days, gave good results in three-quarters of 50

cases so treated by McInnes (SouthM&S 108 105 1946) Uritone (methenamine) 2 Gm intravenously once daily has been highly recommended (Littlejohn SouthM&S 101 463 1939) Cream of tartar (potassium bitartrate) half a teaspoon t.i.d. recommended by Grandma is not to be scorned

Cortisone acetate 25 mg t.i.d. or q.i.d., is especially helpful in cases of drug allergy and in those patients whose urticaria resembles serum sickness or erythema multiforme, and in patients suffering from emotional exhaustion ACTH sometimes works better than cortisone

Histaminase (Torantil) may be given in 5 unit enteric-coated pills, 2 or more tablets each 2 hours, sometimes with good effect on the hypothesis that urticaria is due to histamine and that the ingestion of the histaminase does away with it In 35 cases, Laymon (MinnM 25 466 1942) reported 21 cures with daily doses varying from 60 to 120 histamine-detoxifying units.

Chronic urticaria was attacked by Burgess (BMJ 1 662, 1939) by a program which included elimination of focal infection elimination of foods to which the patient is sensitive investigation of psychologic troubles, treatment of dyspepsia with hydrochloric acid, the administration of glucose and calcium and some method of desensitization such as autohemotherapy

Local applications which may alleviate the itching include carbolized calamine lotion with or without 1 to 3% of alcoholic solution of coal tar saturated aqueous solution of sodium carbonate or bicarbonate or of borax isotonic baths of sodium chloride ammonium chloride or magnesium sulfate and applications of vinegar Salves are not satisfactory Medicated soap woolen garments, and irritating local applications are among the things to be avoided. The relief of fatigue and irritability is usually important Interdiction of coffee and the administration of aspirin are serviceable measures. Some patients find no lasting relief despite every effort.

FOREIGN BODY GRANULOMAS

Responses of mesodermal tissues to substances gaining access to them in various ways are of basic interest in the comprehension of inflammation (q v) A number of cutaneous lesions depend on such phenomena.

Tissue Reactions to Lipids.—Mesodermal reactions to injections of olive oil cod liver oil and their fractions were investigated by Hass (APath 26 956 1938) Reaction to the whole oil was mild with olive oil, and some of it remained in situ unchanged after 3 weeks. With cod-liver oil however the reaction was inflammatory and none remained unaltered in situ after 3 weeks. The glycerol fractions provoked little reaction, but fractions of cod liver oil were more irritating than those of olive oil Nonsaponifiable fractions caused severe reaction, and sloughs resulted unless the dose was kept small destruction resulted mainly from the alcohol-soluble compounds of the nonsaponifiable fractions of both oils. Fatty acids provoked the most intense reactions of the lot and those from cod liver oil were more irritating than those from olive oil. Reactions to methyl esters of *saturated* acids were comparatively mild, for the material was rapidly hydrolyzed in the intercellular environment, acid crystals appeared in the zone and giant cells applied themselves to these foreign bodies. To methyl esters of *unsaturated* acids of cod liver oil the reactions were more intense and there formed in the intercellular regions quantities of semisolid, amorphous matter which served as a potent stimulus to the formation of giant cells. *Intensity of inflammatory response increased with increase in average unsaturation* of the lipoid fraction tested Epithelium partook of the reaction for cysts developed as a defense mechanism deriving demonstrably at times from the epidermis or from the accessory structures, so as to engulf the fibrotic zone of connective tissue reaction.

When unassimilable substances are injected, there occurs early an influx of polymorphonuclear leukocytes which subsides in a few days (Tompkins AmJSyph 20 22, 1936) Monocytes appear the third day after the injections they enlarge and become more active Clasmatocytes appear in 5 days, then epithelioid and transitional forms within 8 days. Giant cells of foreign body

and epithelioid types are present after about 10 days. When lecithin, which is assimilable is injected, focal increase in macrophages occurs but degenerative changes do not, and epithelioid and giant cells do not appear. Assimilable lipoids are removed from zones without residual modification of the tissues.

Reactions to fractions isolated from tubercle bacilli were described by Sabin (PhysRev 12 141 1932) see also Tuberculosis pathology. The phosphatid fraction is phagocytosed by monocytes, degrades them and provokes tubercle formation. The unsaponifiable waxes stimulate the production of undifferentiated connective tissue irritate and call forth leukocyte infiltration wax is the acid fast material. The acetone-soluble fraction, being a mixture of fatty acids, calls forth varied responses. Tuberculoprotein is provocative of plasma cell infiltration. The polysaccharides are chemotactic and toxic to neutrophile leukocytes and provoke necrosis and hemorrhage.

Tissue reactions of mice to killed tubercle bacilli appeared the same as to live bacilli and specific sensitization did not alter the histologic reaction, reported Pagel (AmRevTuberc 46 295 1942) although live bacilli induced eosinophilic granules in foam cells, while killed bacilli did not.

Intradermal injections of staphylococci in sensitized rabbits produced epidermal cysts and follicular comedones (Hopkins et al. JID 16 339 1951)

Petrolatum is capable of provoking acneic follicular dermatitis due to foreign body reaction (see Oil Acne)

Paraffinoma (Oleogranuloma) may follow injections of paraffin beneath the skin for cosmetic purposes. Such pseudoneoplasms develop in a fairly large percentage of the cases thus treated, but a considerable period of time from 6 months to 5 years, generally elapses before their appearance. The lesions are rounded or oval in outline and firm in consistency. In color they range from yellowish to reddish or purplish. Symptoms are practically absent but the deformity is sometimes extreme (Mook and Wander ADS 1 304, 1920 Gougerot BSocfrançD 41 1770 1934 Calnan BJD 65 565 1953) Similar lesions develop following the injection of paraffin mixtures employed as vehicles for mercurials, camphor and other medicines (Brown et al JLabClinM 29 259 1944 Conrad et al J 121 237 1943) Injection treatment of hernia may cause them (Whittaker PSMMC 11 22, 1936)

In paraffinoma the foreign substance is encapsulated in fibroconnective tissue. Cavernous spaces, surrounded by smaller cavities, give the area a Swiss cheese appearance. The mass comprises granulation tissue like that of early tuberculosis before caseation. Oil droplets are encased in giant cells.

Paraffin oil in the tissues shows vivid turquoise fluorescence under Wood's light (Cornbleet and Popper ADS 47 637, 1943) Tissue reactions to foreign lipids have been studied experimentally by Hass (APath 26 956 1938) Hirsch (AmJClinPath 9 279 1939) Tompkins (BullJHH 70 55 1942) The beeswax and peanut oil of penicillin injections may cause a pseudocellulitis presumably due to foreign body reaction (Lesnick et al. Surg 24 989 1948)

In diagnosis one must distinguish fibroma erythema induratum and keloid. The location color shape and history suffice for recognition.

The lesions progress to a certain point and then remain stationary. It was once thought that the tumors were harmless, but carcinoma and sarcoma have arisen in them. The only satisfactory treatment is total excision. X ray fails to benefit the condition.

Grease Gun Finger—An accident with a high pressure grease gun may force oil into the hand through a tiny puncture. Surprisingly painless at the time of the accident, swelling and numbness being the immediate symptoms, *pain follows and gangrene is likely*. The grease cannot be squeezed from the part even after incision (Byrne J 125 405 1944) See Smith (J 112 907 1939) Brooke (BMJ 2 1186 1939) Bell (BJPlasticSurg 5 138 1952)

Oil Blast Gangrene—Fine droplets of unassimilable oil may be forced into the skin under high pressure by a Diesel engine if a valve is opened during the operation of the machine and the body intercepts the blast of oil

Fig. 171.—Paraffinoma.

Fig. 172.—Paraffinoma, illustrating "Swiss cheese" structure.

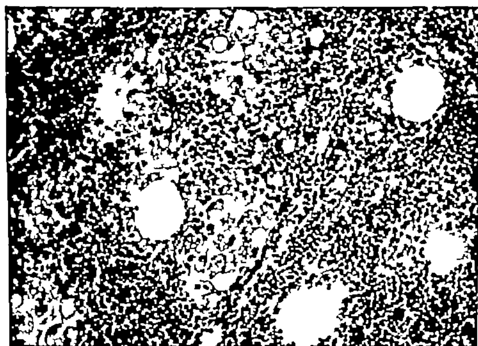

Fig. 173.—Phagocytosis of oil globules which have reached a lymph node from paraffinoma experimentally produced in a monkey (Dr Fred Weidman)

droplets. Swelling pain and likely gangrene result. Prompt free incision into the infiltrated tissue may prevent sloughing. See Dial (J 110 1747 1938) Hughes (J 116 2848 1941)

Air Blast may cause an injury analogous to the percutaneous injection of oil under high pressure though subcutaneous emphysema with typical 'crackling' swelling generally recedes spontaneously within a few hours (Whitewell BJIndustM 1 179 1944 Desmond BMJ 1 842, 1947)

Metallic Foreign Bodies may be carried into the skin by *showers of sparks* from spot welding (Reynard and Smith BMJ 1 843 1947)

Lipogranuloma (Fat Necrosis) is characteristically due to trauma with resultant necrosis of underlying adipose tissue and the formation of benign inflammatory tumors. The lesions are generally of hazelnut to walnut size, and somewhat raised above the skin level. They are purplish or reddish at first firm but becoming cystic. The breast is a common location and the *tumor must be distinguished from malignancy* (*Dunphy ASurg 38 1 1939* Livingston and Lederer SGO 68 230 1939) The scrotum was the site in 3 fat little boys noted by Hinman and Johnson (JUrol 41 726 1939) Trauma accidental or surgical is the most frequent causative factor but a history of trauma was present in only 41 of 110 breast cases reviewed by Adair and Munzer (AmJSurg 74 117 1947) Attachment to the skin existed in many of these and the resemblance clinically to cancer was notable in 45% positive diagnosis requires gross and microscopic examination of excised tissue.

The course of the lesion is chronic with the likelihood of rupture through the skin and the discharge of sterile oily and caseous material. Histologic study reveals foreign body reaction with numerous phagocytes and giant cells. Treatment should be expectant in early cases which may resorb. Excision, a speedy and satisfactory procedure often becomes necessary. If spontaneous healing takes place it is sluggish to do so, and the lesion may be called a *sclerosing lipogranuloma* (*Smetana and Bernhard SouthMJ 43 702, 1950*) See Edit (J 112 631 1939) Smetana and Bernhard (APath 50 296, 1950) Opeskin (SouthAfrMJ 25 778 1951)

Refrigeration may produce adiponecrosis of the face with circumscribed benign infiltration, which disappears spontaneously in a few weeks (Haxthausen BJD 53 83 1941) Such cases have occurred in military aviation

Fat Necrosis in the Newborn.—Fat necrosis such as occurs in adults may also occur in infants. *Gray (BJD 45 498 1933) distinguished (1) edema* neonatorum, which is true edema, perhaps from hunger and hypoproteinemia (2) scleroderma which is true scleroderma and very rare (3) induration secondary to fatal disease described as preagonic cadaveric induration of the celluloadipose tissue and (4) fat necrosis which is a benign induration. This disease is a self limited, localized process affecting areas which are usually symmetrically situated over the bony prominences. The patients, born after difficult labor as a rule, are usually well nourished and of large size differing from patients with sclerema (q v) which affects debilitated infants and generally proves fatal

The lesions become manifest in 2 to 20 days after birth as deep-seated, subcutaneous indurations. They range in size from small nodules to large areas covering the greater part of the back and buttocks, and appear to be slightly elevated above the niveau. The color is usually bluish red at the outset, suggesting at times a phlegmonous process. This disappears gradually the skin assuming its normal color even before the lesions have softened and disappeared. The surface of the skin is usually smooth. The lesions are not tender. The induration of the subcutaneous tissue dose not pit on firm pressure nor does it allow the skin to be pinched up in folds. The hardness resembles that of wood or rubber. The areas have fairly well-defined borders, and small nodular lesions are usually freely movable. Fluctuation has occasionally been noted. The favorite sites are first the back, then the cheeks,

arms, thighs, and buttocks. Almost every part of the body may be affected except the palms and soles, abdomen, inner aspect of the thighs, and axillae. An exceptional case with internal adipose tissue involvement was studied by Zeek and Madden (APath 41 166 1946) The course of the disease includes a period of evolution and one of involution both processes may be present simultaneously Softening and absorption of the indurated areas begin from the fifth to the sixth week and are complete as a rule in 3 or 4 months. The

Fig. 174.—Sclerema neonatorum, showing fat necrosis in deeper part of panniculus (Dr A. M. H. Gray)

Fig 175—Sclerema neonatorum, Sudan III stain, showing disintegration, liquid fat and cellular infiltration of fat globules. (Dr A. M H Gray)

Fig 176.—Sclerema neonatorum. Subcutaneous tissue shows clefts underneath of fatty acid crystals, giant cell response to altered fat and rosettes of crystals within some giant cells. (Patient of Dr Patricia Hart Drant photomicrograph from Dr Fred Weidman.)

lesions disappear completely and only in rare instances do they leave any trace such as slight atrophy The general health usually remains good, the temperature is not altered and there is a steady normal increase in weight.

Diagnostic criteria of this well-defined disease are solidity of fat during life typical histologic structure including calcification and anisotropy of the crystals in frozen sections of fat roentgen demonstration of calcification; excess of calcium, phosphorus and cholesterol in the fat and raised melting point of the fat (Harrison and Simpson quoted by Belisario AustralJD 2 94, 1953)

Pathologic changes comprise mainly necrosis of fat and epithelioid and giant cell reaction thereto. Protoplasmic meshes surround spaces formed by elongated needlelike crystals of neutral fat which is dissolved in preparation. In the fat cells there are similar crystals in rosettes or sheaths. Some giant cells are filled with crystals radiating from the center. There is evidence (McIntosh et al. AmJDis Child 55: 112, 1938) that infant and adult fats are chemically different: in the newborn the melting point is higher than normal body temperature because infantile fat is lower in olein content than adult. Obstetrical trauma is the main precipitating factor in infantile fat necrosis, and the triglycerides are altered mainly in their physical aggregation for in scleredematous tissues no lipase is present which is demonstrably capable of hydrolyzing them. Tozzati and Hansen (PSExpB 46: 325, 1941) reported that the abnormal fat is largely palmitic and in sclerema contains an excess of saturated fatty acids of low melting point and molecular weight.

See Fox (ADS 27: 237, 1933), Lichtenstein and Rader (SouthMJ 30: 527, 1937); Cornbleet and Rattner (ADS 40: 829, 1939); Reich (ADS 45: 342, 1942); Davis and Brain (JIJD 59: 312, 1947); Hughes and Hammond (JPed 32: 676, 1948); Nooljin et al. (JID 12: 331, 1949); Keiser (abs J 152: 1484, 1953) case attributed to DDT intoxication; Brain (JIJD 65: 373, 1953) case resolved in 3 months; Collins et al. (AnnSurg 138: 880, 1953) followed hypothermia used in surgery for congenital heart disease.

Indelible Pencil Injuries.—The basic aniline dyes used in making the leads of indelible pencils may provoke inflammatory necrotizing and foreign body reactions, the seriousness of which is partly dependent on their location. Ocular injuries have frequently been reported and in some cases the eye has been destroyed. The hands are especially liable to the injury. The point of the pencil is accidentally introduced within the tissues and perhaps broken off. The result depends on the chemical nature of the lead: toxicity increases among the aniline dyes from green, yellow, red and brown to blue, methyl blue being sufficiently poisonous to cause systemic reactions such as diarrhea and icterus. The acidic and neutral dyes cause little inflammation, but the basic ones do. Within an hour after the injury irritation is apparent, and within 24 hours there is evidence of necrosis, which is aseptic and lacking in leukocytes. The central semiliquid material is stained with the dye, and sloughing may follow or the necrotic matter may become walled off so as to form a pseudocyst, or perhaps it becomes merely a mass of colored granulation tissue. Since the dye dissolves slowly and diffuses slowly the lesions may persist for weeks or months, sometimes undergoing spontaneous acutely inflammatory exacerbations. Best treatment if it is anatomically applicable, is excision. To attempt to remove the fragile material with a forceps through a small hole results in crushing it and in the production of a violent exacerbation of the lesion. Mere incision and drainage are followed by recurrences of symptoms (Mason and Allen: AnnSurg 113: 131, 1941, hand cases; Srokolik: AmJOphth 10: 515, 1927, eye cases).

Silica and Silicates, notoriously damaging to pulmonary tissues, also cause cutaneous lesions. Talc is magnesium silicate. Ground into the axillary skin by the pressure of a brace it caused a suppurative tumor in the case of deSavitsch (MAnnDC 9: 169, 1940). Tissue reactions to subcutaneous injections of quartz were studied by Irwin and Gibson (CanadMAJ 39: 349, 1938). Talc on surgeons' gloves may provoke serious trouble (Lichtman et al. SGO 83: 531, 1946) and gray nodules of talc granuloma at edges of old scars were described by Flenberg (APath 24: 36, 1937). Talc granuloma of the eye following surgery for correction of muscle imbalance was observed by McCormick (AmJOphth 32: 1252, 1949).

Silica granuloma developed in the cheek of a patient of Epstein (AD 71: 24, 1955) several years after an accident resulting in the introduction into the skin of a splinter of glass. The histologic reaction was sarcoidal and cortisone had a promptly beneficial therapeutic effect. Edema and inflammation since they appear in such cases long after implantation of the foreign substance may be due to allergy, the initial stages of which seemed recognizable to Epstein et al. (AD 71: 645, 1955). Silica granuloma appeared in a young woman 11 years after she scraped her knees on gravel, reported Crossland (AD 71: 457, 1955) who found in the sarcoidal tissue reaction the doubly refractile crystals, demonstrable under polarized light, which suggest, but do not identify silica. Positive identification requires roentgen spectrography. Papular lesions of the face followed injury in an explosion in the case of Arzt (JID 24: 165, 1955).

Potassium bitartrate (Seelig: J 128: 113, 1943) or heated gelatin powder (Correll and Wise: Sci 105: 570, 1947) may be substituted for talc on surgical gloves. Talc is an irritant ingredient of a powder intended for treating dermatitis of the feet if the epidermis is broken, for silicates provoke mesodermal tissue reaction.

Asbestos spicules may provoke tiny warts on the fingers (Alden and Howell: ADS 49: 31., 1944). An injection used in treating hernia by sclerosis contained silica and caused 4 cases of granuloma reported by Kaplan (J 151: 1163, 1953). See also Traumatic dermatoses. Dermatitis Venenata, industrial, glass wool.

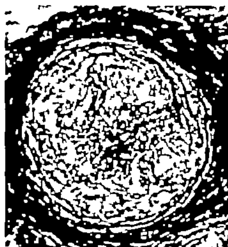

Fig. 177, 178, and 179.—Beryllium granuloma (Nichols and Dominguez: J 140: 855, 1949). Fig. 177 shows location of pathologic lesions deep in dermis. Fig. 178 shows an epithelioid cell nodule at high magnification. Fig. 179 shows the sarcoidal granulomatous process and its encapsulation.

Beryllium Granuloma.—Cutaneous exposure to beryllium can cause (1) contact dermatitis, (2) ulcers from implantation of crystals of beryllium sulfate, lesions which do not heal until the substance is removed, and (3) sarcoidal lesions in cases either of pulmonic berylliosis or of cutaneous in

jury with contaminated articles, such as broken fluorescent light tubes. Dusky purplish papules of from 1 to 3 mm diameter on the hands of a worker whose job it was to coat fluorescent light tubes with a liquid containing beryllium oxide and who also had disseminated pulmonary fibrosis, were noted by Pyre and Oatway (ArizM 4 21 1947) Similar lesions had been seen by Hardy and Tabershaw (JIndustHyg 28 197 1946) and the tuberculoid microscopic structure was described by Grier et al (JIndustHyg 30 228 1948) Lacerations with broken fluorescent bulbs may result in nodules and ulcerations closely simulating Boeck s sarcoid and the view that these lesions are due to beryllium and can be cured only by wide excision was stressed by Coakley et al (J 139 1147 1949) The structure of the pulmonary fibrosis and of the skin nodules is the same (Nichol and Dominguez J 140 855 1949)

Numerous cases have been recognized (Dutra ADS 60 1140 1949; Neave et al: ADS 61 401 1950; Gerrie et al: CanadMAJ 62: 544 1950 Lange et al: SouthMJ 44: 36 1951; Curtis: ADS 64: 470 1951 DeNardi et al: AIndustHyg 8: 1 1953) Since beryllium minerals are widely found, explosions may result in these granulomas, presumptive cases of which not recognized at the time they were reported include those of German (AmJClinPath 10: 45 1940) Sommerville and Milne (BJD 62 105, 1950) and Lohe (DWehn 1 1: 82, 1950)

The usual treatment is excision Cortisone ointment was accredited with a cure by Fisher (ADS 67 523 1953)

Beryllium granulomas of the skin were experimentally induced in hogs by Dutra (AIndustHyg 3: 81 1951) ACTH therapy yielded good improvement in a case of pulmonary fibrosis (Kennedy et al CanadMAJ 62 426 1950)

Lycopodium may cause foreign body granuloma The spores, introduced by means of the surgeon s gloves into surgical wounds, provoke inflammatory reaction and masses of tuberculoid tissue at the site of the operation. Persistent sinuses as well as masses of adhesions may be the result. Such sinuses must be distinguished from tuberculous and actinomycotic lesions (Antopol and Robbins J 109 1192, 1937)

Surgical Suture material causing granuloma has interested many authors (Orr ASurg 54 37 1947 Meade and Brewster AmJSurg 45 419 1939) The lesions are small sterile abscesses surrounded by dense fibrous tissue requiring sharp dissection for their removal

Plant Spicules as Foreign Bodies.—See trichrome dermatitis (p. 98)

Various Foreign Bodies have been reported as causing skin lesions hair impacted in the foot like a splinter (Schulze ADS 61 668 1950) finger and hand lesions from picking chickens, an industrial hazard (QMN: J 115 76 1940) a furuncular lesion where a sewing needle migrated (Ronchese Rhode IslMJ 32 264 1949 see Rogers Lancet 2 535 1942 on migration of foreign bodies) sulfonamide powder in a wound causing a chronic sinus tract and granulomas (Williams CanadMAJ 59 50 1948) tissue reaction to Gelfoam (Taylor and Kaplan ADS 62 548 1950) thorium dioxide injected into a breast causing a granulomatous tumor (Mora J 115 363 1940) See Hair Cyst.

DERMATOSES DUE TO VIRUSES

Viruses are organized living bodies which are usually invisible by ordinary microscopic methods of examination. They have a diameter of less than 0.[illegible] μ and can often be filtered through candles and membranes impermeable to ordinary bacteria. They have not as yet been cultivated in cell free media, but they multiply freely in the presence of susceptible cells in vitro or in vivo. They frequently invade one particular species of host, and tend to affect one particular tissue giving rise there to characteristic intracellular inclusion bodies, and they cause latent or overt infection followed as a rule by lasting immunity. The law of obligate communicability of virus infections was expounded, along with an able review of the nature of the agents, by Rivers (BullNYAM 14: 383, 1938). In the human being they produce diseases of as many varieties as bacteria do with comparable properties of communicability. Since viruses do not live free, but must exist intracellularly their ecology and epidemiology differ in important and characteristic ways from their bacterial analogues.

Viruses may be thought of as microorganisms, evolved by parasitic degeneration from larger organisms, manifesting reproductive activity, variation, survival, mutational and heritable faculties and interaction with their host (Burnet: Virus as Organism, Harvard U Press, 1945): "Every virus particle like any other organism derives by genetic descent from some similar particle." Elementary bodies of viruses are grouped within inclusion bodies, which are intracellular, in fowl pox, vaccinia, and molluscum contagiosum, while the virus of herpes simplex invades and spreads in axis cylinders of peripheral nerves. Many human pathogens can be cultivated and some cannot, in the chick embryo (Goodpasture: AnnIntM 13: 1, 1939).

A number of viruses, including that of herpes zoster for the first time, were cultivated on human skin grafted onto the chorioallantois of the chick embryo (Goodpasture and Anderson: AmJPath 20: 447, 1944; Blank et al.: PSExpB 69: 341, 1948).

See Sanders: APath 28: 541, 1939 (methods of cultivation); Ebert and Otsuka: ADS 48: 438, 1943 (review); Lennette: Sc 98: 415, 1943 (size, structure, chemistry); Rivers: Sci 95: 107, 1942 (immunology); Beveridge and Burnet (Cultivation of Viruses and Rickettsia in the Chick Embryo, HMSO, London, 1946); Schultz and others: J 136: 1075, ff., 1948 (Virus diagnostic laboratory); van Rooyen and Rhodes: Virus Diseases of Man, Nelson, 1948 (monograph); Bedson et al.: Virus and Rickettsial Diseases, Williams & Wilkins, 1950; Smith: Introduction to the Study of Viruses, Pitman, 1950 (fascinating reading 106 pp.); Markham: ADS 41: 261, 1940 (viruses not found in pityriasis rosea, psoriasis, lichen planus, lupus erythematosus, erythema multiforme, mycosis fungoides); Fisher: JID 8: 123, 1947 (chick embryo inoculations negative with warts, molluscum contagiosum, seborrheic keratoses, dermatitis herpetiformis, psoriasis, lichen planus, pityriasis rosea); Hillman: ADS 61: 210, 1950 (virus nature of pemphigus and dermatitis herpetiformis unproved); Rivers et al. (Viral and Rickettsial Infections in Man, Lippincott, 1952, p. 719); Rhodes and van Rooyen (Textbook of Virology, Williams & Wilkins, 1953, p. 441); Blank and Rake (Viral and Rickettsial Diseases of the Skin, Eye and Mucous Membranes of Man, Little, Brown & Co., 1955).

EXANTHEMATA

Under this title may be grouped the acute epidemic diseases with skin lesions which are important features of the diseases themselves and of especial clinical importance in their recognition. Several members of this group are of virus causation: smallpox, varicella, measles and German measles. Scarlet fever is streptococcic. See also Fourth, Fifth and Sixth Diseases, and Erythema symptomatic.

SMALLPOX

Symptoms.—The incubation period of variola varies from 8 to 12 days, and is usually about 10. The abrupt onset includes characteristically fever, intense frontal headache, severe lumbar backache and vomiting. The eruption is first visible on the third or fourth day. It begins as a macular erythema, on which develop shotty papules in a few hours. These soon vesiculate and they become pustular by the fifth day. There is *only one crop*, the lesions of which mature in the order of their appearance, earlier on the face and arms. The papules are usually discrete, but on the face confluence may occur, and the extent of the eruption on the face is a measure of severity. The vesicles are tough, deep-set, multilocular and umbilicated. The pustules show less definite umbilication, rest on hyperemic bases, and are smoothly rounded and of uniform size.

Usual Course.—Forehead and flexural surfaces of wrists are usually involved first. Face, forearms, palms and soles seldom escape. Mucosae are generally involved. The abdomen is usually least affected, and the eruption on the trunk is discrete. *The initial high fever falls with the appearance of*

Fig 180.—Smallpox, discrete eruption at its height. (Dr S. D. Sneltzer)

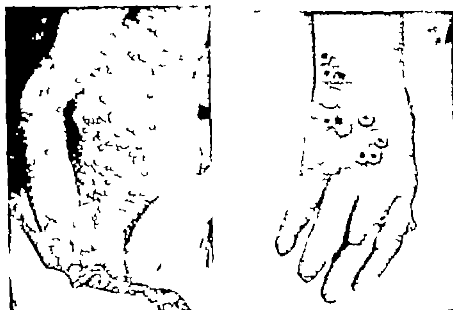

Fig. 181.—Smallpox (Dr Jay F Schamberg)
Fig. 182.—Smallpox on seventh day of eruption (Dr Jay F Schamberg)

the eruption concomitantly with abatement of the constitutional symptoms, but rises on the eighth or ninth day at the maturity of pustulation. On the ninth or tenth day of the eruption, many pustules rupture spontaneously or as a result of slight trauma. The lesions then begin to undergo desiccation, and

form dry brownish crusts. Shedding extends over a period of a month or more. Scarring which is depressed and atrophic depends on the depth of the lesions and the extent to which destruction of connective tissue occurs.

Secondary infection, as well as self inflicted trauma abet damage done by the disease.

Figs. 183 and 184.—Smallpox.

Fig. 185.—Smallpox, confluent on face. (Dr. Neilson Campbell.)

Sulfonamides may help (McCammon J 112 1936 1939) and penicillin has been reported to shorten the course of the disease (Jeans et al Lancet 2 44 1944 Weeks and McClelland USNMBull 47 707 1947)

The virus survives for several months at least in the dry crusts (Downie and Dumbell Lancet 1: 650 1947)

Varioloid is smallpox which has been modified by previous vaccination and partial immunity. It is generally milder in every way. The lesions are

fewer smaller and of briefer period of incubation, and there is less scarring Varioloid may be manifested by fever only (Napier and Insh Lancet 2 483 1942) On the other hand, immunity from vaccination may have fallen so low that more or less classic smallpox occurs (Conybeare Pract 157 191 1946)

Alastrim (Variola Minor) is milder than classic smallpox (variola major) but other diagnostic differences are not clear cut The inclusion bodies were thought to be larger and fewer than those in smallpox giant cells and ami totic figures were common and the reaction to Paul s test weaker in alastrim

Fig 186—Confluent smallpox with petechia in early stage (Drs. W tson Campbell and C S. N wman.)

Fig 187—Pemphigoid eruption in smallpox, a are phenomenon (D Sam E. Se hier)

according to Torres (ProcRoySocM 29 1325 1936) Cross immunity was not complete in experiments with monkeys (Horgan and Haseb JHyg 39 615 1939) The disease is less disfiguring than smallpox wrote Hay (SouthAfrMJ 12 639 1938)

Diagnosis of Smallpox.—In chicken pox prodromal symptoms are brief and comparatively mild The eruption comes early is polymorphous, appears in successive crops for 3 to 5 days, matures rapidly and involves first the cov ered surfaces rather than exposed areas. Its vesicles are monolocular They are superficial fragile and rarely umbilicated Each rests on a wide irregular erythematous flare Cases of dermatitis medicamentosa particularly from

iodide and bromide, do not as a rule have severe constitutional symptoms and the lesions do not involve the hands and wrists by predilection. History is important. In the pustular syphilid the papules are not hard or shotty. The varioliform syphilid prefers the perioral region especially in Negroes. There is no tendency to vesiculation. Constitutional symptoms are comparatively mild. There are general lymphadenitis, mucosal involvement and positive serum reaction. The usual diagnostic error made even by experts is to mistake smallpox for chicken pox (Smith BMJ 1 179 1948). One should distinguish hemorrhage into the pustules of smallpox from purpura variolosa which is rapidly fatal. See Dept Preventive Medicine Leeds Univ (The Diagnosis of Smallpox Lumby 1951)

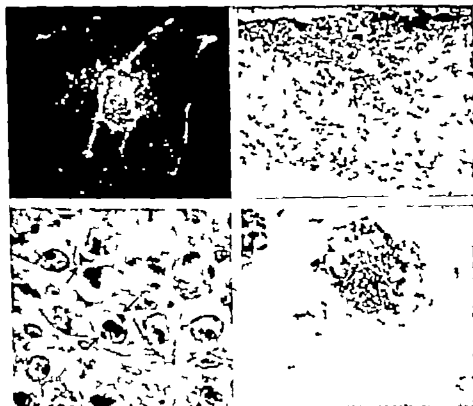

Fig. 188—Cultivation and demonstration of virus of smallpox (Buddingh AmJHyg 28: 130 1938)

Upper left Chorioallantois of chick embryo, actual size, showing gross alteration produced by inoculation with variola 72 hours previously. The unfixed, fresh specimen dark field photograph.

Upper right Chorioallantois, sectioned 72 hours after infection, showing inflammation of epithelium, proliferation, and vesicle formation.

Lower left Guarnieri bodies seen by high magnification of tissues shown at upper right.

Lower right Paschen bodies seen in and about the smear of an infected epithelial cell; 72 hour lesion prepared by the Morosow technic

The virus of smallpox causes a distinctive infection of the chick chorioallantois, which varicella does not (Buddingh AmJHyg 28 130 1938; Bohls and Irons: AmJPubH 32: 300 1942). Vaccinia and variola can be distinguished by chick embryo inoculation (North et al. MJAustral 1 437 1944)

A flocculation test utilizing a suspension of material from the lesions incubated with an antivaccinal rabbit serum, is both rapid and useful (Craigie and Tulloch Spec. Rpt. 156 M. Res. Council London, 1931)

A complement fixation test more sensitive than the flocculation test was described by Craigie and Wishart (CanadPubHJ 27 371 1936)

Scrapings from the bases of early lesions may be stained with Löffler's flagellar mordant and carbolfuchsin so as to demonstrate distinctive elementary bodies, larger than those of varicella (Van Rooyen and Illingworth BMJ : 526, 1944)

Fig. 189.—Accidental vaccination of hand.

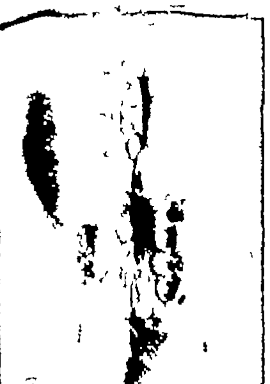

Fig. 190.—Vaccinia involving child's vulva. (Dr Hans H. [illegible].)

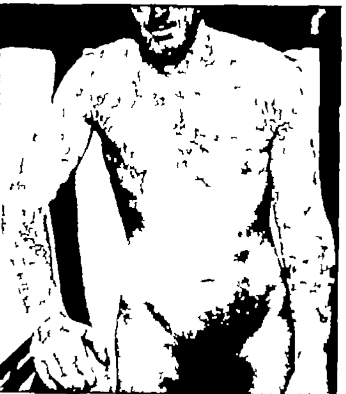

Fig. 191.—Generalized vaccinia, due to vaccinating a man who previously had eczematous dermatitis. (Dr Fred Weidman.)

Identification of the elementary bodies of variola and vaccinia, by microscopic means indistinguishable, can be made by electron micrography (Nagler and Rake: JBact 55: 45, 1948). Electron micrographs of the development l forms of vaccinia virus were published by Gaylord and Melnick (Sci 117: 10 1953).

PAUL'S TEST.—The content of the vesicopustules, scraped with a sterile knife onto a glass slide and dried for 3 days, is taken up with 50% glycerol in water and inoculated into the scarified cornea of a rabbit. Minute elevations of the corneal epithelium appear within 36 hours if the test is positive. Paschen bodies are found in these elevations. See Michelson and Ikeda (ADS 15 139, 1927); Paul (WienKlinWchn 60: 862, 1910); Guarnieri (AItalBiol 19: 193 1893), Paschen (ZtschrBakt 1 4: 89 1932) Amies (Lancet 2: 658, 1932) elementary bodies; Ebert and Otsuka (ADS 48 635, 1943).

Vaccination.—One applies a droplet of vaccine on the clean skin, which must be free of antiseptic (acetone may be used) the needle is pressed tangentially to the skin several times in such a manner that the point breaks the horny layer in an area some 3 mm. across and the lymph is allowed to dry. No dressing is necessary (Leake BHRpts 42 221 1927). The sole may be used for inoculation for cosmetic reasons, in infants (Cantor BMJ 2 1050 1953). Intracutaneous vaccination is feasible, using cultured vaccine virus (Rivers and Ward JExpM 62 549 1935). Vaccination of the newborn is satisfactory and safe (Donnally and Nicholson J 103 1269 1934). Vaccination during pregnancy is said to be safe (Bellows et al. PHRpts 64 319 1949) yet a fetus was born with generalized vaccinia 28 days after vaccination of the mother (Lynch ADS 26 997, 1932). See Crookshank (History and Pathology of Vaccination London 1889) and Downie (BMJ 2 251 1951) history.

COURSE OF NORMAL VACCINATION.—On the first day there is a traumatic wheal. Nothing is visible for a day or so then a tiny group of coalescing vesicles appears on a small zone of erythema. From the fifth to the ninth day the vesicle grows, and the area of redness extends. There is fever of 101° F to 102° F on the eighth and ninth days, with some malaise. The vesicle fluid is clear at first but becomes cloudy and eventually purulent. From the ninth to the twelfth day the zone of erythema spreads widely with thickening and induration of the surrounding skin after the twelfth day involution occurs with blackening shrinking and loosening of the crust at the periphery. The crust eventually drops off leaving a red and pitted scar which slowly pales and becomes atrophic (the Jenner reaction Gloyne J 122 395 1943). See Armstrong (PHRpts 44 1871, 1929).

INTRACUTANEOUS VACCINATION offers less opportunity for secondary infection and by its use one may secure a take in individuals who repeatedly fail to react to ordinary methods. It may result in generalized vaccinia or a nodular subcutaneous scar (Jacobs and Orris JPed 17 626 1940).

REVACCINATION.—An individual who has been vaccinated will respond to subsequent vaccinations sometimes in the same degree as to the first. Usually however the lesion appears sooner and involutes more rapidly. Revaccination is simple harmless, and dependably protective. It should be performed whenever real or suspected exposure to smallpox has been incurred. Heat killed inactivated vaccine induces responses simulating reactions of immunity this immediate reaction is a manifestation only of allergic sensitivity to the vaccinia virus and should not be mistaken for proof of immunity nor called the reaction of immunity according to Benenson (J 143 1238 1950).

VACCINIA is a highly infectious disease dangerous to unvaccinated individuals who already have dermatitis, and readily transmissible (Traub ADS 60 1021, 1949) causing even epidemics of cowpox (Hamburger abs J 138 782, 1948). Because of exposure to smallpox, patients of a dermatological ward, other than those with atopic dermatitis, were vaccinated by Dewar and Finn (GlasgowMJ 35 141 1954) only 4 complications occurred in 84 patients.

Generalized vaccinia is rare. It is likely however to complicate the ill advised vaccination of a person already suffering from some widespread dermatitis. Vaccinia complicating infantile eczema results in a typical syndrome resembling Kaposi's varicelliform eruption (Ellis: J 104: 1891 1935). Death

may result (Petersilge and Toomey APed 61 454 1944 Keidan et al. ADisChild 28 110 1953) Clinical differentiation from Kaposi's eruption is possible (Riley and Callaway JID 9 321 1947)

COMPLICATIONS include regional or generalized (multiple) vaccinal lesions, urticaria, purpura, erythema multiforme and secondary infection such as infectious eczematoid dermatitis (Bloch Lancet 2 504, 1942) rarely keloid (Skeer ADS 42 1165 1940) See Curth et al (JID 10 197 11 167 1948) Accidental vaccinia of the eyes can generally be avoided (Laval AOphth 24 367 1940) Vaccinia of the eyelid was apparently benefited by Aureomycin reported King and Forrest (J 153 31, 1953)

Bullous, pemphigoid complications were reported by Howe (JCutDis 21 254 1903) and by Mook (JCutDis 33 667 1915) and many of these such as have not been seen recently led to death The vesicobullous lesions seen by Mali et al (abs J 158 608 1955) involved the face, extensor aspects of the extremities, and upper trunk and disappeared in a week or two without scarring

Figs 193 and 194.—Vaccinia virus, above ×57 066, and below ×62,506 (Dawson and McFarlane, National Institut for Medical Research Nature 161 464, 1948)

Peripheral neuritis and radiculitis occasionally complicate vaccinia (Winkelman ANeurPsych 62 421 1949) Postvaccinal encephalitis, while rare killed 30% of 240 cases collected in Austrian experience 1925 to 1935 (Kaiser and Zappert Postvaccinal Encephalitis, Springer 1938) 27 cases were studied by Miller (ANeurol 69 695 1953) 16 of which were of encephalitis and 3 of transverse myelitis.

Paravaccinia (Red Vaccinia)—The lesion appears at the site of antismallpox vaccination as a red, rounded or cruciform papule with precipitous margins. The pea-sized papule reaches its peak of development in 10 to 14 days and regresses gradually passing through the color changes of a hemorrhage

MILKERS NODES AND SHEEP POX

Milkers Nodes.—Nodular inflammatory lesions infectious and transmissible from cow to man, and from man to man have been observed on the hands of milkers and others whose occupations bring them in contact with the usual source of the disease It may give rise to epizootics in stock, especially

in the summertime. Transmission to man may give rise to small epidemics. It produces characteristically granulomatous efflorescences at the sites of inoculation on the hands with or without lymphangiitis and secondary ex-

Fig. 194.—Orf. The lesion, contracted from a sheep, involves the eyelid. (Peterkin: BJD 49: 492, 1937.)

Fig. 195.—Milkers' nodule of finger: a Missouri case.

Figs. 196 and 197.—Milkers' nodules: lesions of fingers of one patient and thumb of another. Severe lymphocytic inflammation and subepidermal vesiculation of minor degree are seen in the photomicrograph. (Donnerve: BJD 49: 164, 1937.)

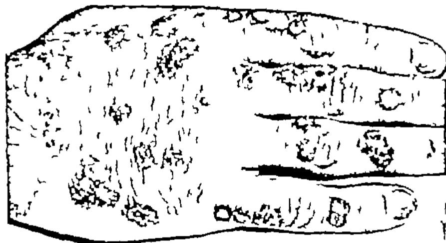

Fig. 198.—Orf. (Ferguson: BJD 63: 268, 1951.)

anthemas. The disease disappears without treatment in a few weeks, leaving no trace. Histologic study reveals an infiltration of lymphocytes and fibroblasts, with some polymorphonuclear leukocytes. There are no giant cells or

plasma cells. *The acanthotic epithelium shows some minute vesicles.* There are no inclusion bodies such as Guarnieri s. Paul s test is negative and patients take vaccinia in an ordinary fashion when inoculated (Becker J 115 2140 1940) The presumably causative virus has not been isolated (Nomland and McKee ADS 65 663 1952) but the disease was transmitted experimentally from man to man by rubbing biopsied material onto abrasions, by Sonck and Penttinen (ActaD-V 34 420 1954)

See Bonnevie (BJD 49 164 1937) Blank (ActaD-V 29 100 1949) Da is nd J nes (Lancet 2 1534, 1938), cowpox on hands f farmworkers; Findlay and Haig (BJD 64 451 1952) first report of South African cases, culti ation of infectious agent on chick chorioal lantois pathogenic *for cow not man*; Cawley *et al.* (SouthMJ 46 : 21 1953) *cases from* Vi ginia; Green (J 153 757 1953) calls attention to article in NOrlM&SJ 97 12, 1944 Sonck (ActaAllergol 4 241 1951) cases with secondary papulovesicular rashes on hands and forearms.

Orf (Sheep Pox, Ecthyma Contagiosum)—This contagious, pustular dermatitis of sheep known as orf to the farmers of Scotland is transmissible to man In the human Peterkin (BJD 49 492, 1937) described the initial lesion as a dark red papule which grows to the diameter of a threepence or half-crown. It is firm and practically painless. It resembles a huge molluscum contagiosum tumor with well marked central umbilication. The depressed center is covered with thin white skin and contains clear exudate The exudate gradually becomes purulent probably because of secondary infection, and granulations soon heap up If the lesions are treated with antiseptics, they tend to shrivel up in a few weeks without purulent discharge or granulations appearing See Schoch (ADS 39 1040 1939) Nomland (ADS 42 878 1940) Kingery and Dahl (ADS 51 359 194) Wallace (BJD 59 379 1947) Wheeler et al. (AD 71 481 1955) believed ecthyma contagiosum and sheep pox due to distinct viruses.

Scabby mouth of sheep a vesiculopapular eruption usually confined to the lips and surrounding tissue, has long been known in Queensland, Australia. This *can be transmitted to man* (Barrack AustralJD 1 135 1951) The infection in a man was successfully inoculated into a sheep and smears from the vesicles in the animal showed a virus (Lloyd et al. Lancet 1 720 1951) Isolation of the virus of orf and demonstration of its identity with that of contagious pustular dermatitis of sheep were claimed along with experimental transmission of the infection to man, by Blakemore et al. (BJD 60 404 1948)

Diagnosis.—The diseases of this group closely resemble one another Peterkin distinguished orf from milkers nodes by the fact that the lesion of orf in man is usually single and much larger than the lesion of milkers nodes, *is notably umbilicated does not cause lymphangitis such as often is seen in* milkers nodes, and in healing always passes through a stage of resemblance to granuloma pyogenicum Foreign body lesions due to hairs embedded in the skin of a milker s fingers are differentiated, such lesions being called milker s panaritium (Preser ZentralblChir 35 28 1908) Symmetrical calluses on the thumbs from milking by the Swiss method are plainly distinct from milkers nodes.

CHICKEN POX

Symptoms.—The period of incubation of varicella ranges from 11 to 24 *days, averaging about 17 Droplet infection is the method of spread,* and the disease is readily communicable Infectiousness is slight after the sixth day of the rash (Gordon and Meader J 93 2013 1929) The stage of invasion may be marked by some pyrexia, headache and malaise, but these symptoms are often altogether lacking Lesions usually appear in crops. Trunk, face and scalp are the sites of predilection. Volar lesions are only occasionally present. The eruption is at first macular and erythematous, and vesicles and vesicopapules develop in the centers of these areas within a few hours. The vesicular lesions are pinhead to pea-sized rounded, dome-shaped, monolocular and translucent with or without pinkish red hyperemic areolae. *The typical efflorescence of chicken pox resembles* a dew drop on a rose

Fig. 199.—Chicken pox. (Dr. J. F. Schamberg.)

Fig. 200.—Chicken pox. (Dr. E. Wood Ruggles.)

Fig. 201.—Chicken pox.

petal (Donnie) The vesicles rupture easily If not broken by scratching they generally begin to desiccate at the end of 48 hours. There is some itching The crusts are thin and of the same outline as the lesions. They become detached within a week to 10 days. The resultant scars are circular and atrophic. Hemorrhagic extreme cases are occasionally seen (Tilley and Warren BMJ 1 1265 1938) In adults the disease is likely to be severe.

Corneal involvement is probably not rare and it apparently is not dangerous (Loewenstein: BJOphth 24: 391, 1940) It begins deep in the cornea and rises to the surface but does not induce photophobia. Mucosal and visceral lesions have been described (Johnson: APath 30: 292, 1940) Intrauterine infection has occurred (Oppenheimer: BullJHH 74: 240 1944) Complications with pneumonia, otitis media, abscesses, suppuration cellulitis, erysipelas, septicemia, nephrosis and encephalitis have been observed (Bullowa and Wishik AmJDisChild 49: 923, 1935) Of 119 cases of encephalitis collected by Underwood (BJChildDis 32: 83, 177 241, 1935) 1 % died and 15% had lasting sequelae See Walcott (NEngJM 1 : 123, 1937); Waring et al. (AIntM 29 334 1942); Appelbaum et al. (AmJMed 15: 223, 1953); Humphries (JMAAla 23 198 1954) The severe virus type of pneumonia, with bilateral nodular infiltrations in the lungs, may be due to the varicella virus, for it clears as the skin lesions improve (Saslaw et al: AIntM 91: 35 1953)

The presumably causative virus was cultivated by Weller (PSExpe Biol 83 340 1953)

Fig. 202.—Chicken pox vesicle, showing location of fluid in the epidermis, which is free from inflammatory cellular infiltration Endothelial destruction has allowed perivascular hemorrhage Intense inflammation surrounds this vessel. (Johnson APath 30 292, 1940.)

Diagnosis.—See Smallpox. The Paul test is negative in varicella An eruption indistinguishable from varicella occurs in a small proportion of cases of zoster (q v) especially in severe ones (Bullowa AmJDisChild 49 923 927 1935) The relationship between the viruses of varicella and herpes zoster appears to be a close one but is debated. Postzoster serum may protect a varicella contact from developing the disease (Whigham and Handelman BMJ 1 812, 1944) Cross agglutination of the elementary bodies of herpes zoster and varicella was shown by Amies (Lancet 1 1015 1933) The elementary bodies prepared in pure suspension by high speed centrifugation are infectious, while the supernatant fluid is not (Eagles and Ledingham Lancet 1 823 1932)

MEASLES

Rubeola is an acute febrile virus infection characterized by catarrhal involvement of the upper respiratory tract and a diffuse, erythematous, macular eruption which ends with fading and desquamation. The incubation period

is fairly uniformly 8 to 10 days, but the appearance of the rash may rarely be delayed even until the twelfth day (Goodall BMJ 1 336 1936) The onset of the disease is gradual and the early symptoms include slight fever head ache chilliness, coryza lachrymation, sneezing cough, and photophobia Lesions may be noted first on the buccal mucosa as small, irregular bright red Koplik s spots, each of which is marked centrally by a minute bluish white speck. Koplik spots were observed in the mucosa of the colon of a man with a colostomy; such lesions doubtless account for diarrhea and gastroenteritis (Hobson Lancet 2 134 1940)

The eruption, which consists of small pinkish, slightly edematous maculopapules, appears first on the face and neck and then spreads rapidly to the trunk and extremities. On the abdomen and back the lesions often tend to form crescentic or arcuate patches surrounded by normal skin. The eruption is of a deeper darker red than that occurring in scarlet fever The peculiar shotty lesions of variola are never present. The fever and the catarrh persist until the eruption begins to regress. In severe cases, hemorrhagic measles may develop with petechiae or even extravasations of blood into the lesions. After the eruption has persisted for 4 or 5 days, it gradually disappears to be slowly followed by furfuraceous, branny desquamation

A presumably specific viru wa cultivated and propagated in tissue cultures by Enders and Peebles (PSExperBiol 66: 77 1954)

Diagnosis may be made in the prodromal stage by the demonstration of peculiar large multinucleated giant cells by Papanicolaou staini g of glairy mucu from high i the nose according to Tompkin and Macaulay (J 15 : 11, 1955)

The cough and malaise are ameliorated by Empirin with codei e. Cutaneous distress is palliated with cool compresses of aluminum acetate, 1:500 and inunctions of mineral o l. It hing responds to antihistamine drugs with some satisfaction Gamma globulin given at the time of exposure can prevent infection with passive immunity or markedly attenuate the severity of the disease if it is contracted. It benefits toxic patients. It may delay the appearance of the rash until after the f brile period.

Cases with bullous eruptions have been reported (Ronaldson: BJChildDis 34: 99 1937) If convalescent serum is i jected intradermally at the onset of the disease, the rash is inhibited at that site in the majority of cases (Debré phenomenon: Phillips: AmJDisChild 55: 1257 1938)

Measles is likely to interrupt pregnancy and has been found present in the newborn when the mother contracted the disease near term (Dyer: SouthMJ 33 601, 1940) The hazard to the mother is not great. Possible damage of the fetus resulting in congenital malformations (compare R bella) was reported by Hagström er (abs J 139: 1040 1949) When measles was introduced into the Faroe I lands, where there had not been a case in 65 years, 6000 of the 8000 inhabitant were infected (Panum: see Edit InternatMDig 53 164, 1948)

GERMAN MEASLES

The period of incubation of rubella lies probably between 14 and 21 days. The onset is fairly abrupt and is characterized by mild constitutional symptoms and usually the enlargement of postauricular suboccipital, and post cervical lymph nodes. The eruption consists of rounded or oval pinhead to split pea size, pinkish macules or maculopapules. It usually appears first on the face but quickly spreads to the chest, trunk, and limbs. The lesions are discrete as a rule but they may be grouped or even confluent. The rash seldom persists longer than 3 or 4 days, and its appearance is not followed by desquamation. Catarrhal symptoms, if present, are relatively mild. The patient s temperature seldom exceeds 100° F and there may be no fever whatever Relapses are infrequent.

Experimental inoculations have succeeded when nasopharyngeal washings or blood obtained 2 days prior to the appearance of the rash was used as the source of the virus by Krugman et al. (J 151: 285 1953) The incubation period proved to range from 9 to 16 days. Experimental rubella was contagious, and t caused both typical disease and rubella w thout rash. A virus grown and propagated in monkey kidney tissue produced the disease in volu teers, reported Anderson (La cet 1107 1954)

Complications include pneumonia, empyema, lymph node abscesses rthritis (Shaw: JIndianaSMA 29 227 1936) and meningoencephalitis (Briggs JPed 7: 609 1935) Purpuric lesions and severe adenitis were seen by Briggs among the later cases in the St. Paul epidemic of 1935. In a British epidemic of 1940 many patients had stiff neck, oc-

cipital headache and swelling of the oral and nasopharyngeal mucosa (Bennett and Copeman BMJ 1: 9*4 1940) While the throat might manifest follicular pustules, oral symptoms were not severe, though aching of the gums for 48 hours, starting usually on the second day was a complaint. Desquamation started as soon as the rash began to fade and in some cases was as intense as that of scarlet fever. Severe but transitory encephalomyelitis was attributed to rubella in a man studied by Mitchell and Pampiglione (Lancet 1-50 1954)

Fetal Injury—While practically without complications to the patient rubella in pregnancy is highly hazardous to the fetus, especially during the first 8 weeks resulting in cataract cardiac abnormality mental retardation, deaf mutism and other anomalies (Albaugh J 129 719 1945) The first recognition of congenital defect associated with maternal rubella was by Gregg (TrOphthSocAustralia 3 35 1941) See review by Miller et al. (ADS 62 477 1950) of anomalies associated with various dermatoses in the mother also Tedeschi et al. (NEngJM 249 439 1953) Cataract and microphthalmos as well as cardiac defects in 5 cases where the mother had rubella during the first 2 months of pregnancy were observed by Long and Danielson (Arch Ophth 34 24 1945) Such congenital cataract may be operated upon at an age of 2 or 3 months, before nystagmus begins (Goar and Potts AmJOphth 29 566 1946) Congenital deafness was of especial concern to Hopkins (AmJDisChild 72 377 1946) who reported 10 cases. Congenital heart disease interested Gibson and Lewis (AmJDisChild 83 317 1952)

Fig 101—Morbilliform rash of German measles (Dr J F Schamberg)

It is highly desirable that women have rubella prior to pregnancy and Anderson (MJAustralia 2 389 1950) was able successfully to inoculate volunteers with throat washings preserved virulent by refrigeration.

Diagnosis.—German measles differs from scarlatina in these respects its longer *period of incubation absence of severe systemic symptoms, particularly* fever and angina first appearance of lesions on face and forehead and absence of desquamation. The pinkish, evanescent character of the lesions, relatively mild nature or absence of respiratory symptoms and the presence of cervical lymph node enlargement will usually serve to distinguish it from measles.

HERPES SIMPLEX

Herpes Simplex is a specific virus infection, commonly manifested as fever blisters, which comprise an acute eruption of a group of vesicles set on an erythematous, swollen base. Early manifestations are sensations of itching and tension, followed by localized hyperemia. The patches are usually few in number and closely grouped. Vesicles, which range from pin point to large pinhead size and which are filled with clear fluid develop on the swollen reddened areas within a few hours. Suppuration may occur. If unmolested, the vesicles dry up and form thin, yellowish or brownish crusts

which drop off within 7 to 14 days. As a rule no scar results, but atrophic scars may follow severe cases. When the face is affected the lips, perioral regions and cheeks are the parts most frequently involved although the external ear particularly the auricle, is occasionally attacked The inner surfaces of the lips are sometimes affected Herpes of the genitalia is frequent Here abrasion is probable, and, when the patient is seen only a group of raw circumscribed erosions, the bases of the former lesions are visible

Fig. 204.—Herpes simplex, with herpetic fever and painful lymphadenitis.

Fig. 205.—Herpes simplex. This patient's husband had a similar lesion, at the same time on the left side of his chin.

Fig. 206.—Herpes simplex of penis.

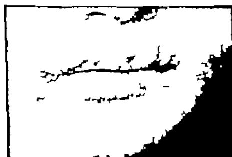

Fig. 207.—Herpetic stomatitis

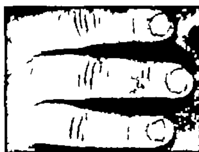

Fig. 208.—Recurrent herpes in unusual location.

The eruption can appear on any part of the body Finger and forearm lesions, with fever lymphangitis and lymphadenitis, were shown to be due to the herpes virus by Trice and Shafer (ADS 67 37 1953) Volar herpes was noted by Kipling and Downie (BMJ 1 247 1948)

Rarely does herpes produce lesions on the hard palate but it may by affecting the great superficial petrosal nerve inducing a kind of Hunt s syndrome (q v) because of the branches to the tympanic plexus and otic ganglion (Wakeley and Mulvany Lancet 1 746 1939)

Herpes simplex may be primary or secondary As a primary affection, its severity is occasionally considerable, with malaise fever and satellite lymphadenitis. The constitutional symptoms of herpetic fever' may precede the eruption some 24 hours or more The patient is generally a child, and stomatitis is the usual manifestation (Anderson and Hamilton MJAustral 1 308 1949) or vulvovaginitis (Scott NEngJM 250 183 1954) No specific treatment is as yet known (Edit BMJ 2 403 1954) although cortisone effectively palliative in herpes zoster deserves trial

Secondary herpes occurs in the course of many febrile diseases, including the common cold, influenza pneumonia malaria, meningitis, and salmonella food poisoning It frequently follows sunburn or fever therapy and may be quite severe Corneal involvement provokes acute disease with pain, lacrimation and photophobia the epithelial lesion being characterized by swelling vacuolization and necrosis, multiple dendritic or latticelike (Noé IowaSMSJ 29 400 1939) Cranial nerve palsies following general anesthetics were accompanied, for the most part by labial herpes and were attributed to herpes by Humphrey and McClelland (BMJ 1 315 1944) Herpetic encephalitis, with disorientation, drowsiness, scanty physical signs but severe histologic changes of malacia, has been recognized the 2 cases of Whitman et al. (J 131 1408 1946) were fatal and records of 10 fatal cases were gathered by Cambier (PresseM 63 286, 1955)

Herpes infection may complicate infantile eczema (Barrow BMJ 1 482, 1954) see Kaposi s Varicelliform Eruption.

After artificial pyrexia, symptomatic labial herpes was of higher incidence and greater severity in perso s who had previously experienced attacks of h rpes than in those who had not had herpes before (Sutton BullUSAMD 3: 115 1944) Vaccination with smallpox vacci e prior to fever therapy did not prevent the development of postpyrexial herpes (Keddie et al. J 117: 1337 1941) The frequency of herpes following fever therapy is considerably less following a second pyrexia tha following the first (Warren et al. JExpM 71 155, 1940)

Herpes followed Salmonella food poisoning in 15% of the ca es (D Albora et al.: J 129 10 1945) It occurred in 33% of the cases, was often severe, and bore no prognostic significance in meningococcus meningitis, reported Harries (BMJ 423, 194.)

See d Morder ba J 111 2531, 1938), encephalitis with labial herpes Armstrong (PHRpts 58 16 1943) herpes virus in spinal fluid in case resembling lymphocytic choriomeningitis, Hamin and Rabens (JNeuropath 3 355 1944) meningoencephalitis Rivers (J 132 427 1946) herpetic encephalitis resembles that of lower animals, with numerous eosinophil nuclear inclusions Scott (NEngJM 250 183 1954) diagnostic technics and clinical varieties of herpetic infection, including skin, mucosal and ocular lesions, meningoencephalitis and generalized illness

Vesicular (Herpetic) Stomatitis.—Dodd et al. (JPed 12 95 1938) reported 88 cases in children of a disease which resembled aphthous stomatitis. The onset was sudden with fever and malaise Within 24 hours lesions appeared on the tongue, the inner surfaces of the lips and the buccal and sublingual mucosae, with swelling of the gums, pain on eating and cervical lymphadenitis. Herpes of the lip was present in 5 cases, and on the finger perhaps from autoinoculation in 2 The disease was self limited. Familial infections occurred.

Inoculations of the corneas of rabbits produced transferable purulent keratoconjunctivitis. Rabbits which survived infection were immune to further inoculations and were immune to herpes simplex too

Herpetic stomatitis is a highly infective but benign and uncomplicated disease occurring sometimes in epidemic form (Breese AmJDisChild 61 675 1941 Scott et al J 117 999 1941) The incubation period is from 5 to 7 days, and fever is marked Vesicles appear and become small ulcers with grayish bases on the fauces, palate and tonsils, and undergo evolution

and healing in due time Burnet and Lush (Lancet 1 629 1939) concluded that aphthous stomatitis in infancy is a common manifestation of primary infection with herpetic virus.

Herpangina so named by Zahorsky (SouthMJ 13 871 1920 AMediat 41: 181 1924) is the name preferred by Parrott et al (NEngJM 245 275 1951) who demonstrated 4 immunologically distinct viruses in 22 cases and found neutralizing antibodies against homologous strains of virus in all convalescent serums.

Adults are subject to herpetic aphthous stomatitis, the virus being demonstrable only while the aphthae are present (Rogers et al.: NEngJM 241 330 1949; Kilbourne and Horsfall AIntM 88 495 1951)

See Rochaix and Delbos (AnndeD 9, 169, 1938) aphthous fever with buccal and cutaneous lesions; Levine et al (J 112 2020, 1939) epidemic in summer camp; Burnet and Williams (MJAustral 1 63 1939) aphthous stomatitis and symbiosis of virus in man Cahn and Hart is (AmJOrthodont 28 140 1942) herpetic aphthae and rabbit cornea inoculations, immunity transitory; Anderson and Hamilton (MJAustral 1, 308, 1949), orphanage epidemic, antibody study children younger than 11 months did not become infected, subclinical infections; Huebner et al (J 145: 628, 1951) epidemic herpangina in Maryland, abrupt febrile onset, headache vomiting, sore throat, small ulcers in pharynx, virus identified as related to Coxsackie group A Sulkin and Stulberg (AmJDisChild 83: 421 1952) herpetic hepatitis; Buddingh et al (Pediat 11 595, 1953) recovery of herpes virus, demonstration of placental transmissions of neutralizing antibodies Kravis et al (Pediat 11 113, 1953), herpangina, Philadelphia epidemic of 1951, 3 types of Coxsackie group A viruses identified in stools and throats; Schlack (DeutschMWchs 78 213, 1953) coincidence of herpangina, poliomyelitis and Bornholm disease in Stuttgart in 1950; Nathanson and Mori (OralSurg MedPath 6 1284 1953) herpetic stomatitis associated with infectious mononucleosis.

Stomatitis and Diarrhea of Infants.—Diarrhea may be the serious manifestation of an epidemic of herpes virus infection. While stomatitis is usually present at the early stage generally about the anterior tongue regions, vesicles disappear within 24 hours, leaving a red and excoriated surface that heals only after a week or two and stomatitis may be quite mild or even overlooked (Buddingh SouthMJ 39 382 1946)

Vulvovaginal Herpes produces a typical clinical picture with symmetric, erosive lesions of the labia majores and minores, becoming tender ulcers with grayish yellow membranes. Painful for a week and similar to ulcus vulvae acutum (q v) it heals without scar Cases proved due to the herpes virus were recorded by Slavin and Gavett (PSExpBiol 63 343 1946)

Herpes Gestationis.—This resembles dermatitis herpetiformis (q v)

Recurrent Herpes probably is due to exacerbations of chronic herpetic infection. The lesions appear repeatedly at intervals of weeks or months in the same nerve region but not necessarily in identically the same spot. They may recur with the menses, and such cases may respond to the administration of estrogenic substances (Andersen abs YBD 1948 p 148) Herpes may follow trauma (Findlay and MacCallum Lancet 1 259 1940) While recurrent herpes was accepted as a virus disease the recurrences seemed to Blank and Brody (PsychosomM 12 254, 1950) to require a flaring factor which they thought sometimes to be of a psychiatric nature

Etiology —The cause of herpes is a filtrable virus. Supplemental factors which may provoke eruption are indigestion, febrile and toxic states, exposure to sunlight, and fever therapy The virus travels along motor sensory or sympathetic nerve fibers.

If the content of a herpetic vesicle is inoculated into the scarified cornea of a rabbit, there results keratitis which is transmissible and which travels by way of the nerves into the brain (Perdrau BJD 39 1 1927) its rate of travel from cornea to brain via the fifth nerve is constant and even (Doerr J 107 980 1936) Inoculation into the brain of the rabbit produces encephalitis, and the rod-shaped inclusion bodies measuring 0 1 to 0.2 by 0.3 to 0.5 micron in experimental herpes of the rabbit brain nerves and cornea are particles of virus (Nicolay and Kopciowska AnnInstPast 60 401 1938)

The chorioallantois of the chick embryo is infectible with the virus of herpes, although this does not affect the adult bird (Dawson AmJPath 9 1 1933) The chorioallantoic lesions show characteristic histologic changes, the epithelial nuclei undergoing enormous enlargement and trabeculation,

with fine basophile granules in the compartments. Virus isolation on the chorioallantois is aided by using penicillin 500u/Ml. and streptomycin 100 microgm./ml. to keep out contaminants without damaging the virus or the egg (Coriell et al JLabClinM 34 402, 1949)

Neutralizing antibodies, demonstrable by their inhibitory effect on chick chorioallantoic inoculations, are constantly present at a high level in individuals infected with herpes, and a heated preparation of the virus when inoculated intradermally provokes a specific erythematous reaction, regularly correlated with the presence of circulating antibodies according to Nagler (JImm 48: 13, 1944) Active immunity can be evoked in animals by the injection of sublethal doses of the virus (Rivers Filterable Viruses, Williams & Wilkins, 1928)

The virus was found to be present in the conjunctival secretion and saliva of patient with active lesions by Levaditi et al. (AnnInstPast 36: 63, 1922) but it apparently disappears between attacks of recurrent herpes (Hruszek: DWehn 90: 677, 1933) Electron microscopy studies showing the elementary bodies present in early lesions but absent from later lesions, were presented by Coriell et al. (JBact 59 01 1950)

The virus may persist despite high titer of antibodies in the host and carriers exist (Burnet and Lush: Lancet 1: 629 1939) Genital lesion in the female are not rare and the disease may be transmitted as a venereal infection (Sharlit: ADS 42 933, 1940) Antigenic dissimilarity of strain of herpes virus have been demonstrated by Jawetz et al. and by Womack and Hunt (Sci 120: 227 1954)

Complement fixation tests proved the separateness of herpes simplex and zoster to the satisfaction of Bedson and Bland (BJExpPath 10: 67 1929); see Dudgeon (JClinPath 3 230 1950); Gajdusek et al. (J 149 235 1952)

Human skin grafted onto the chorioallantois of the chick embryo is infectible with the herpes virus, which causes a vesicular lesion, while the lesion produced by infection with the zoster virus is pustular (Goodpasture and Anderson AmJPath 20: 447 1944)

Pathology—The vesicles are tough walled deeply seated and intra epithelial Eosinophilic inclusion bodies can be found within the nuclei of ballooned epithelial cells. Dense perivascular infiltration with small round cells underlies the vesicles and follows the vessels deep beneath the surface lesion This inflammatory reaction seems to provide fertile soil for cancerous proliferation, for neoplastic leukoplakia commonly invades at the site of labial herpes simplex. Epithelial cell smears from the vesicles of herpes simplex zoster and varicella show identical features which differ from those of any other vesicular disease (Blank et al J 146 1410 1951)

Diagnosis.—In vesicular contact dermatititis, the vesicles are close set rupture readily exude gummy serum, are associated with intense itching and are distributed on the skin without regard to the innervation. In impetigo contagiosa vesicles are discrete and autoinoculable develop serially and reach mucosae only by extension. Herpes genitalis may be confused with chancroid, and rarely with chancre In chancroid painful ulceration is always present and the lesions, while often multiple are never grouped as in herpes. The satellite lymph node of herpes is not abscessed. In syphilis the chancre is usually deeply infiltrated, lymph node involvement is almost invariable and dark field investigation is likely to reveal the spirochetes The satellite lymph node of herpes is larger and sorer than that of the syphilitic chancre

Prognosis.—The lesions take about 2 weeks to heal Recurrences are likely Herpetic encephalitis is a grave complication rarely met Secondary bacterial infection is possible and inept treatment often complicates and intensifies the disease before the physician sees it In severe cases scarring results.

Treatment.—All sources of irritation and focal infection should be removed in recurrent cases. Locally aluminum acetate 1:600 in water is comforting applied by means of a bit of cotton as a cold pack Spirits of camphor alcohol alone or with 0.2% zinc sulfate added or cologne water with 2% alum may be prescribed but camphor and strong mentholated ointments are in my opinion of little value if not irritant. Ammoniated mercurial ointment is harmful Aureomycin ointment seems helpful but Aureomycin has no influence in vitro or in vivo on the herpes virus, according to Baldridge

and Blank (PSExpB 72 560 1949) In a severe case with pain cortisone acetate 25 mg t.i.d. for 5 days affords good palliation. X ray therapy is advocated by some authorities 2 or 3 doses of 100 r may be given.

IMMUNIZATION —Freund (DmedWchn 54: 350, 1928) found that guinea pigs vaccinated against smallpox showed increased resistance to the herpes virus, and that patients with herpes had no further recurrences after such vaccination. Vaccination is now recognized as a means of preventing recurrences of herpes simplex; see Wise NYSJM 33: 1321, 1933); Foster and Abshier (ADS 36: 294, 1937); Davis (J 114: 2098, 1940) I have often cured recurrent herpes about the mouth by removing foci of infection, including malplaced third molars with pockets beneath them and by giving smallpox vaccine intracutaneously as recommended by Woodburne (ADS 43: 543, 1941) Vesicle fluid from the patient's early lesions was used as the immunizing antigen by Schmidt (ADS 32: 106 1935) Repeated injections of novocaine into the site of the lesion may prevent recurrences (Tzanck and Sidi: BsocfrançD 41: 1604 1934) Moccasin venom 0.. cc. of 1:3,000 dilution given subcutaneously each week, may work when vaccine fails (Fisher: ADS 43: 444 1941)

A peculiar repetitious spotty rash of the forehead and lips of a boy, impetiginoid and with crusting of the eyelids, was palliated by intracutaneous smallpox vaccination (Savitt and Ayres: ADS 60 633, 1949)

Kaposi's Varicelliform Eruption was originally described (1887) as a complication of infantile eczema. Pustulosis varioliformis acuta was the name given by Juliusberg (AfDuS 45 21 1898) Sudden in onset umbilicated erythematovesicular elements rapidly develop on the face and head especially and the neck sometimes on the elbows and wrists as well. The lesions become pustular desiccate and resemble those of chicken pox. Some scarring is usual. Fever precedes the eruption by 24 hours and persists for 1 or 2 weeks, falling by lysis. Differing from smallpox, new lesions may appear during a period of several days.

The disease is now recognized as herpetic, but it has been thought identical with generalized vaccinia (q v) which it certainly may resemble The fact that vaccination takes after recovery from Kaposi's eruption was reported by Freud (DWchn 98 52, 1934) Wenner (AmJDisChild 67 247 1944) and others.

There is some justification for taking the view that Kaposi's varicelliform eruption is a fitting clinical name for two different diseases, one being the result of vaccinal infection and the other of herpes (Whittle et al.: BJD 62 195, 1950; Sommerville et al. BJD 63 203 1951 Grist GlasgowMJ 34: 1 1953) for they apparently can be distinguished only by identification of the virus, just as streptococcic and staphylococcic impetigo can be positively identified only by cultures; see Anderson (BJD 61: 157 1949) on virus pyoderma. Generalized vaccinia occurs in persons with widespread dermatitis and in infants with eczema and it cannot readily be distinguished from Kaposi's eruption. But the virus of herpes has been demonstrated repeatedly and, while pathogenic cocci may also be found, Kaposi's disease is not vaccinia and may be defined as a specific, varioliform manifestation of herpes, according to Barton and Brunsting (PSMMC 18 199, 1943) Lane and Herold (ADS 50: 390, 1944) Lynch (ADS 51: 129 1945) and Lynch and Stevens (ADS 55 327 1947) Pepple et al. (SouthMJ 35: 667 1942) translated Kaposi's description in full.

There were 17 deaths among the 67 cases reviewed by Barton and Brunsting (ADS 50: 99, 1944) who demonstrated herpes virus in one of their patients. Of the 67 cases, 63 had atopic dermatitis, and 51 were 3 years of age or younger The 4 cases of Ruchman et al. (ADS 56 846, 1947) proved to be due to herpes virus, included 3 adults who had been successfully vaccinated against smallpox. The herpes virus has been demonstrated in many cases (Blattner et al. Sci 99 433, 1944 SouthMJ 4.: 812, 1949; Berke and Hallinger J 135 149 1947; Sims and French abs BJD 60 425, 1948, 9 cases with 5 deaths, and example of cross infection Wiley and Kletz BJD 61 166 1949 corneal ulcer; Baker et al. BMJ : 1334, 1952) A nurse contracted the disease from her patient, and the herpes virus was identified in both by Simpson (BJD 65 129 1953) In the course of an epidemic in children, several nurses contracted herpes (Brain AustralJD : 109 1954)

In treatment penicillin may be recommended only if secondary infection occurs along with such efforts as may be suitable in smallpox. Aureomycin topically and orally has seemed helpful to Baer and Miller (JID 13: 5 1949) Dareston and Carliner (JID 13 13 1949) Leier (ADS 63 456 1951) and McConachie and Anderson (BJD 63 307 1951) It was without benefit

in the case of Buerk and Blank (NEngJM 244 670 1951) Symptomatic therapy may include boric acid compresses and appropriate sedation. Cortisone is worth trying

Ulcus Vulvae Acutum.—The disease apparently an entity occurs in the form of vulvar ulcers in girls not exposed to venereal infection. Half the patients were virgins in the 20 cases of Olson (ADS 1: 279 1920) Flaherud (ADS 13: 55 1926) described the two types, gangrenous or severe and veneroid, which is more common. Compare Behçet's Syndrome, Vesicular Stomatitis, and Kaposi's Varicelliform Eruption.

Gangrenous.—The lesions are multiple but few in number located usually on contiguous aspects of the labia minora, accompanied by redness, swelling and burning pain. The onset is sudden, with fever as high as 40 C. The lesions are pea to dime-size round, with reddish areolae. The edges are soft and steep. The membrane covering the surface is thick or thin, gray yellow or bluish-black and firmly adherent to the base. It separates in 3 or 4 days, exposing the soft ulcer which has a smooth floor with a thin fibrinopurulent coating Fever and pain disappear at this time, and healing is complete in 10 days or so. *Sharply circumscribed, smooth, atrophic scars result.*

Fig 209 —Kaposi varicelliform eruption. (Brown BJD 46 L 1934)

Veneroid.—This resembles chancroid but Ducrey's bacillus is not present. Symptoms are mild. The tender ulcers are shallow and are located usually at the introitus. They vary in number and size. The edge is serrated and the shape rounded, oval, irregular or fissure-like New sores appear as old ones heal, so that the disease lasts a month or more. On the labia majora there may occur a miliary eruption of pinhead-sized lesions, with slightly elevated margins and depressed purulent centers, which persist only a few days. Smears reveal multitudes of *Bacillus crassus*, which closely resembles nonpathogenic *Lactobacillus acidophilus*. Virgins are the victims in 70% of the cases. Papuloerythematous or vesicular rashes, sometimes pustular of general distribution rarely accompany the disease.

Etiology —Factors capable of lowering the patient local tissue resistance hypothetically render the saprophytic *B crassus* pathogenic. The organism is perhaps identical with Doderlein vaginal bacillus and is ever present in the lesions existing as a thick (0.5 micron) and usually long (3 to 9 microns) *gram positive bacillus* with ends sharply right angled to its long axis. It is easily demonstrated in smear preparations from the ulcer sur

face. The identity of *B. crassus* Döderlein's bacillus and *Lactobacillus acidophilus* is likely according to Topley and Wilson (Principles of Bacteriology, Wood, 1937, p. 684); see *B. vaginae* Kruse and *B. crassus* in Bergey's Manual (Williams & Wilkins, 1948, pp. 362, 400). The significance of finding a luxuriant supply of a member of the vaginal flora in vulvar sores is highly dubious. The few cases I have seen looked like Kaposi's varicelliform eruption and ran the same course with abrupt onset, numerous discrete poxlike lesions, pain, fever and spontaneous resolution at the end of 10 days or so. Cases are rare, and opportunity to seek the herpes virus has not presented itself to me. Compare vulvovaginal herpes.

TREATMENT.—Weak antiseptics and rest suffice. No specific agent is known but the disease is benign and self limited. I should like to try cortisone for palliation.

See M. Donath (DJD 28: 286, 1924); Tsalov (ADS 30: 510, 1934); Popoff (DBoerfrangD 1938, p. 1264); Berlin (ADS 36: 69, 1939). There is no reference to an article on this subject in the Quarterly Cumulative Index 1946-1952, or in Excerpta Medica, section 13, 1948-1954.

HERPES ZOSTER

Symptoms.—Herpes zoster (shingles) is an acute virus infection of nerve structures manifesting cutaneous lesions in the form of groups of vesicles distributed along one or more peripheral sensory nerves. The disease occurs perhaps more frequently in individuals who are overworked, ill, or affected by the absorption of certain drugs, particularly arsenic, but it has been observed even in the newborn (Freud et al.: AmJDisChild 64: 895, 1942; Johnson: BMJ 1: 821, 1940). The appearance of the eruption is generally preceded by malaise of variable severity and by neuralgic pain or hyperesthesia in the affected region. The lesions are vesicles seated on slightly elevated erythematous plaques. They appear in successive crops along the course of the affected nerve. The number of patches is 1 or 2 to 12 or more. Each consists of half a dozen to a score of vesicles. In some cases, perhaps no visible lesions appear (see Segmental Neuralgia). In mild cases only a few lesions develop, the site of their location being hyperesthetic for several hours before they are manifested. They persist for a week to a fortnight, dry up, form crusts, and disappear. In severe cases involvement may be intense and extensive. The vesicles range from pinhead to pea-size and are usually filled with clear fluid. Their walls are comparatively tough. Their content may become seropurulent. Rarely the lesions are hemorrhagic. Gangrene may supervene due to either the severity of the disease or secondary necrotizing infection. In healing zona generally leaves corymbose, atrophic, white scars.

The disease afflicts approximately 2 per 1 000 population per year (Seiler: JHyg 27: 253, 1949). Small epidemics are common. During periods when the incidence of chicken pox is high, so is that of herpes zoster. The incubation period is between 1 and 2 weeks (Brostoff: BMJ 1: 790, 1955).

Any neural segment may be involved. Regional lymph node enlargement is usual. Pain is a variable symptom. In sturdy young persons the affection may give rise to little discomfort, but in elderly persons pain is generally a prominent feature throughout the attack, and neuritic sequelae are common (Hamilton: Pract 159: 122, 1947). The distribution of the eruption is practically always unilateral, although bilateral cases have been reported (Rattner: ADS 38: 436, 1938; Hailey: SouthMJ 47: 728, 1954). Occasionally the disease may involve widely separated regions at one time. It is common to find scattered varicelloid lesions over the trunk during the eruptive period (Grindon, Jr: ADS 39: 865, 1939; Barker: ADS 40: 974, 1939). The concurrence of varicelliform eruption with herpes zoster has an incidence approximating 8% of the cases, and has been interpreted as indicating a close relationship between zoster and varicella (McCallum: BMJ 1: 520, 1952).

In some 2,000 cases with lesions in over 2,500 segments, no sex or side preponderance was noted by Berggreen and Skjelo (DWch 106: 16, 1938) but the trigeminal and third cervical segments were the most frequent locations: trigeminal, 16%; cervical, 25%; dorsal, 48%; lumbar, 9%; sacral, 2%. Ophthalmic cases are rare in children (Bjork: Abs BJD 63: 199, 1951). See Katayama (Abs ADS 4_: 349, 1940).

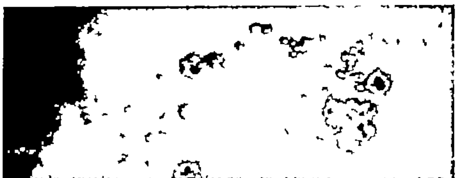

Fig. 215.—Herpes zoster involving right T 11, T 12, L 1 and L 2. (Dr Sam B Weidman.)

Fig. 216.—Herpes zoster early central gangrene.

Fig. 217.—Herpes zoster gangrenous lesions of back.

Fig. 218.—Supraorbital herpes zoster severe.

When zoster occurs in a patient with leukemia, especially lymphatic leukemia, nodules of leukemia cutis (q.v.) may appear in the herpetic dermatitis (Wile and Holman: ADS 42 587 1940)

Chronic recurrent herpes zoster is rare but indubitably is seen (Skoog: J 91 791, 1928) A patient of mine had a number of attacks in the second sacral distribution of his left thigh over a period of four years, during which the elimination of focal infection and

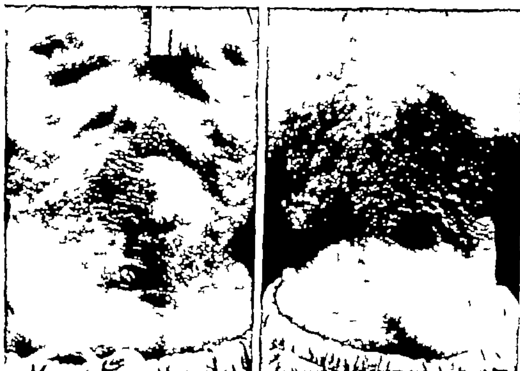

Fig 219.—Bilateral herpes zoster (Epstein and J cobson ADS 34 ### 1936.)

Fig 220.—Bilateral herpes (Dr Howard H ley)

repeated intracutaneous vaccinations with smallpox vaccine availed nothing In a woman I saw recently sacral segm nt recurrences were associated with distressing symptoms of cystitis, and these were ent rely relieved by cortisone.

Geniculate ganglion involvement, with ear pain auditory symptom and facial nerve palsy was described by Hunt (JNervMentD 34: 73, 1907) Involvement of th auricle may be associated with f cial palsy or Ménière s complex (Wakeley and M lvany: Lancet 1: 746 1939) Hunt s syndrome (aural herpes) is not necessarily du to geniculate

ganglion disease for cervical or other cranial nerve affection may cause otalgia, aural herpes and facial palsy (O'Neill: AOtol 42: 309 1945) Chronic otalgia may result (Bryan: WiscMJ 34 320, 1935)

Motor complications of zoster are neither rare nor remarkable and weakness of an upper extremity in cases of brachial plexus zoster may persist for many months (Taterka and O'Sullivan: J 122: 73 1943) Unusual cases exemplifying motor involvement were noted by Parkinson (BMJ 1: 8, 1949) Six cases complicated by Bell's palsy were reported by Spillane (BMJ 1: 236 1941) who thought that some cases of Bell's palsy are in fact geniculate ganglion herpes. Two cases of maxillary fifth nerve zoster followed in three weeks by facial paralysis were noted by Costello and Scott (ADS 60: 5?8 1949)

Unilateral tongue and palate involvement with impairment of gustatory sensibility was reported by Stepan (WienMWchr 103: 25? 1953)

Zoster involving the vagus nerve was described by McGovern (SouthMJ 44: 137 1951) Pain is confined to one side of the hypopharynx and larynx and to the homolateral ear nausea is a conspicuous feature; bradycardia and hiccough may be present. Dysphagia and extreme pain accompany herpes in the larynx.

Acute retrobulbar neuritis with sudden blindness, from which the woman recovered, occurred in a case of ophthalmic nerve involvement (Parry and Laid: BJOphth ?7: 467 1943)

Reported in herpes zoster have been myelitis (Whitty and Cooke: JNeurol 1 : 183, 1949); transient meningitis (Touraine: AnndeD 6: ?40 1935); lower motor neurone palsy (Carter: BMJ 1: ?34 1941); lower extremity weakness and loss of muscle stretch reflexes so as to simulate poliomyelitis (McIntyre: BMJ ?: 716 1951) encephalitis (Schmidt: DMedWchr 71: 308, 1947)

Etiology—A virus as the causative agent was long suspected but Fine (Filterable Virus Diseases in Man, Wood, 1932) stated that, while *transmission to man had frequently been effected, transmission to animals had been uncertain,* and filtrability had not been proved. Kundratiz (ZtschrfKinderh 39 370 1925) transmitted zoster to 14 of 22 children inoculated with vesicle fluid. Successful cultivation of the virus of herpes zoster was achieved by inoculating human tissue grafted onto the chick chorioallantois, by Goodpasture and Anderson (AmJPath 20 447 1944) see Blank et al. (PSExpB 69 341 1948)

The electron microscope reveals scanty but characteristic brick-shaped bodies in the fluid of early vesicles (Rake et al.: JBact 56: ?93, 1948) They closely resemble, but may be smaller than, those of varicella.

Arsenic may act as an exciting or supplemental etiologic factor (Knowles and Bolton PaMJ 41: 3 0 1938) Trauma as an inciting factor such as lumbar puncture, intramuscular injections, osteopathic manipulations and x-ray therapy, concerned Klauder (J 134 245 1947; ADS 64 407 1951) and Klauser (BJD 64: 224 195_) Zoster developing *after irradiation, especially in patients with cancer of the breast, occurred with greatest incidence some 3 to 6 months after treatment* (Ellis and Stoll: BMJ 2: 1323, 1949) Parfitt (BMJ 1 111 1936) reported the case of a person struck by lightning who developed zoster 14 days later Herpes zoster may appear during tabetic crisis (J 110: 67 1938)

A woman with Hodgkin's disease given nitrogen mustard developed zona, high fever and vesicular rash; she died, and at autopsy intranuclear inclusion bodies were demonstrated in various neural and visceral tissues by Cheatham (AmJPath 29: 401 1953)

Spinal fluid changes, motor neuron involvement, and encephalomyelitis, with their resultant symptoms, were discussed by Gais and Abrahamson (AmJMSc 197 817 1939) *Spinal fluid may show abnormality in albumin content, sometimes cells, increased pressure, and a right shift of the gold curve* (Schmidt: DWchr 100: 381 1935)

Herpes Zoster and Varicella.—The relationship between chicken pox and herpes zoster has received considerable attention. Some observers hold that *herpes zoster actually is an atypical manifestation of chickenpox virus. Traub and Tolmack* (NYSJM 31: 1072, 1931) believed that *evidence does not suffice to prove that the association is not fortuitous.* Zoster is not transmitted as is herpes simplex to the rabbit skin or cornea, and varicella does not immunize against zona, although the inoculation of zoster fluid into infants does indeed sometimes result in varicelliform eruptions (Brunsgaard BJD 44 1 1932) Chorioallantois inoculation experiments of Goodpasture et al. (Edit. J 126 898, 1944) indicate that the viruses are not identical. One finds numerous reports of the appearance of a case of zoster being followed by cases of varicella without other apparent contacts, such as those of Matheja (Arch J 114 2277 1939) and Garland (NEngJM 228 336 1943) and other reports of exposure to varicella being followed by zoster such as those of Kern (NJMSJ 42: 1 9 1945) and Horton (USNMB 43 74_, 1943) However when cases of zoster entered an isolated island community observed by Woolley (BMJ 1 802, 1946) *no varicella ensued.*

See McEwen (ADS 2 706, 1920); Roxburgh (BJD 39 12, 1927) Barrett (SouthMJ 31 193, 1938); Campbell (BJDisChild 38 31, 1941) Lynch (ADS 44 62, 1941); Platt et al. (JLabClinM 26 851 1940) Taylor (BMJ 2 388, 1946); Simpson (Lancet 2 1299 1954) varicella epidemic following zoster exposure, identity of viruses

Pathology—The vesicles, deeply seated and multilocular involve the lower rete and papillary layer The cavities are filled with serum, disorganized *prickle cells and leukocytes. Some degenerated epithelial cells* resemble protozoa and have been mistaken for parasites. Histologic changes in the cutaneous nerves can be seen after the 13th day of the eruption, comprising an irreversible degeneration with diminution of numbers of fibers in some bundles in the lower dermis (Ebert ADS 60 641 1949)

In the nervous system, histologic changes characteristic of zoster were found by Denny Brown et al. (ANeurP 51 216 1944) (1) ganglionitis showing necrosis and intense lymphocytic infiltration, with or without hemorrhage (2) poliomyelitis which is unilateral, localized and segmental and involves posterior horn and root; (3) mild localized leptomeningitis and (4) peripheral mononeuritis not only in the nerve distal to the ganglion but also in the anterior nerve root proximal and contiguous to the affected spinal ganglion.

Fig 111—Vesiculation of herpes zoster (Dr H. F Michelson.)

Diagnosis.—The neuritic distribution pain, and course of the eruption are distinctive. Prior to the eruption confusion with surgical disease can be embarrassing as in a patient who seemed to have a perinephritic abscess (*Bosher and Williams Surg 23 773 1948*)

Prognosis.—One attack usually confers immunity The disease runs an acute course, and the eruption heals in from 14 to 30 days. Hemorrhagic and gangrenous cases are serious. In supraorbital herpes zoster corneal damage sometimes occurs blindness may follow Scarring is variable. Bacterial secondary infection is possible and sometimes serious it is best prevented by keeping the lesions dry Neuralgia subsequent to zoster is sometimes enduring and extremely distressing especially in the aged, where pain seemingly irremediable can bedevil an old person into his grave It is usual however for neuralgia to fade gradually in a few months.

Treatment.—The administration of amidopyrine aspirin sodium salicylate codeine or Demerol gives symptomatic relief *Pain generally precludes* the patient s continuance with his work he is better off at rest, but if the

patient is getting off easy and so desires, he may do whatever is within his capacity for the disease is a self limited one presumably not hazardous to the public health.

Cortisone and ACTH give noteworthy relief (Nickel ADS 64 372, 1951 Poulin MaineMAJ 43 301 1952) Cortisone has become the mainstay of my treatment both during the acute stage and subsequently if neuralgia occurs. In adults who do not have peptic ulcer diabetes mellitus or tuberculosis I give 25 mg. with KCl 5 gr q i d. and feel that benefits are dependably conspicuous. Cortisone frequently dissipates neuralgia of a patient who is not seen until after his skin has healed, and the drug in such a case is given adequately but intermittently in amounts sufficient to control the symptoms. Favorable reports on the effectiveness of cortisone and ACTH in ocular herpes zoster include those of Doenges (IllMJ 106 131 1954) and Scheie and Alper (ArchOphth 53 38 1955) In postherpetic neuralgia which occurred in about a fourth of his patients Sauer (AD 71 488 1955) found the drugs effective in about 70% of the cases.

Comforting is a dusting powder freely applied and covered with a big snug bandage Melted paraffin may be applied as in the treatment of burns. Collodion, zinc stearate powder and cotton batting were recommended by Barney (OhioSMJ 39 42, 1943) Tense painful vesicles should be incised Radiant heat is often acceptable but hyperesthesia is characteristic in the affected region, and poultices, heat pads, ice bags and the like do not please the patient

Locally the use of counterirritation, such as ethyl chloride spray over the affected ganglion, has been recommended X ray therapy 200 r daily at 200 KV with 1 mm Cu filtration over the affected root ganglia for 4 or 5 days, is helpful best if started early (McCombs et al AmJMSc 200 803 1940) Intense ultraviolet erythema induced over the whole affected area stops pain A R. Taylor told me but I have not tried it.

Regional subcutaneous anesthesia with Novocain may be tried (Secunda et al. NEngJM 224: 501 1941) and hyaluronidase would probably simplify this. Injection of 0.5 cc. of 0 06% quinine and urea hydrochloride solution into the nerve so as to block it for a week gives prompt relief Lapp told me but Craig (PSMMC 11 677 1936) stated that even sectioning of the nerve may not relieve the pain. Findley and Patzer (J 128 1217 1945) preferred procaine infiltration of the appropriate sympathetic ganglion and described in detail the technic of paravertebral block, which does palliate in some cases (Rosenak Lancet 2 1056 1938) Postherpetic pain however remains unsolved by the neurosurgeon whose radical treatment, tried in desperation, may fail (Wartenberg J 134 94 1947)

Sulfonamides and antibiotics are without specific value but are needed if secondary infection appears.

Sodium iodide 1 0 Gm intravenously each third or fourth day for 3 or 4 doses, has been highly recommended (Ruggles ADS 23 472, 1931) 2 Gm given on the first, second fourth and seventh days was the dosage of Beers (J 112 2552 1939)

Pituitary extract given by injection occasionally relieved pain in a dramatic fashion (see J 115 2300 1940) The contraindications were coronary or myocardial disease hypertension and pregnancy (Somers and Pouppirt CalWM 42 370 1935) While pituitary was not infallible, it was dramatic when it worked (Gillett Lancet 2 307 1934) Ergot controlled pain in 17 of 30 cases of Combes et al. (JID 14 53 1950) Thiamin in 2 000-unit doses yielded only indifferent results in the experience of Rattner and Roll (J 112 2585 1939) Liver extract given because it was the only medicine available helped the prisoner-of war patients of Diekle (BMJ 1 942, 1946)

Biologicals which have been used with avowed good effect include convalescent blood (Gunderson AOphth 24 137 1940 Becker ADS 58 265 1949) gamma globulin (Grua DMedWehn 77 1074, 1952) autohemotherapy (Jones and Alden SouthMJ 30 735 1937 Poth ADS 60 636 1949); diph

theria antitoxin (Walker and Walker AOphth 20 304 1938) moccasin venom (Dennie and Morgan JID 12 153 1949) smallpox vaccination (Tillie NYSJM 43 857 1943) gamma globulin, 10 c.c. initially and 5 c.c. every other day thereafter (Weintraub J 157 1611, 1955)

FOOT AND-MOUTH DISEASE

Symptoms.—Foot and mouth disease is an epizootic infection of cattle, hogs, sheep, goats and other animals man being occasionally attacked. The virus is present in the fluid of the vesicles. Inoculation occurs through abrasions of the skin and mucous membranes. The disease was prevalent among the flocks and herds of England in the latter half of the nineteenth century and many cases of stomatitis were attributed to it (Arkwright: Lancet 1: 1191, 1928)

In man, the incubation period ranges from to 5 or even 10 days. The onset of an attack is usually attended with constitutional symptoms of moderate severity and a feeling of dryness and burning in the mouth. The buccal mucosa becomes congested and swollen Within * or 3 days small vesicles develop on the lips, tongue and pharyngeal walls. The manifestations of constitutional disturbance gradually subside After 48 to 7 hours the vesicles rupture spontaneously, leaving reddish extremely tender ulcers. The individual lesions are from 3 to 10 mm. in diameter They at first contain clear watery fluid, but secondary pyogenic involvement is common. The regional lymph nodes are swollen and tender The ulcers usually heal promptly with little or no scarring (Sutton and O'Donnell J 66: 947 1916) Nonfebrile disease limited to the oral cavity is probably not foot and mouth disease which evokes primary vesicles at the port of entry with later generalization. Cases of proved human infection were reported by Arocha (MedMex 27 163, 194) and Rille (DWchn 110: 146 1947)

Etiology—Loeffler and Frosch (ZentralblfBakt 23 371 1899) attempted to free the vesicular lymph from corpuscular elements by passing it through Berkefeld filters; they discovered that the filtrate was as actively provocative of the disease in cattle as was unfiltered material. This was the first time animal disease had been shown to be due to a filtrable virus. Pape and Waldmann (BerltierarzWchn 3 : 349 449 1921) reported the successful transmission of the disease to guinea pigs by inoculation of the volar skin. Following this the animals became immune to that strain of the virus. This procedure is the customary diagnostic test; *it may not be performed in the United States without special permission from the Bureau of Animal Industry permission which is not given except to State and Federal veterinarians.* In Great Britain, permission must be had of the Ministry of Agriculture.

There are three types of virus, A B and C, which do not show cross immunity (Waldmann abs YBD 1937 p. 196 Wagener: abs J 110 1409, 1938) and the disease has been transmitted experimentally to man. The virus is very minute (Schlesinger and Galloway JHyg 37 445 463, 193 ; Elford and Galloway BJExpPath 18 155 15 1937)

The virus survives quick freezing, which prevents the acidification of rigor mortis, and survives in frozen liver kidney and lymph nodes of diseased cattle, so as to be infective to swine under experimental conditions (Henderson and Brooksby: JHyg 46: 394 1948)

Treatment.—The course is self-limited. Treatment is symptomatic. The Waldmann vaccine prevents the disease in cattle (Rushmore BullUSAMD 3: 94 1945)

WARTS

Warts are small circumscribed, autoinoculable epidermal and papillary growths. Several clinical forms are recognized

Verruca Vulgaris is the common type. This kind begins as a tiny circumscribed grayish epidermal thickening The lesions are single or multiple and become pinhead to pea size, rounded papilliform excrescences. In color they are grayish yellowish or brownish. They give rise to no subjective symptoms. The lesions are usually discrete but may coalesce forming rugose plaques. Although the dorsal surfaces of the fingers hands, and wrists are the sites of predilection, no region is exempt.

When the wart is shaved in the plane of the skin, radiating brown structures which are hypertrophied papillae become readily visible against the background of translucent calluslike epithelium (Corson UCutRev 38 120 1934) The hyperkeratotic material interstitially located between the papilla may be macerated or chewed away by a child, and a digitate or filiform effect produced. Beneath the hyperkeratotic surface of a large wart the epithelium is altered and becomes towlike and pasty Using cautery or desiccation treatment, one must wipe the corium bare of this to cure

Warts about the nails are often difficult to eradicate. The hyperkeratosis and elongation of papillae produced by the verrucous process are recognizable.

Fig. 222.—Verrucae vulgares, with involvement of nail folds.

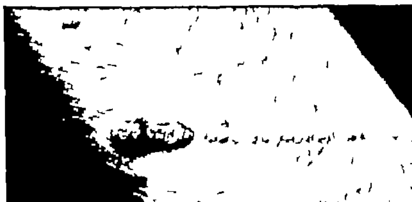

Fig. 223.—Warts on forearm, showing linear autoinoculation. (Dr J. Lame Calloway.)

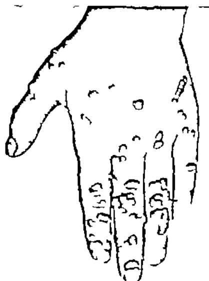

Fig. 224.—Verrucae vulgares.

Fig. 225.—Filiform warts.

Warts may involve the folds of the nail sometimes encircling it, even pushing beneath it Such lesions may be quite painful and of confusing clinical appearance Picking at them and manicuring lead to their perionychial dissemination. See Montgomery and Culvert (ADS 10 425 1924)

Warts of the eyelids may provoke conjunctivitis and keratitis as molluscum contagiosum does (de Rotth AOphth 21 409 1939)

Verruca Plantaris.—Lesions of peculiar aspect result when the soles are involved. They are called stone bruises by the uninformed This is a com

Fig 226—Plantar wart. (Dr Clyde L. Cummer)
Fig 227—Plantar warts macerated by salicylic acid plaster

Fig. 228—Plane warts, face

Fig. 229—Plane warts, hand.

mon condition epidemics in schools being seen (MacKenna BMJ 1 509 1938) The lesions are frequently located under the second metatarso-phalangeal joint or on the heel. They resemble small, oval calluses. They are sensitive, causing pain like a thorn in the foot When the overlying epidermal lid is removed, a well like cavity, partially filled with moist, tough tow colored corneous material, is exposed and tender bleeding tips of the hypertrophied papillae become apparent They are carefully to be distinguished from calluses (Montgomery and Montgomery J 124 756 1944)

Fig. 230—Condyloma acuminatum. (Dr Sam Sheltzer' patient.)
Fig. 231—Condyloma cuminatum, perianal (Dr Osw ld G Costa.)

Fig. 232—Cornuat warts of prepuce

Fig 233.—Filiform wart t the naris.

Spontaneous regression of plantar warts, not those of the mosaic type was described by Rasmussen (ActaD-V 34 144 1954) This apparently took place in about 3% of more than 5 000 cases. Warts in regression became dark, perhaps black the surface dry the periphery perhaps scaly the wart material crumbly and the underlying papillary vessels black because of thrombosis. The phenomenon was more common in children than in adults.

Mosaic Warts.—Large composite patches of warts are seen fairly commonly on the sole These are characteristically spread over a large area, are dry comparatively painless, progressive and radioresistant. They are difficult to cure See Montgomery and Montgomery (NYSJM 37 1978 1937 ADS 57 397 1948)

Papillomas with Pearly Bases and erythematous halos lacking the hard hyperkeratotic top and surrounding callus of the ordinary wart were segregated as a special clinical type by Straus et al. (PSExpB 72 46 1949; JID 15 433 1950) They demonstrated in the lesions, obtained from the palms and soles of children spherical, viruslike particles of crystalline appearance which tended to aggregate in regular nets. The lesions were easy to remove with a curette. Pyknotic nuclei were numerous in the lower layers of the thickened epidermis, and intranuclear round eosinophilic inclusion bodies occurred in the Malpighian cells immediately external to the basal layer The elementary bodies resembled but were much smaller than those of molluscum contagiosum.

Fig 234.—Verruca simulating early squamous carcinoma. (See Fig. 235.)

Fig. 235.—Verruca, section of lesion seen in Fig. 234.

Verrucae Planae.—Flat warts are small polygonal, yellowish or brownish pinhead to pea size flat or dome topped growths which develop especially on the face forehead and dorsal surfaces of the hands. They may be discrete but are usually grouped and may coalesce They are asymptomatic but are quite resistant to treatment These are often disseminated by cold cream and hand lotions. A pigmentary form simulating *seborrheic keratoses* was observed by Becker (ADS 34 265 1936)

Verruca Digitata.—This variety which occurs most frequently on the bearded region and scalp is characterized by its architectural scheme being composed of filiform projections with pointed horny caps, closely grouped on a narrow base.

Verruca Filiformis.—This is a small slender flexible, threadlike growth covered with smooth epidermis. The sites of predilection are the neck and the eyelids, and the bearded area in men whose shaving inoculates and disseminates them widely. A filiform wart on the nose of a newborn was seen by Ronchese (ADS 65 231 1952). Multiple lesions resembling filiform warts about the corona penis produce a curious appearance descriptively named hirsuties papillaris penis (Wigley and Haber BJD 61 427 1949 Tomlinson BJD 61 429 1949). See Winer and Winer (Trans. Western Sect Amer Urological Assn., July 1955).

Fig. 236.—Mossy foot.

Fig. 237.—Warts causing mossy foot. (Costa ADS 53 644, 1946.)

Lymphostatic Verrucosis (Mossy Foot)—Verrucose change accompanying chronic edema has been recognized for many years pointed out Loewenthal (J 152 475 1953). The name mossy foot was given by Thomas (AnnTropM 4 95 1910). Cases were reported by Loewenthal (Ann TropM 28 47 1934) who was convinced that elephantiasic lymphostasis was the cause. Some 200 cases were described by Clark (TransRoySocTropM 42; 287 1948). The condition responds to firm prolonged pressure by elastic bandages. Treatment with measures usually employed in attacking common verrucae failed in the case affecting an amputation stump reported by Schamberg (J 150 1653 1952). Compare chromoblastomycosis and elephantiasis.

See Per Letter Crumder (J 155 1000 1954), Hales (J 156 874 1954) Loewenthal (J 155 1827 1954) priority of name [illegible] D [illegible] (AD 71 644 1955) case, obese female.

Verruca Acuminata.—This variety also known as condyloma acuminatum or incorrectly venereal wart develops on moist tissues near the mucocutaneous junctures. The formations consist of closely aggregated pointed tufted or pedunculated pinkish or purplish projections, of variable length and consistency. About the vulva or beneath the foreskin they may vegetate become covered with pus, and stink with macerated epithelium and decomposing secretions. They are autoinoculable seldom disappear spontaneously and are transmissible to the sex partner (Barrett et al J 154 333 1954 Ronchese ib p 1198 Squires J 155 511 1954) Despite sex transmission *the disease should not be considered venereal (Edit AmJSyph 38 609 1954)* Anal mucosal lesions were present in the patient with anal condylomata *observed by Chester and Schwimmer (AD 71 149 1955)*

Etiology.—Wile and Kingery (J 73 790 1919) inoculated warts successfully by intracutaneous injection of bacteria free filtrate of wart material Templeton (ADS 32 102, 1935) obtained takes as long as a year after inoculation. *An epidemic of warts among a group of employees was shown by* McLaughlin and Edington (Lancet 2 685 1937) to have been due to contaminated glue Warts can be spread by ointments.

Warts occur in practically all of the familiar animals, and in cattle sometimes attain a *remarkable degree of severity Immunologic therapy, effective in treating cattle* is of dubious value in human infection but Biberstein (ADS 50 1, 1944) reviewed pertinent literature described a method of preparing vaccine, and claimed to have cured 60% of his cases of vulgar and plane types.

A filtrable agent was grown in the chick embryo inoculated with macerated, filtered material from a verruca vulgari by Blvins (JID 70: 471, 1953; Sci 117: 300, 1953) Tiny hard, whitish pearls developed on the chorioallantois. It was Waelsch (AfDuS 124 625, 1918) who showed that inoculation of an extract of condyloma into human skin produced the common wart while inoculation into a mucous membrane resulted in condyloma.

In rabbits, in which the Shope virus produces papillomas that have received intensive study because of their tendency to become malignant, Kidd (JExpM 65: 703 1938) observed that immunologic reactions to this virus are similar to those of classic immunologic antigens. Shope papilloma virus took embryo rabbit skin transplanted in species resistant to the infecting agent reported Greene (CancRes 13: 59 1953); see Carcinoma, etiology virus.

See also Asbestos warts. The prick of a thorn is often alleged by the patient *to have infected his wart. A tiny wart feels subjectively as if it contained a foreign* bod

Pathology.—The first stage of the development of verrucae is characterized by localized acanthosis with hyperkeratosis. Underlying papillae are *lengthened and the papillary body is stretched and flattened* Some papillae are *thinned and elongated. Epidermal cells infected by the intracellular parasite* undergo degenerative changes. In the juvenile wart marked hyperkeratosis is absent but the epidermal cellular alteration is present.

Meticulous observations of the keratohyaline changes were reported by Meirowsky et al (BJD 60 275 1948) The only changes in individual cells distinctive of verruca were found in the nuclei (Blank et al. JID 16 19 1951) and cytoplasmic bodies were deemed nonspecific. Early changes in the deep layers become more marked as the cells move toward the surface and culminate *with complete filling of the nucleus with inclusion material, so that it* is two or three times the size of a normal nucleus its fine structure being replaced with a dense homogeneous mass. Mature inclusion filled nuclei are easy to see even at low magnification as dense ovoid bodies likely to be surrounded by ballooning degeneration such as is found in other virus diseases of the skin The inclusion material is rich in nucleoprotein, apparently of the desoxyribose form.

Some warts contain inclusion bodies and others do not, according to Lyell and Miles (BMJ 1 912 1951) Warts with inclusion bodies (type I for inclusion) are usually volar or paronychial. Those without (type B for banal) are verrucae vulgares, and mosaic warts are of this kind They would limit the name verruca vulgaris to warts lacking inclusion bodies, while those with inclusion bodies they would call myrmecia after Celsus.

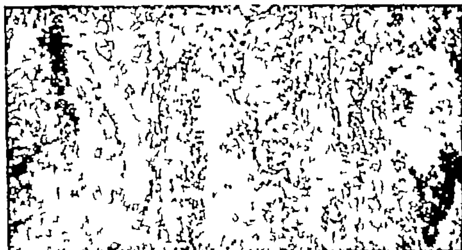

Fig. 238.—Verruca vulgaris (× [illegible]). Distention of nuclei with basophilic inclusion material begins in deeper prickle cell layers. Large dense fully formed "inclusion bodies" are surrounded by a clear zone of "ballooning degeneration." (Blank et al.: JID 16: 19, 1951.)

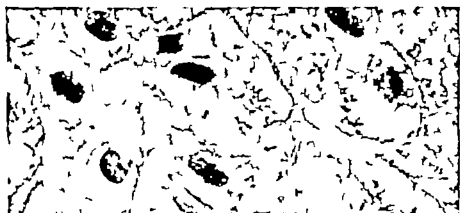

Fig. 239.—Verruca vulgaris (×[illegible]). Cells containing densely filled nuclei ("inclusion bodies") possess degenerated, swollen cytoplasm. (Drs. H. Blank, M. Buerk, and Fred Weidman.)

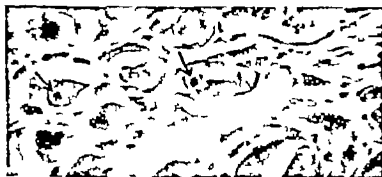

Fig. 240.—Verruca vulgaris (×[illegible]). No diagnostic "inclusion bodies" are seen. Arrows indicate large nucleoli indicating site of synthesis of nucleoprotein. Dense masses of keratohyalin, various in size, may confuse. (Blank et al.: JID 16: 19, 1951.)

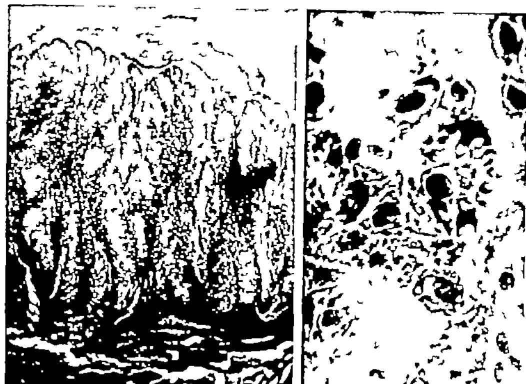

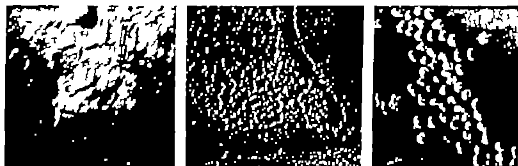

Fig. 241.—Papilloma yielding viruslike particles, ×30. (Strauss et al. PSExperBiol 72 46 1949.)

Fig. 242.—Papilloma tissue (×1200) from Fig. 241. Not round, solitary intranuclear inclusion bodies not so dark as adjacent irregular chromatin masses. Solid cytoplasmic bodies are evident. (Dr. M. J. Strauss and collaborators.)

Figs. 243 and 244.—Electron micrograph (×11 400) of viruslike particles from papillomas with intranuclear inclusion bodies. Preparations are from 1 patient. (Strauss et al. PSExperBiol 72 46, 1949.)

Fig. 245.—Elementary bodies (×11 400) from molluscum contagiosum. (Strauss et al. PSExpt Biol 72 46, 1949.)

Diagnosis.—Ordinary warts are familiar. The plantar type may be confused with corns but can be recognized by shaving off the superficial layer so as to expose the papillary tips. Juvenile warts are distinguished from lichen planus by their color, distribution and lack of pruritus. Early squamous carcinoma (q.v.) is often wartlike. For differentiation from epidermodysplasia verruciformis (q.v.) see Waisman and Montgomery (ADS 45 259 1942). A plantar wart is an ordinary wart pressed into the cutis, and calluslike hyperkeratosis surrounds it.

Prognosis.—Warts are benign but are liable to infection Plantar warts are painful even incapacitating Verrucae involving the nail folds are resistant and difficult to treat. Individuals differ in vulnerability to wart infection and an untreated wart persists on the average some 2 or 3 years then heals spontaneously Rulison found (ADS 46 66 1942)

Treatment.—For oral administration no remedy is reliable Injections of bismuth and of normal saline were equally effective in the experience of Goodman and Greenwood (ADS 30 659 1934) Bistrimate 2 tablets 3 times a day which may intoxicate cured 8 of 14 cases of multiple warts for O Connor and Tweedall (JMoMA 45 25 1948) Vitamin A 100 000 units a day by mouth may cure (Fisher and Chamberlain PaMJ 51 151 1947) Methionine 2 Gm. per day cured 2 patients of Merklen (PresseMéd 64 284 1954) Subcutaneous injections of the Shwartzman typhoid bacillus filtrate gave outstanding results as reported by Jacobi et al (UCutanRev 43 274 1939)

Using mechanical methods, an anesthetized lesion can be scraped out Cauterization with dichloracetic acid, acid nitrate of mercury or similar caustics may be used. Any means of blistering will serve if used with skill including solid CO (Holdin Davis BMJ 2 18 1938) An annular wart resulted when vesiculation with cantharides cured only the central portion in a patient of Lewis (ADS 51 66 1945) Fulguration is a rapid, clean, efficient procedure An electrosurgical cutting technic was described by Karp and Frank (ADS 45 728 1942) One should destroy only epithelium and those elongated papillae which project above the niveau so avoiding scar Epidermis must be sacrificed to a distance of 2 or 3 mm peripherally to reduce the likelihood of recurrence After healing though there is no scar depigmentation results and may be conspicuous in brunets.

One may inject a few drops of Iodobismitol into the base of the wart (Shellow IllMJ 66 332, 1934) Quinine and urethane 50% urea, sodium morrhuate or potassium oleate may be used similarly (MacKay ADS 41 736 1940)

Occlusion obtained by tightly binding elastoplast over the warts and redressing once a week may cure (McAusland BMJ 1 1123 1935) Occlusion by adhesive tape after a preliminary application of trichloroacetic acid or phenol was recommended by Frank (ADS 65 617 1952) Outstanding success in treating periungual warts, which may be considered difficult indeed was claimed by Halpern and Lane (JMoMA 50 765 1953) by applying 80% aqueous monochloracetic acid, then covering the lesions with 40% salicylic acid plaster trimmed just a trifle larger than the wart pressed on, and left in place for from 3 to 4 days. A similar method using trichloroacetic acid was recommended by Prazak and Lazar (ADS 69 230 1954)

Formaldehyde 3 or 4 cc. in half an ounce of Aquaphor can be applied twice a day to the wart, which hardens, is shaved off weekly and may eventually disappear (Lynch and Karon ADS 62 803 1950) Formaldehyde commercial 40% a teaspoon to the quart of water is useful for daily foot soaks in treating mosaic warts. Freezone containing zinc chloride salicylic acid, castor oil alcohol and ether has considerable usefulness in dealing with warts, corns, soft corns and calluses.

Individualization of treatment of the lesions was stressed by Burrows (BJD 55 60 1943) and Lane (J 144 1361 1950) in papers which discussed the treatment of warts comprehensively

Radium is a useful tool. An applicator of 5 mm diameter containing 5 mg of radium delivers a dose just short of vesiculating when applied in close contact without filtration for about 10 minutes. It is especially helpful in dealing with small warts located where an electrosurgical procedure would make an undesirable wound

X ray therapy is excellent if used with skill The curative dose is given in one dose (Pipkin et al. SouthMJ 42 193 1949) After shaving off the

excess corneous material the wart is accurately shielded so as to expose a margin of about 2 mm A dose of something like 1 400 r at 100 KV no filter added is administered. Small warts require a larger dose, and large areas should receive somewhat less. Reaction is apparent after about 12 days but is mild consisting only of slight tenderness, swelling and erythema. This fades, and the wart comes to resemble the translucent corneum of a healing blister About 40 days after the dose the wart is ready to peel off It may do so spontaneously but if it is not peeled off the virus, unaffected by the x ray infects the new epithelium beneath. Therefore the patient is emphatically requested to return on or about the fortieth day after x ray treatment so that débridement may be performed by the physician. This essential second visit changes the statistics of cures obtained from about 70% to nearly 100% Having once given an area a large dose of x ray therapy such treatment may not be repeated without causing radiation atrophy See Sutton (GI 2 19 1950) Oliver (ADS 42 302 1940) Montgomery and Montgomery (NYSJM 41 371 1941) Contact therapy with low voltage was recommended by Thomsen and Rauschkolb (ADS 65 553 1952)

Suggestion therapy by psychiatric means has a large literature and undoubtedly is effective in a fair proportion of cases. The methods of folklore include such measures as rubbing the wart with some curious substance removing the mother wart plucking a hair for each wart and burning it tracing the region on paper and burning that etc (Sulzberger and Wolf MRec 140 552 1934) The practitioner of suggestion therapy must believe that it will work and convince the patient that this is so see Bloch (KlinWchr 6 2271 2320 1927 Vollmer PsychosomM 8 138 1946 Bett Pract 166 77 1951 Allington ADS 316 1952) Obermayer reported a success with hypnosis (ADS 60 1222 1949)

VERRUCAE PLANAE —A single accurate careful application of Vleminckx solution may suffice The cautery can be used with suitable accuracy Cannon (ADS 49 66, 1944) recommended the ethyl chloride spray and curet followed by 50% phenol wiped off with alcohol.

MOSAIC WARTS may respond to 60% salicylic acid paste carefully delimited in its application and occasional painting with strong silver nitrate solution (the Montgomery ADS 45 1023 194) Thompson (BJD 55 307 1943) advised soaking the lesion for 10 minutes each evening in 3% formol. The white macerated plugs that develop should be débrided and the treatment persisted with for the 3 to 8 weeks required for cure

PLANTAR WARTS.—Dependence is placed mainly on x ray or radium No filter is employed Radon 16 millicurie hours filtered with 0.3 mm of steel 1,200 to 1 900 r single dose was recommended by Mark and Friesen (NEngJM 223 851 1940) If a single dose of 3 to 5 E does not cure although it does in about 9 of 10 cases some other attack should be undertaken. Electrodesiccation and electrocoagulation are preferred by many Electrosurgical methods have been given in detail by Lewis (NYSJM 33 1 1933 Frank ADS 45 439 194 Karp ADS 53 496 1946) Using local anesthesia all verruca bearing epidermis is completely separated from the dermis. The second degree burn is dressed with a bland, antiseptic grease such as Aureomycin ointment. The actual cautery may be so used with satisfaction in dealing with large warts. Blistering adequate to cure may be accomplished by the firm application of solid carbon dioxide for 3 minutes after Windemuth (Crow and Scott Lancet 2 31 1934); I have not tried this.

The curett with local anesthesia was recommended by Beale and Richardson (Ho thMJ 49 573 1953) Bleeding is profuse but the application of Merthiolate an antibiotic ointment and pressure dressing is followed by cure in most instances the stated)

One may pare the wart use a ring pad and salicylic acid ointment and treat the lesion successfully with phenol and t l ed accomplishing a cure by chemical cauterization (Black ADS 56, 430 1947) It is possible to use podophyllin in conjunction with paring and occlusive dressing so as to achieve a cure though this is not the easiest way (Kurtin and Wetter ADS 57 303 1948 W L ADS 63 490 1953)

Injection of various chemicals to the base of the wart may prove successful. Aqueous bismuth solution has been so used Simply Novocain may be effective (Jim son and Rhea N E gJM 49 631 1933) The injection should be made at the stratum germinativum t and, although this would be technically hard to achieve The injection must influence the dermoepidermal junction for it to be effective One half per cent phenol, although it hurts a bit at first can be used in this way (Anning Lancet 1: 976 1948 Hemphill BMJ 1 71 1933)

Euphorbium resinifera commonly known as wart weed was tried by Goldblum and Curtis (JID 20: 43 1933), who reported that the 30% alcoholic solution produced lysis of rete cells in human and guinea pig and, when applied to plantar warts, cured 59 of 60 cases within 4 months. Less enthusiastic was the report of Martin-Scott (BJD 60: 5 1954)

Each wart should be treated individually. Surgery is not the first but the last resort in treating plantar warts, for they are likely to recur in the scar of an excision wound. Plastic surgery is required when a plantar wart has been mistreated, particularly with x-ray therapy, and this is by no means a rarity (Brown et al J 108 4 1937; 146: 623 1951; Shaw: BMJ 1: 11 1948). Amputation of the plantar condyle of the underlying metatarsal head was recommended in some cases to relieve pressure by DeVries (J 1[illegible]: 1902, 1933)

ACUMINATE WARTS AND CONDYLOMATA respond in a gratifying way to podophyllin. This resin 25% in liquid petrolatum was reported efficient by Kaplan (NOrMSJ 94 388 1942): a single application meticulously applied only to the moist warts being followed by considerable inflammation and then exfoliation. Culp and Kaplan (AnnSurg 120: 251 1944) confirmed this observation, noting that, of 200 cases 8_% were cured with one application and all were cured by a few subsequent applications. Cohen (Pract 156: 133, 1946) warned against transferring the agent to places where it is not desired. Sullivan found 20% podophyllin in alcohol preferable and Mark (JMoMA 44: 749 1947) recommended 15% in compound tincture of benzoin, for it stays where it is put. The use of 1.5% podophyllin in polyethylene glycol to be applied daily by the patient is safe reliable and less painful than the strong concentration (Warner DWebu 1 1: 178 1950); 3% seemed a more satisfactory strength to Scott (BMJ 2: 297 1954)

Podophyllin must not get into the eye, for it would cause severe and serious conjunctivitis. Its effect, Sullivan and King (ADS 56: 30 1947) discovered, much resembles that of colchicine. Podophyllotoxin is the active ingredient of the resin (Sullivan et al: SouthMJ 41: 336 1948). Alpha and beta peltatin are also effective (Sullivan and Hearin: ADS 66: 706 1952). Violent reaction necessitating a dorsal slit may follow the use of podophyllin beneath the foreskin; the patient should be circumcised first (Finkle and Frishwasser JID 8 190 1947)

The chemical is useless in treating verrucae vulgares (Frank and Cohen: ADS 56 109, 194). A review of its dermatologic applicability was given by Nelson (ADS 67: 458, 1953). Unusual pseudoepitheliomatous reactions to podophyllin were seen by Maxwell and Lamb (ADS 70: 510, 1954). Toxic encephalopathy apparently due to podophyllin was fatal in a pregnant Negress whose huge vulvar lesion was treated with the drug (Ward et al SouthMJ 47 1204, 1954)

Repeated painting of moist lesions with Fowler's solution has effect comparable with, but gentler than podophyllin according to Pa losky and Leider (JID 13: 73 1949)

MOLLUSCUM CONTAGIOSUM

Symptoms.—Molluscum contagiosum ("water wart") is a virus disease of the epithelium characterized by small waxy globular tumors which generally show tiny rounded concavities at their apices. The lesions range in size from pin point to pinhead and develop slowly. At first they are acuminate or globular in shape with broad bases, but as they grow larger they become flattened and umbilicated. The number of lesions is from 2 or 3 to 20 or more. The mucous surfaces, particularly the borders of the lips and lids, are occasionally involved. Lesions of the eyelids may provoke mild conjunctivitis. The lesions are at first firm but become somewhat softened and ultimately may suppurate, finally healing without scar. Sometimes the tumors disappear spontaneously but if untreated generally persist for many months. The lesions are discrete and may be grouped. They give rise to no symptoms unless inflamed. Numerous and minute miliary mollusca resemble verrucae planae (Beehet ADS 37 897 1938)

Etiology and Pathology.—A like disease occurs in birds, "fowl pox," and in animals. It is autoinoculable and contagious. Juliusberg (DeutschMWchn 31 1598 1905) demonstrated the filtrable nature of the causative agent in human beings. Successful human inoculations with sterile filtrates were obtained by Wile and Kingery (JCutD 37 431 1919)

Strongyloplasma hominis is manifest as spheric particles which are 0.25 micron in diameter, numerous and nonmotile in fresh preparations (Lipschutz AfDuS 10 : 237 1911). Aggregates of them form acidophilic inclusion bodies within the cytoplasm of

Fig. 246.—Molluscum contagiosum. The largest lesion is uncommonly large. The central puncta are plainly shown. (Dr. F. Ronchese.)

Figs. 247 and 248.—Molluscum contagiosum.

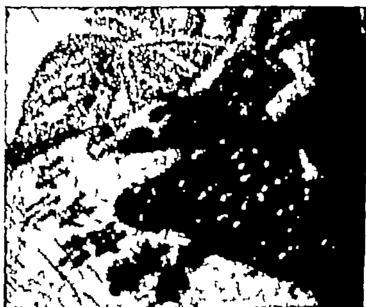

Fig. 249.—Molluscum contagiosum inoculated by tattoo 6 weeks previously. (Dr. John Butler.)

infected epithelial cell The lesions are formed by hyperplasia of infected epithelial cells. Cytoplasmic inclusions push aside the nuclei and bulge the cell walls (Melrowsky et al.: JID , 105, 1940) Fragment of a inclusion body i fowlpox were proved to be infectious by Woodruff and Goodpasture (AmJP 6: 713, 1930) Intracerebral inoculation of the virus in chicks produced a characteristic and fatal disease (Buddingh: JExpM 67 9?1 933, 1938) An attack of molluscum contagiosum does not confer immunity and while its virus and that of birdpox are similar the two diseases are quite different (Low: EdinMJ 53: 657 1946)

Diagnosis.—The size color appearance and recent acquisition of the lesions, together with the fact that their contents can be squeezed out are distinctive Fibromas, milia comedones and verrucae are to be excluded. Mil

Fig. 251—Molluscum contagiosum, microdissection of infected epithelial cell. (Van Rooyen JPathBact 46 425, 1938) *A* One needle in cell to steady it, other in molluscum body *B* Molluscum body moved slightly both needles in focus. *C* Molluscum body taken from bed, which remains a cavity

lary cases are sometimes confusing but careful study of the lesions with a hand lens should clarify the diagnosis. Large solitary lesions sometimes resemble carcinoma (Tobias ADS 64 208 1951) Inflamed lesions of the lid margins may simulate styes.

Prognosis and Treatment.—The disorder is primarily harmless, but the lesions if untreated are persistent and if secondarily infected are painful and dangerous. One should incise squeeze out the contents, and apply tincture of iodine to the cavities Fulguration is effective (Goodman BJD 47 413 1935) Sulfadiazine in a dose of 4 Gm per day will cure in a week or two Laymon (ADS 53 643 1946) reported in confirmation of Sommerville (BJD

53 255 1941) and this approach may be desirable when lesions are so numerous that surgical methods would be difficult Schiff (RhodeIMJ 30 806 1947) succeeded in a miliary case with sulfadiazine, and cures have been reported with oral Aureomycin (Guy et al. ADS 60 629 1949) and Terramycin (Mopper ADS 65 613 1952)

Eyelid margin cases with conjunctivitis can actually cause corneal ulceration (Gifford and Gifford AOphth 50 227 1921) They are best treated surgically (Julianelle and James AmJOphth 26 165 1943)

See Goodpasture and King (AmJPath 3: 385, 1927) cytology Goodpasture and Anderson (APath 30 12, 1940) immunity and chorioallantoic grafts Pinkus and Frisch (JID 11 280, 1949) skin test suggesting inflammatory reaction represents sensitization Blank (ActaD-V 29 92, 1949) histology, electron microscope studies of Boswell (JHExpPath 128: 351 1947), Rake and Blank (JID 15 81 1950 Melnick (Sc 114 484 1951) Mescon et al. (JID 23: 293, 1954) histochemical studies of inclusion bodies as they develop.

LYMPHOGRANULOMA VENEREUM

Symptoms.—Venereal lymphogranuloma is an infectious disease which is generally transmitted by sexual activity The first symptom is often a small ulceration a papule or a herpeslike lesion of the genitals The character of this primary lesion which often is unrecognized is variable Primary anorectal inoculation probably occurs (Grace and Henry NYSJM 40 285 1940) The incubation period is thought to range from 2 to 6 weeks from inoculation to lymph node enlargement The primary sore is often on the prepuce but adenitis may precede the appearance of a recognized primary A genital lesion may start to heal when the bubo develops but in the absence of bubo the ulcerations may be resistant (Brandt VDI 22 248 1941) In women the portal of entry may remain obscure The nodes which drain the portal of entry usually the inguinal nodes of one or both sides become swollen and tender and ultimately the overlying skin assumes a purplish hue and finally ulcerates. Multiple sinuses connect the suppurating nodes with the surface Healing is slow and cicatrices are thick and puckered Adenitis was bilateral in 21% of the cases of Prehn (ADS 35 231 1937) and it showed no predilection as to side Lymph nodes became suppurative in 75 of the cases The temperature averaged 100° F the highest noted was 106° F Slight anemia and slight mononucleosis characterized the blood picture Contact infection are possible Cases have involved the tongue and submaxillary glands Hellerström described infection of a physician's finger the axillary lymphatics underwent the usual course of venereal lymphogranuloma Extragenital lesions, including those of head and neck, were reviewed by Slaughter (SGO 24 390 1940)

Anorectal Lymphatics rather than the inguinal may be involved usually in women for anatomic reasons. The chronic inflammatory response and lymphatic obstruction lead to rectal stricture and perineal distortion even elephantiasis esthiomene This becomes a most stubborn and resistant condition The chronic ulcerative process involving the labia, perineum anus, and lower rectum may be of the superficial, perforating hypertrophic or mixed type Rectal strictures involve the female by preference (Cole J 101 1069 1933) and are located in the lower 10 cm of the bowel generally not higher than 6 cm They may be bandlike or tubular Stricture has been seen in male homosexuals. Some cases of ulcerative colitis are due to venereal lymphogranuloma Urethral anorectal and genital syndromes in women overlap Treatment of rectal stricture is largely by mechanical and surgical means, the requirement for which has not been supplanted by the limited benefits obtainable with antibiotics (Daniv SouthMJ 46 269 1953)

Constitutional Symptoms Exanthems and Complications —Along with local lymph node reaction one occasionally finds generalized lymph node enlargement The spleen may be enlarged Polyarthritis may be present Abdominal and pelvic inflammation have been shown due to lymphogranuloma

tosis in fatal cases. General skin manifestations, such as erythema nodosum erythema multiforme-like eruptions, urticaria scarlatiniform eruptions, and disseminated ulceration have been noted. When erythema nodosum occurs, it becomes manifest simultaneously with the development of cutaneous allergy and reaches its maximum when the inguinal adenitis is most intense (Heller

Fig. 252.—Esthiomene and perianal fist la, positive Frei test. (Crossen Diseases of Women, Mosby ed. 8 1953.)

Fig. 253.—Perianal scarring with rectal stricture. (Crossen Diseases of Women, Mosby ed. 8, 1953.)

Fig. 254.—Venereal lymphogranuloma penil lesion and lymphadenopathy Note two positive Frei test reactions on forearm. (Cole J 101 1049 1932.)

ström ActaMScand 109 1 1941) it may develop after interventions which alter the allergic status, such as the performance of the Frei test. A rash was elicited by exposure to sunshine in 60% of women with chronic disease a smaller proportion of acute cases and of cases in males, according to Sonck (abs ADS 54 216 1946) Erythematous papules and wheals were noted,

sometimes quite itchy affecting especially the extensor aspects of the extremities. Photosensitivity apparently occurs from 5 to 6 weeks after the lymphatic symptoms start and it disappears when the disease is cured

Ocular Lesions have been attributed to lymphogranuloma venereum (Macnie AOphth 25 255 1941) The infection can cause conjunctivitis, keratoconjunctivitis and uveitis (Espildora and Coutts AmJOphth 25 916 1942) Curth et al. (J 115 445 1940)

Parinaud's syndrome and keratoconjunctivitis have been proved to be of this nature (Schele et al. J 135 333 1947)

Genitourinary Manifestations may be primary with infection of meatus or urethritis. Later stricture of the urethra or perigenital sinuses and fistulae may develop Invasion of the posterior urethra and spread to prostate seminal vesicles and epididymis may take place Secondarily the bladder neck may be deformed displaced or compressed, and even the pelvic ureter may be forced to dilate (Coutts JUrol 49 595 1943) Urethral discharge with inguinal adenopathy calls for a Frei test for the primary sore of lymphopathia may be intraurethral just as the syphilitic chancre may be

Pregnancy and lymphogranuloma venereum rarely influence one another unless mechanical interference occurs (Wilson and Hesseltine AmJOG 43 459 1942)

Bone and Joint Manifestations are not common, but arthralgia acute polyarthritis, and chronic recurrent polyarthritis have been noted. In 2 of 4 such patients of Hickam (ADS 51 330 1945) pustular eruptions and fever followed Frei testing Osseous lesions were reviewed by Wright and Logan (ASurg 39 108 1939) they described instances of necrosis of the pubes possibly due to direct extension of the infection.

Neurologic Involvement was described by A Hamm and D Annov (J 106 1642 1936) whose patients had fever headache sweats, and painful stiffness of the neck. Active virus was obtained from the spinal fluid The spinal fluid showed enormous increase of total protein but responded to sulfonamide therapy in the cases of acute meningoencephalitis of Zarafonetis (NEngJM 230 567 1944)

In Children.—Ten nonvenereal cases in children 2 weeks to 14 years of age (Levy JPediat 11 812, 1937) and the case of an infant reported by Thompson and Higgins (AmJSyph 33 473 1949) show that the disease must be considered in the differential diagnosis of lymphadenopathy in young patients.

Etiology Pathology and Diagnosis.—The presence of venereal lymphogranuloma infection is often obfuscated by other venereal diseases. No especial racial susceptibility is discerned, although Negroes are often the victims. The disease is of world wide distribution most frequent in the Tropics (J 116 2405 1941)

In studying the venereal transmission of the disease and the high preponderance of male victims Bejarano and Calatayud (Crón. Méd. 1933, p. 771) found 11 4 of 75 apparently healthy prostitutes gave strongly positive Frei tests despite negative histories and examinations. Some observers believe that a woman may be a carrier of the disease without being a sufferer from it.

The inflammatory process may be acute subacute or chronic according to Hornbleth (BOH 63 90 1936) who determined that the histologic unit of the disease is an inflammatory nodule which undergoes necrosis. Primary lesions and lymph nodes in cases proved by isolation of the virus showed the same structure being granulomas composed of large mononuclear cells forming about the small vessels, which undergo compression and obliteration. This leads to necrosis in the center of the granuloma and abscess formation not due to thrombosis or endothelial proliferation and there is little fibrosis either in acute or healed lesions according to Sheldon and Heyman (AmJPath 23 653, 1947) See Favre (Annal) D 49 1940) photomicrographs of histology and granular corpuscles, silver staining

Serum Proteins are increased by the infection, sometimes before the Frei test becomes positive Serum protein exceeded 8 Gm./100 cc in 63 of 67 cases of Kampmeier et al (AmJMSc 198 610 1939) While this change is not specifically diagnostic it is significant, and hyperglobulinemia responds to sulfonamide treatment (Schamberg: AmJMedSci

Fig 255.—Lymphopathia venerea. (Dr O G Costa.)

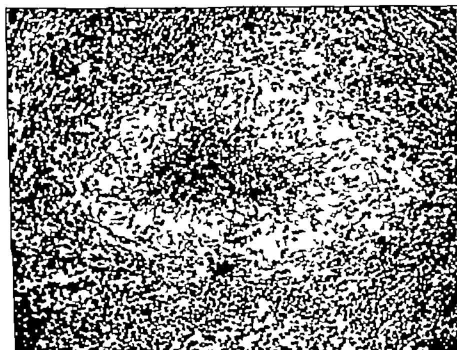

Fig. 256.—Venereal lymphogranuloma. Epithelioid nodule in a lymph node removed 2 months after onset of symptoms. Note invasion of the center by leukocytes and plasma cells, and absence of extensive necrosis. (Kornblith, [illegible] 43: 99, 193[illegible].)

201: 67 1941) The Formol gel test, indicative of hyperglobulinemia, affords reliable help in diagnosis and interpretation of response of the disease to treatment, according to Combes et al. (AmJSyph 29: 611 1945)

See Howard et al. (AmJSyph 22: 32, 1938) hyperproteinemia with reduction of albumin and increase of globulin reverts toward normal with healing of active lesions; Rosen et al. (ADS 39: 211 1939) hyperglobulinemia in 100% of 116 cases, most marked in rectal stricture, while serum lipids are decreased in lymphopathia venerea, not in chancroid.

COMPLEMENT FIXATION TESTS probably have significance (Beeson and Miller: AmJ PubH 34 1076, 1944; Wall et al. AmJSyph 31: 89 1947)

THE VIRUS.—Hellerström demonstrated the existence of a filtrable virus as the cause, and he transmitted the infection to animals. Miyagawa (JapJD 39 103 1936) reported the cultivation of the virus in the allantois of chick embryos. Beautiful illustrations of virus colonies developing in the epithelial cells of corneal cultures from puppy embryos were published by Malamos (ZtschrBakt 142: 1 1938); see Meixner (DWchn 106 325 1938) Coutts et al. (JTropM 43: 137 1943) Transmission of the virus to monkeys and the virucidal property of human serum from patients with the disease were described by Hellerström and Wassén (Epidemiology and Etiology of Lymphogranuloma Inguinale, Masson, 1934) Tamura (J 103: 409, 1934 JLabClinM 20: 393 1933) grew the virus in tissue culture in Tyrode medium and transmitted it thence to guinea pigs. The heated culture he found therapeutically useful. Wassén has inoculated human beings with virulent mouse brain antigen and obtained typical infection (Hellerström: ActaD-V 21 231 1940) The incubation period was from 15 to 24 days. Wilmoth (JTropM 39: 173, 1936) transmitted the disease to a human subject, using virus grown artificially

FREI TEST.—Frei (KlinWchn 4: 148, 1925; J 110: 1633, 1938) first demonstrated a specific skin reaction with sterile bubo pus. The reaction becomes positive within a few weeks after lymphadenitis appears. Frei test reactivity apparently remains positive during life once it has become positive. It is uniformly positive if the bubo has lasted 40 days. Mouse brain or chick yolk sac infections provide satisfactory antigens.

The Frei test is a small scale reproduction of the disease. The typical nodule comprises a shell of palisaded layers of epithelioid cells with a central granular core composed of the debris of leukocytes lymphocytes and endothelial cells. Plasma cells develop after the more acute phase. The spread of the process may lead to the formation of sinuses or abscesses; the involved nodes may coalesce or remain distinct. Sometimes there occurs spontaneous healing. Donovan bodies are not found in lymphogranuloma inguinale

Treatment.—Surgical removal of infected lymph nodes was at one time recommended but injections of Frei antigen and the use of sulfonamides and antibiotics are followed by better results. Fluctuant buboes should be aspirated (Kornblith AmJDigD 6 712, 1939)

Human antigen for therapeutic purposes was prepared by Hellerström (ActaD V 17 293 1936) from pus obtained by aspiration from a fresh bubo. This was diluted 1 to 8 filtered through paper and inactivated by 2 hours exposure to 60° C He added 0.5% phenol and gave doses of from 0.5 to 2.0 cc intravenously Wien and Perlstein (BJD 49 63 1937) thought the intradermal method of giving antigen in treatment seemed to hasten resolution. The intradermal route was preferred by Anderson and Harmos (Surg 3 41 1938) starting with 0.05 cc and increasing by that amount to a maximum of 1.0 cc. Vaccinal therapy with specific antigen is best accomplished by using subcutaneous injections in courses alternated with intravenous, allowing short rest periods after each of the latter Focal reactions and variable febrile and constitutional symptoms may be expected. Autogenous blood serum contains specific antigen and may be injected subcutaneously in treatment (Marks SouthMJ 35 1092 1942) Injections of the specific antigen may provoke undesirably severe systemic reactions and rashes.

Supportive measures should be maintained during courses of injections and rest periods. These include the urging of fluids, bed rest and light diet during the febrile stage of the disease aspirin medication and local heat applications for arthralgia and myalgia aspiration of fluctuant buboes enemas daily of 1:5000 potassium permanganate low residue diet, mineral oil and mild laxatives for anorectal cases iron medication for secondary anemia douches and the frequent application of 25% balsam of Peru ointment for vulvar and vaginal ulceration. Colostomy is likely to become necessary in rectal cases.

Mice infected experimentally can be saved by sulfanilamide a therapeutic response different from that of other virus diseases, excepting influenza (MacCallum and Findlay Lancet 2 136 1938) Sulfanilamide has been used in

human cases with good effect (Shaffer and Arnold ADS 38 705 1938) The dose must be large. Probably the best treatment available in 1948 comprised Frei vaccine intravenously on alternate days, sulfanilamide rest and artificial fever therapy in hospital (Costello and Cohen ADS 44 391 1941) After review of 388 cases at Bellevue Hospital, Costello and D Avanzo (ADS 57 112 1948) concluded that sulfonamides and bed rest were the best treatment in the early stage Fever therapy and sulfonamide were given together by Trautman and Thomason (NOrlM&SJ 92: 441 1940) with good results claimed. Sulfonamide was adjudged specific and was said to reverse the Frei test in many cases, by Stein (AmJSyph 24 454, 1940) After sulfathiazole has been given for 2 weeks, the virus can no longer be cultivated from the bubo (Heyman et al AmJSyph 31 81 1947) while in untreated cases chick embryo cultures remained positive for 3 months or more The dose should maintain a blood level of from 3.5 to 6 mg % and sulfadiazine and sulfamerazine were preferred by Rake (AmJTropM 28 555 1948)

Aureomycin has exhibited striking activity against many rickettsiae and certain viruses, and is highly effective in the treatment of mice infected intracerebrally with the virus of lymphogranuloma venereum Available to Wright et al. (J 138 408 1948) in vials for intramuscular injection, it was given to human cases in doses of from 10 to 40 mg per day In all cases so treated there was reduction of the size of buboes within 4 days, and the inclusion and elementary bodies showed degeneration and disappearance within 48 hours. Improvement and relief of pain in 4 days were observed in 40 cases treated with Aureomycin by Prigot et al. (NYSJM 49 1911 1949) although Robinson et al (AmJSyph 34 46 1950) expressed disappointment with this drug The late manifestations were helped more than the early ones by Aureomycin especially those with proctitis or stricture according to Wammock et al. (JID 14 427 1950) who recommended a dose of 0.5 Gm q.i.d to a total of from 20 to 30 Gm. Tetracycline is curative also (Maynard et al. AmJSyph 38 606 1954)

Terramycin proved highly effectual in West African males treated with 1 Gm. 4 times a day for 7 days by Henley (BritJVD 29 36 1953) and chloramphenicol is also effective according to Robinson (ADS 64 284, 1951)

Potassium antimony tartrate 5 cc of the 1% solution given twice a week may be beneficial in the early stages. Lithium antimony thiomalate (Anthiomaline) was recommended by Law (Lancet 1 300 1943)

Carcinoma of the female ano-genital region is an unusual concomitant probably merely coincidental, but one must be alert to the possibility so as to apply treatment which is appropriate (White and Miller AmJSyph 37 177 1953)

GENERAL REFERENCES.—Coutts (JTropM 37 97, 1934) Greeks and Romans knew the disease, which is also illustrated on Incan pottery; Sturber and Ploch (ADS 32, 86, 1935), penile and scrotal elephantiasis Thompson (J 104 1869 1935) general description De Wolf and Loring (J 106 1874, 1936) contact infection, encephalitis, oral lesions, D'Aunoy and Schenken (J 110 709 1938), pelvic inflammatory disease; Stokes et al. (AmJMedSci 197 878, 1939), review and bibliography Torpin et al. (AmJSurg 43: 688, 1939) 146 cases of which 96 affected females, grouped among 4 classes, genital, urethral, inguinal, anorectal, and sulfonamide therapy; Favre and Hellerström Rev d'Hyg 61, no 6-7, 1939) 87 pages, no pictures, extensive bibliography D'Aunoy and v Haam (APath 27 1032, 1939) review and bibliography Costello and Cohen (ADS 44 391 1941) 187 Bellevue cases, treatment with sulfonamide and Frei antigen Pund and Lacy (AmSurg 17 711, 1951) among cases of anogenital cancer a high proportion had positive Frei test, questionable etiologic relationship.

RECTAL STRICTURE.—DeWolf and VanCleve (J 99 1065, 1932) on rectal stricture Bloom (BGO 58 827 1934) on esthiomene and lymphatic anatomy Stillman (AnnSurg 101 1284 1935) stricture and colostomy VanderVeer et al. (AmJMedSci 190 178, 1935) 47 cases with 21 rectal strictures causing increasing constipation, pain, bleeding fecal incontinence, rectal discharge Wein et al (APath 10 121, 1935), autopsies on 3 Negro women Peyton (AmJSyph 24 360, 1940) types of stricture Grace (J 122 74 1943) anorectal cases Longmire (Surg 15 997 1944) pararectal abscess, fistula, rectal ulcer stricture, colostomy anemia from bleeding, hemorrhage, obstruction, perforation, acute belly from lymphopathia venerea.

EXANTHEMS.—Coutts (DWchn 87 1664, 1933) marginate glossitis sometimes with bullae, and cervical adenopathy Myerson (J 117 1077, 1941) pharyngeal and laryngeal lesion, Sezary (ADS 31 348, 1935) disseminated eruptions, nodular papular esteulopustule following x-ray therapy of primary or Frei testing Wein and Perlstein (J 109 27 1937), cutaneous ulcers Miescher (DZtschr 73 337, 1936) bulla; Meissner and Epps (DWchn 107 1466, 1930; AfDuS 176 100, 1938) morbilliform rash with fever e. multiforme and e.

nodosum with fe er anemia, cachexia; Costello and Cohen (ADS 41 557 1940) lymphadenitis neck and groin, recommending Frei test in any case of unexplained adenitis Simpson (ADS 66 526, 1952) metastatic bubo, neck and groin.

NEUROLOGIC INVOLVEMENT.—Gutman (NYSJM 39 1420 1939) myalgia, arthralgia and meningeal irritation Rubin and Aring (J 1?0 1276, 191) meningoencephalit case cured with sulfonamide, Laifer (ADS 55 899 1947) CSF normal in 2, etc Vinberg et al (JVDI 30 291 1949) of 82 cases, 19 show d CSF abnormality mainly with colloidal changes f protein content.

FREI TEST.—Grace and Suskind (ADS 34 65 1936) mouse brain antigen best for routine use, Strauss and Howard (J 106: 517 1936) mouse brain antigen unreliable Connor et L (JInfectD 60 62, 1937) Frei test latent period ranges from 5 t 39 days Hinkley et L (ADS 38 383 1938) human antigen preferred to mouse brain antigen Brandt nd Torpin (AmJSyph 24 632, 1940) interpretation of skin test Smith (ADS 41 128, 1940) histology of Fre test papule Rakin et al. CAT SCRATCH DISEASE

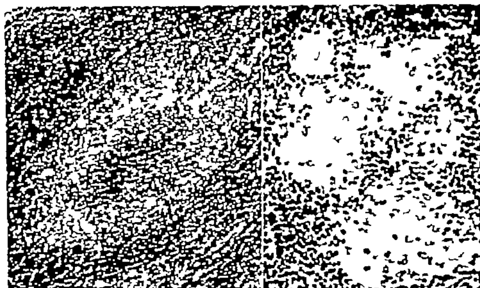
This self limited infection presumably viral, is clinically suggestive of but milder than, tularemia. Seen more frequently in children than in adult It is characterized by subacute lymphadenitis which sometimes suppurates (Debré et al. SemHôp 26: 1805, 1950) This may be painful, is accompanied by mild fever and malaise and i usu ally preceded by a small maculovesicular kin lesion. A primary lesion, a scratch scar covered by a crusted erythematous papule at the site of inoculation may be found within

Fig. 25 —Cat scratch fe er Mal 36 years old, with cervical lymphadenitis and pink macula rash becoming vesicula on rms and forearms (G eer and Keefer NEngJM 244 545, 1951)

2 t 4 days The adult patient of Gree and Keefer (NEngJM 44: 545 1951) had a macular pinkish ra h which grad ally became vesicular and wa located on the extenso surfaces of th arms. Epstein (ADS 66: 40 195) described the skin lesions, the ecthymatous chancre and the rashes resembling erythema multiforme or erythema nodosum Systemic manifestations are slight and transient, wh le local manifestations comprise typicall) aden pathy which m y be huge with bubo formatio and drain g sinuses.



Suppuration took place in about one-third of the 60 American cases collected by Dan els and MacM rray (AnnIntM 37 697 195.) The bubo pus is bacteriologically sterile (Thelin and Martin du Pan: Praxis 40 74 1951) and leukocytosi i sually ab sent

Antigen analogous to the Frei antigen of lymphopathia venerea can be m de from bubo pus nd yields positive tuberculoid and/or erythemato skin tests (W ters et al.: Ped. 10 311 1952) The antigen tested in 40 cat owners who denied experiencing symptoms of the disease proved positive in 3, suggesting that the disease m y be specific a d inconspicuou t t mes (Battley and I rb rn Lancet 1 520 1953)

The disease has been known to occur in small epidemics (Lemaire and Debray: BullmemSocmédHôpParis 66: 375, 1950 see Edit.: J 149 746 1952) Cases have been reported by Tonge et al. (MJAustral 81 1953) from Queensla d, and by Thompson and Miller (AnnIntM 39 146, 1953) whose e cephal ti pat nt contracted the disease b dressing rabb ts. Twelve cases from South Tex w re reported b Daeschner et al (JPediat 43: 371 1953) The infect on a sed the death f th patient of Gräff (Monatsch Kinderh 102 23., 1954)

While the history of exposure to cats is usually clear the disease m y occur following exposure to other a imals (Bennett and Melton: JMAGa 40: 466, 1951) Sniffi g cat uri e apparently resulted in throat inoculation with cervical adenopathy in a case of Daniels and MacMurray (AIntM 88: 720 1951)

The possible relation to Parinaud s oculoglandular syndrome was discussed by van Veelan and Stibbe (abs J 153 453, 1953), whose patient manifested conjunctivitis edema of the lids, swelling of the left ear and jaw and regional lymph node enlargement in 1948 and gave a positive reaction to cat scratch antigen in 195_. This idea had occurred to de Lavergne et al. (BullmémSocMHôp 67: 953, 1951) and was promoted also by Cassady and Culbertson (AOphth 50: 68, 1953); see Edit. (J 152: 1717 1953) The uveoparotid syndrome of Heerfordt (AfOphth 0 _54, 1909) might be of this nature; a case with headache, iridocyclitis, f cial palsy parotid swelling, and high total protein in the spinal fluid, as in infectious neuronitis was described by Tepper (BMJ _ 1954, 194)

Figs 248 and 249—Cat scratch disease, histopathology of the enlarged lymph nodes. (W ters and Prior: Pediat 10: 211 1952)

Histologic st dies by Molla et t al. (PresseMéd 58: 1353, 1950) revealed in the lymph nodes reticular hyperplasia which might remain stationary or regress, but which often progressed to the formation of ecrotic foci microscopic abscesses, suppuration and periadenitis. Basophile bodies were fou d in the cytoplasm of the lymphocytes, plasma cells and reticulocytes stai ed by Giemsa s method and were attributed to the presence of a virus by Mollaret et al. (PresseMéd 59 681, 701, 1951) Their presence was con firmed by Jambor and Emura (ADS 67 439 1953) who noted the histologic similarity to lymphopathia venerea of this benign inoculation lymphoreticulosis.

Treatment is as yet nonspecific.

Para-anthrax, allegedly due to *B anthracoides* manifests accompanying lymphadenitis. It followed a cat scratch in the case of Epstein (ADS 57: 664, 1948) and was not responsive to penicillin o sulfonamides.

DERMATOSES DUE TO RICKETTSIAE

Rickettsiae, like viruses, are obligate intracellular parasites. They are, for the most part, microscopically visible gram negative, bacteria like bodies found in the alimentary canals of arthropods and frequently associated with disease in man and animals. Electron microscopy shows cell walls and nuclei and rickettsiae behave immunologically like viruses and bacteria (Mudd: J 126 561 632, 1944) See Rivers et al. (Viral and Rickettsial Infections of Man Lippincott, 1952)

The diseases of man with which species of Rickettsia are associated and of which the epidemiologic character is determined by the life cycles and the feeding habits of the arthropod vectors may be divided into four subdivisions: typhus, Rocky Mountain spotted fever tsutsugamushi and Q fever according to Dyer (J 124: 1165, 1944) whose résumé I quote here extensively The organisms of Q fever which is not associated with dermatologic symptoms, pass bacterial filters which retain other pathogenic rickettsiae.

A characteristic of this group of diseases with the exception of Q fever is the production in patients of agglutinins for the X strains of *B proteus*. Serums from typhus and spotted fever agglutinate the OX_{19} and OX_2 strain while those from tsutsugamushi agglutinate the OXK strain, typically but no strain of *B proteus* has been found which is agglutinated by serums from Q fever The absence of cross immunity also separates subdivisions of rickettsial infections.

Clinically the typhus, spotted fever and tsutsugamushi groups are characterized by sudden onset, rash, fever of fairly well-defined duration mental disturbance and pronounced prostration. Epidemic (louse-borne) and endemic (murine or flea borne) types of the typhus subdivision are recognized. The Rocky Mountain spotted fever subdivision not so clearly delineated but includes other or similar tick borne diseases, such a boutonneuse fever the misnamed São Paulo exanthematic typhus, the so-called tick typhus of India, and South African tick bite fever The tsutsugamushi subdivision embraces also scrub typhus and other mite born diseases of southern Asia and the Southwest Pacific Islands.

Pathologically characteristic changes consisting of vasculitis and perivasculitis are caused by rickettsiae, which, if carefully sought, can usually be found in the endothelial cells lining the blood vessels, especially the smaller ones of the brain, lungs, heart, and skin (Mandelbaum and Hollander: AmM 3: 316, 1947) A skin biopsy selecting a well developed lesion of the macular type is excised sharp fixed in Regaud's fluid, and stained by the Giemsa method. Rickettsiae can usually be found, but if they are not, the proliferative endangiitis is diagnostic The similarities of thromboangiitis obliterans and rickettsial damage to endothelium led Goodman (ASurg 35: 1176 1937) to hypothesize a relationship.

Viable rickettsiae were isolated from a lymph node excised a year after clinical cure of a patient with Rocky Mt. spotted fever by Parker et al. (JImmunol 73 383 1954)

See Weil and Felix (WienKlinWchn 29 33, 1916) serodiagnosis. Hertig and Wolbach (JMRes 44 329 1924), rickettsiae in insects, tabulation and demonstration Cox (Sci 94 399 1941) yolk sac culture, skin test and vaccine Davis (PHRpts 58 1201, 1943), transmission of spotted fevers by *Ornithodorus parkeri*. Castaneda (... J 121 ... 1933) staining of rickettsiae thin smear dry well xylene 3 min ... wash twice with 95% alcohol then with water cover for 3 minutes with saturated solution potassium bichromate wash with water cover with 10% Giemsa solution for 10-20 minutes wash with water dry and examine rickettsiae red or blue on almost colorless background, clearly differentiated. Parker (J 110 1185 1273 1938) valuable résumé of rickettsioses, particularly Rocky Mt spotted fever

Epidemic Typhus.—The body louse and the head louse which are probably not different species, carry typhus (*R prowazeki*) from one human being to another The infection kills the louse within 12 days (Parker J 110 1185 1273 1938) The incubation period is from 5 to 15 days usually 8 to 12 days. Onset may be preceded by a day or two of malaise but the majority of cases show abrupt onset with rapidly rising fever repeated but seldom severe chills and headache. Fever rises steadily reaching a maximum by the end of the first week with slight morning recessions Fever falls by rapid lysis after about 14 days. Headache is a prominent symptom hard to relieve Prostration and cardiac weakness may be evident from the start In severe cases with cardiac weakness there is a tendency toward development of gangrene of the extremities. Confusion disorientation, restlessness, irritability even delirium occur

A characteristic feature of the disease is the rash, which appears about the fourth to sixth day perhaps as early as the third day or as late as the

ninth. The rash is absent in about 10% of the cases, and may be hard to see on pigmented skins (Megaw BMJ 2 401 1942). Conjunctival red spots are an almost constant finding and may be the only distinguishing feature on gross inspection of the body of a person dying of typhus (Avtsin APath 36 158 1943). Rose red macules and papules, at first erythematous but later purpuric increase in number and extend for perhaps 48 hours their profusion being related to the severity of the disease. They occur first on the inner surfaces of the upper arms or on the sides of the chest and upper abdomen then spread to the rest of the chest trunk and extremities, even including palms and soles, but seldom affecting the neck and face. The rash becomes brownish as recovery ensues and eventually disappears. The fatality rate ranges from 20 to 80% in different epidemics.

Endemic (Murine) Typhus, differing from epidemic in epidemiology is due to *R. mooseri* and cases have occurred in every state of the United States. There is a reservoir of infection in the common rat and possibly in other rodents, transmission from rat to rat probably being accomplished by rat fleas and lice. Transmission to man probably is accomplished by infected feces of rat fleas. Clinical manifestations differ from those of epidemic typhus mainly in being milder. The rash seldom appears before the fifth day and may comprise only a few macules which soon disappear. Pink maculopapules becoming bluish red and slaty were described by Donald and Barker (BMJ 2 333 1942) appearing first on the shoulders about the axillary folds, then the upper abdomen and flanks, later on trunk and limbs, and prominently on forearms and dorsa of hands and feet. Fading is succeeded by mottling which may last for a month, with fine branny desquamation. The virus is endemic in various rodents many varieties of which are susceptible to infection (Brigham and Dyer J 110 180 1938).

A preventive vaccine from infected fleas was prepared but not highly praised by Dyer et al. (PHRpts 47 1329 1932).

In treatment para aminobenzoic acid in doses of 2 Gm each 2 hours until the temperature became normal was recommended by Smith (J 131 1114 1946) and the usefulness of this drug was further attested by Levy and Arnold (TexasSJM 42 314 1946). Chloromycetin in full oral dosage was curative in a case of McCrary (ArkMSJ 46 81 1949) and Ley et al. (J 143 217 1950) adjudged the drug promptly effectual. Achromycin was curative in cases of exanthematic typhus treated by Ruiz Sanchez et al. (Antibiot& Chemother 4 402, 1954).

Brill's Disease: see Murray et al. (J 142 1059 1950) rash 4th to 6th day, faint pink, discrete macules or maculopapules 1 to 10 mm diameter usually on front of chest extending rapidly over trunk and proximal parts of extremities, maximum by 7th or 8th day; very scanty in some cases.

Rocky Mountain Spotted Fever is found chiefly in the northwestern states of the Union, prevalent in sheep-herding districts. The disease in man has occurred in most of the 48 states. It affects especially outdoor people in the spring and early summer in the West, later in summer in higher altitudes. In any locale the mortality rate is about constant. In the Bitterroot Valley region of western Montana the rate in adults was near 80%, in infants 35%. In the East it ran about 25% before antibiotics were available.

The attack may be abortive, fulminating or of any degree of severity in between. In ambulatory cases the fever is low, the rash scanty and the duration only 14 days. A temperature of 104° F with fleeting rash and recovery in a week, characterizes the abortive case. Fulminating infections kill in 3 to 5 days with or without a rash which may be blotchy and ecchymotic. The incubation period of severe cases is 2 to 5 days and is prolonged to 3 to 14 days in milder cases. There may be a 2- or 3-day period of prodromal malaise, or the onset may be sudden. It is marked by chill, headache, pain in the upper abdomen, and pains in bones and muscles. The main complaints are frontal and occipital headache, low back pain and malaise. The rash depends patho-

Fig. 260.—Typhus, showing petechial rash. (Courtesy of Dr. J. J. Todd, from Moseby's Practice of Medicine. The C. V. Mosby Co.)

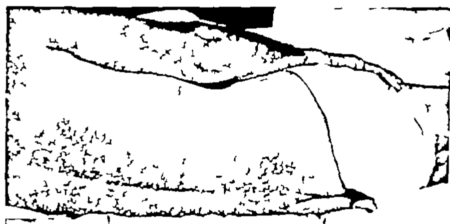


Fig. 261.—Rocky Mountain spotted fever. (Dr. J. J. Sippy.)

Fig. 263.—*Dermacentor variabilis*, female above, male below. (Dr. F. C. Bishopp.)

logically on endangiitis of peripheral vessels. It appears on the second third, or fourth day rarely a day or two later It is first seen on the wrists and ankles, and spreads rapidly to the back, then to the arms, legs and chest and last to the abdomen Palms and soles are frequently involved often the face and occasionally even the scalp First pale and simulating the early rash of measles, the exanthem becomes bright rose in color and maculopapular It soon becomes purpuric and bluish Large sparsely distributed bright spots are of better prognostic import than small ones tending to become confluent.

Fig. 264.—Rocky Mountain spotted fever (Kelsey and Harrell J 137 1356, 1948)

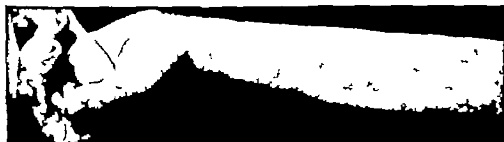

Fig. 265.—Rocky Mountain spotted fever (Drs. W M. Kelsey and G. T Harrell.)

The rash comes in crops, of which there may be one, two or three Sloughs due to endothelial necrosis may involve the scrotum prepuce, vulva, buttocks, or palate (Pullen et al. NOrlM&SJ 97 359 1945) The fever persists for 2 or 3 weeks, and the eruption clears as bruises do if the patient recovers. Desquamation occurs at the end of the third or fourth week (Hutton J 117: 413 1941) The mortality throughout the United States in over 4 000 cases reported 1930 to 1946 averaged 23% (Edit : J 142 1217 1950)

See Ong and Raffetto (JPediat 17 647 1940), 18 cases District of Columbia region Ha ... et al (PaMJ 44 176 1940) 13 cases near Philadelphia Elsmore (OklaSMAJ 36 232, 1943) 7 cases in Oklahoma, tick host thought to be gopher; Smith and Reinhard (JMoMA 40: 166, 1943) and Casford (ib p. 171) Missouri cases Evans et al. (OhioSMJ 43 606,—1947) 70 cases i Ohio with 19 deaths.

ETIOLOGY.—*Dermacentor andersoni*, *D. variabilis* (dog tick) and *Haemaphysalis leporis-palustris* (rabbit tick) can carry *R. rickettsi* which causes spotted fever; other ticks have been proved capable of carrying it. The virus is not transmitted until the tick has been feeding for 8 to 24 hours. The patient of Bauersfeld (J 11?: 1319 1939) was infected by removing a tick from her husband and she died.

PROPHYLAXIS AND CONTROL.—One should wear boots, leggings and puttees and hunt for and remove ticks twice a day; the search must miss no area of the body. All clothing should be removed at night. Persons should sleep separately. The clothes must be kept off the ground. In choosing a camp site select timber country and scant vegetation. Avoid rodents, sagebrush, and old trails. One should avoid infected areas. Dibutyl phthalate rubbed into the clothing gives protection and withstands several launderings of the garments (Council Rpt. BMJ 2: 87 1946).

If specific immune serum is injected into the site of a bite of an infected tick within 48 hours, protection against disease and yet development of active immunity ensued in experimental animals (Edit. J 125: 11 1944). The practical value of this interception of infection has not as yet been determined.

VACCINE is prepared by grinding infected ticks to make a phenolized emulsion; after settling the supernatant fluid is used. It is given in two subcutaneous injections of 2 cc each for adults and 1 cc each for children under 10 years; 3 injections may be given instead of 2. Children are better protected than adults. The vaccination must be repeated annually in the spring and it will protect for the remainder of the year. See Cox (Sci 94: 399 1941), Parker (AmJTropM 21 369 1941). The rickettsiae were cultivated in the chick chorioallantois by Bengtson and Dyer (PHRpts 50 1489 1935). A vaccine prepared from a saline suspension of infected chick embryo membranes, inactivated by formaldehyde and extracted with ether to remove yolk lipids and tissue debris, contains the immunizing antigens (Craigie, CanadJRes 23: 104 1945; see J 139 839 1948). It appears to have value in preventing Rocky Mt. spotted fever (Squibb makes it). Vaccine made from chick embryo cultures entail the hazard of an egg protein content and skin testing should precede its use (Ratner and Untracht: J 132: 899 1946).

TREATMENT.—Rest, hospital care and symptomatic and supportive treatment are required in cases which are not mild. Pointing to the loss of protein and low serum levels which develop Harrell et al. (SouthMJ 39 551 1946) urged a high protein diet because the antiserum, admittedly valuable if given before the third day, does not prevent protein depletion. A high protein, high-calorie diet decreased wastage of nitrogen and loss of body weight in patients of Tierney and Yeomans (JClinInv 25 822 1946) who found depression of the albumin fraction and striking elevation of the globulin fraction in the serums of most cases.

Chloromycetin inhibits various viruses, rickettsiae and bacteria, protecting chick embryos and mice from infection (Ehrlich et al. Sc 106 417 1947). Effective when given orally, doses of 1.0 Gm. initially followed by 0.2 Gm each 4 hours cured typhus in human beings (Smadel et al. cited J 138 432, 1948. BMJ 2 428 1948). It is dramatically beneficial in scrub typhus. Improvement was steady following the first dose and the eruption did not spread, and there were no deaths among the patients treated with Chloromycetin by Pincoffs et al. (AnnIntM 29 656 1948). The drug cured cases of epidemic typhus for Benhamou et al. (PresseMéd 58 317 1950). Symptoms receded after 24 hours and fever lasted only 4 days in 16 patients treated with Chloromycetin by Parker et al. (AmJMed 9 308 1950). Cortisone combined with the antibiotic seemed advantageous to Workman et al. (NEngJM 246 962, 1952).

Aureomycin was effective and preferable to PABA in the experience of Ross et al. (J 138 1213 1948). See Cooke (J 138 885 1948). Terramycin likewise gave striking abatement of symptoms within 48 hours (Powell et al. BullJHH 89 10 1951).

In managing gangrene, which is dry and affects particularly the lower extremities, sometimes costing one or more toes, one waits for demarcation before undertaking surgery (Constantini et al. PresseMéd 46 75 1938).

Topping's antispotted fever rabbit serum may be dramatic if given early in a dose of 1 cc. per kg. according to Meade (VaMMonth 73 16 1946). Para-aminobenzoic acid given in large doses is of real utility (Rose et al. J 129 1160 1945; Flinn et al. J 132 911, 1946; Tierney SouthMJ 40 81 1947; Ravenel ib 40: 801 1947). The dose is 6 to 8 Gm. initially, then 2 or 3 Gm. each 2 hours. To be effective it is to be started before the end of the first week. The blood concentration should be kept around 30 to 40 mg. %

The drug must be stopped if the white blood cell count becomes less than 3,000. Methylthionine chloride, 0.5% added to the diet of experimentally infected mice was more effective than PABA (McClymans and Grant: Sc 105: 181 1947)

Treatment of a comprehensive sort includes restoration of fluid and electrolyte balance by intravenous dextrose in saline or lactate-Ringer's solution, correction of acidosis by one-sixth molar sodium lactate, correction of serum protein depletion by intravenous plasma, provision of high vitamin intake, administration of PABA with alertness to its possible intolerance, and attention to possible complications such as congestive heart failure, pneumonia, and thrombophlebitis (Ravenel: J 133: 989 1947)

Neoarsphenamine dissolved in aqueous Metaphen was recommended by Reich (An IntM 17: 47 194)

See Topping (PHRpts 58 757 1943): immune serum in experimental infections of guinea pigs and monkeys suppressed disease if given early, ameliorated if given within 72 hours. Yeomans et al. (J 129 19 1945): amelioration in human cases; Tierney et al. (JPed 31 1 1947): no deaths in 8 cases treated with PABA; Fraser et al. (AmJDisChild 75 492, 1948): odd seizures by giving sodium salt of PABA; Woodward and Raby (SouthMJ 41 997 1948): blood level 40 mg. lessened fever rapidly, no relapse on discontinuing PABA after temperature became normal; Kelsey and Harrell (J 137 1356 1948): PABA helped, rabbit serum seemed not helpful; Hooten et al. (VMMonth 8 121 1949): PABA the drug of choice at that time.

Rat-Mite Dermatitis.—Dove and Shelmire (J 96: 579 1931 97: 1506 1931) described an acariasis in northern Texas due to the blood-sucking rat mite *Liponyssus bacoti* Hirst. These mites can convey endemic typhus, or Brill's disease. If they are infected, a febrile course follows their bites and persists for about two weeks.

Tick-Bite Fever.—South African tick-bite fever is due to rickettsial infection. It closely resembles fièvre boutonneuse, kedani and tsutsugamushi. In the region of Lorenzo Marques, no newcomer escapes this mild disease which is without mortality. In certain areas infected larval ticks, *Amblyomma hebraeum* are numerous in the tall grass. Their bites result in a pathognomonic initial sore, a raised, bright red, circular indurated lesion of ... cm. diameter with a necrotic black center. Rarely the primary sores are multiple. Two types of cases are distinguished, a mild type consisting merely of primary sore and satellite adenitis, and a severe type with the sore, adenitis, headache, rash, and fever of 10 days' duration with aching pains, photophobia, tremors and even delirium. The rash is not characteristic. It appears about the fifth day, being macular or papular, rosy or blotchy, diffuse or discrete, confined to the trunk, or generally distributed, including the palms and soles. A bright red papular type of rash is common, and it comes out in daily crops. Though not itchy it is somewhat uncomfortable. General symptoms include a step-up fever, severe headache, stiff neck, aching and restlessness. The fever drops on the tenth day. There are never sequelae, complications, or recurrences. The bubo does not suppurate. Immunity is solid following the infection. The serum agglutinates Proteus OX_{19} and OX, but not X Kingsbury (Pijper and Dau: BritJExpPath 1 ... 123, 1931). Infection of ... was achieved by Pijper and Dau (BritJExperPath 9 ...7 1930), who demonstrated rickettsiae in the brains of the animals (JTropM 33 93, 1930). See Troup and Pijper (Lancet ... 1183 1931); Pijper (SoAf MJ 8: 551, 1934); Pijper and Crocker (SoAf MJ 1... 613, 1938)

Aureomycin is successful in treatment, prior to the use of which PABA had been known to yield benefit that was not striking (Gear and Harrington: SoAf MJ 23 507, 1949). Fever drops and malaise dissipates within 72 hours after Aureomycin is started (Henderson et al. EAfrMJ ..: 140 1950)

Boutonneuse (Marseilles Fever) caused by *R. conori*, is closely related to Rocky Mt. spotted fever and may be identical with Kenya typhus. Infection is transmitted by the brown dog tick. The incubation period is 5 to 7 days, rarely as long as 18 days, and the onset is usually abrupt with fever and repeated chills, headache and muscle pains, but comparatively slight prostration. A papular or maculopapular rash appears on the second to fourth day of illness, starting on the trunk, legs and arms, and extending rapidly over the entire body, usually appearing last on the face. Volar skin is commonly involved. The soft palate may manifest small round red spots for only a few days. The lesions, especially in dependent locations, may become petechial but seldom coalesce. A small ulcer presumably indicating the site of the infecting tick bite, may be found early in the disease. It is only ... to 5 mm. in diameter showing a black necrotic center surrounded by a red areola. Chloromycetin is curative (Janbon et al.: PresseMéd 57 10.. 1949)

Tsutsugamushi (Japanese River Fever, Kedani Fever, Scrub Typhus) resembles the other rickettsial infections but is caused by *R. ... pyogenes*. It is probably identical with Malayan scrub typhus, Queensland coastal fever and pseudotyphus of Sumatra. The larval forms of certain mites transmit infection to man from reservoir probably in field mice and other rodents. The incubation period is from 7 to 21 days, generally a little less than two weeks. Prodromal symptoms occur as in typhus, and chilliness, headache and fever characterize the onset. Deafness is not a rare early symptom, and joint pains and drowsiness are often present. Fever with peaks produces considerable prostration, lasts about ... weeks and falls to normal. The striking feature of the patient's general appearance is apathy (Mc...h...lin and Forrester: AmJMSc ..10 33 1945). Fatalities occur in a range of from 1 to 10% in various epidemics (Brumpt: Précis de Parasitologie). Death occurs in coma between the 9th and 15th days.

The most characteristic sign is a small necrotic ulcer such as occurs in bouton euse, a d this is present in the majority of cases in Japan. It is not always found, however in cases called scrub typhus in Malaya. General lymphadenopathy develops and is especiall noticeable in nodes draining the site of the primary ulcer which usually occurs in the *pubic region axilla, or leg. The typical ra h of tsutsugamushi appears on the fourth to* eighth day and consists of macules and slightly elevated rose-red or pink papules. It does not become petechial. It appears first on the trunk and face and extends to the legs and arms. It may be present on the palms and soles, and occasionally the face a d the scalp are involved. The rash reaches its height i about 4 days a d fades within 6 or 7 days. An enanthem may be present on the soft palate. Conjunctivitis and mild edema of the *lids are usual (Ahlm and Lipshutz: J L.A 1095 1044)* Many patients show *bronchial* symptoms, sometimes with mucopurulent sputum, and pneumonia may occur as a complication. Hyperesthesia, pains in muscles and joints, deaf ess, apathy clouded mentality insomnia and delirium may be encountered (Dyer: J I 4 1164 1944)

Some mm nity is co ferred b an attack l t this may lack permanence. Cross immunity complete between rural typhus n Malaya a d tsutsugamushi in the guinea pig rabb t and monkey (Lewthwaite and Savoo : Br.J.Exper.Path 1: 448 461 1936) but this is not true f bu t phus, which f rthermore does not m nifest a primary sore Rocky Mt spotted fe v ine does not protect against ither rbe rural typhus.

Th path logy t th disease was especially st died l y Park and Hart (Am.J.Clin.Path 10 139 1940) wh found th most ignifi a t cha ges in the heart l g l mph odes, testes an l bra n The essential lesion are *disseminated perivascul tis nd focal i* terstitial, monoc t cel lar i filtrat sociated with edema and passive hyperemia, but the thrombot c lesio common in othe rickettsioses are extremely rare

Para-aminobenzoic acid, given so as to maintain 30 to 60 mg % concentration in the blood, apparently reduces symptoms, morbidity and mortality (Tierney: J 131: [illegible]40 1946). Methylene blue appears more effective than PABA, especially in the late stages (Edit.: BMJ 1: 403, 1947). Chloromycetin brings about improvement within a matter of hours, fever persisting on the average less than 30 hours after the drug is started, and is equally effective whether given early or late in the course of the disease (Smadel et al. JCI [illegible] 1196 1949). Infection may be prevented by rubbing dibutyl phthalate into the clothing as a repellent (see BMJ 2: 8 1940).

Trench Fever, also known as five-day fever or Volhynia fever, is transmitted to man by the body louse. This disease disappeared after World War I. The incubation period was from 5 to [illegible]0 days; onset was sudden with headache and pain in the legs and fever lasted about a week but frequently relapsed two or three times. A rash was present in the majority of cases, usually macular, sometimes papular, and was most commonly observed on the trunk. It sometimes disappeared in [illegible]4 hours. The disease was not fatal. It was controllable by installation of body lice.

RICKETTSIALPOX

Symptoms.—An initial lesion and a vesiculopapular type of eruption dermatologically characterize this interesting disorder which was recognized in an outbreak of previously unclassified disease which occurred in a Regency Park housing development in New York City in the summer of 1946. The initial lesion started as a papule, rounded and firm, enlarging and undergoing central, deeply seated vesiculation. The fluid was clear at first but became cloudy and the lesion shrank and dried so that a black eschar resulted. About one week after the start of the initial sore occurred the abrupt onset of chills, fever, sweats, frontal headache, and backache, coinciding with the height of development of the asymptomatic sore which attained a diameter of 5 to 20 mm., with surrounding erythema but no induration. Regional lymph nodes were usually enlarged and slightly tender. The sore persisted for a total of approximately 3 weeks and usually left a small scar. The sore may not have been noted by the patient.

The onset of illness was sudden, with fever low at first but rising rapidly to 103° to 104° F., with morning remissions for about a week, defervescing gradually. Chills occurred in 70% of the cases during the first 2 days and were followed by drenching sweats. Headache was usual and severe, and backache and myalgia resembled those of influenza. Lassitude was always present, photophobia sometimes and, less frequently, anorexia, dryness of the throat and nausea.

A rash appeared in all cases, usually being noted at the onset of fever or within a day or two later. The lesions were maculopapular, discrete and erythematous, the papules roughly circular, firm, and sometimes surrounded by erythema. They ranged from 2 to 8 mm. in diameter and underwent summit vesiculation simulating varicella within a day or two. The vesicles dried, a black crust formed, and healing occurred without scarring. The rash was scanty, moderate or abundant, and was without a pattern, though the volar skin was spared, and it endured usually for from 4 to 7 days. There were no physical signs of systemic disease other than those associated with fever. There was no fatality. Moderate leukopenia with occasional relative lymphocytosis was observed. The histopathology of the cutaneous lesions was described by Hersherberger and Huebner (PHRpts 62 1740 1947).

Etiology.—The mouse mite *Allodermanyssus sanguineus Hirst*, inhabiting the domicile of infected persons, was proved to carry the rickettsia, *R. akari*, which was shown to be the cause of the disease (Huebner et al. PHRpts 61 1605 1946; 62 777 1947). The house mouse was the probable carrier of the vector. The organism was grown in the yolk sacs of fertile eggs and produced illness in mice and guinea pigs. A yolk sac antigen gave specific complement fixation tests with human convalescent serum. Agglutinations with *B. proteus* OX_{19}, OX_2, and OXK were negative. An interesting account of the finding of the mites by Pomerantz, an exterminator, and Shankman, a physician, is given by Roueché (The New Yorker, Aug 30 1947 p 28). See Sulzberger et al (ADS 57 767 1948).

Fig. 272.—Rickettsialpox, vesicular and crusted lesions of face and tongue. (Dr. Morris Greenberg, New York City Department of Health.)

Treatment has been symptomatic, but aureomycin in full dosage by mouth restored the temperature to normal in 24 hours and relieved malaise in 5 cases, while untreated the disease could be expected to cause fever and symptoms for a week or more (Rose et al. AmJMed 9: 300, 1950).

See Rose (NYSJM 48: 2266, 1948) more than 350 cases on record; Greenberg et al. (PHRpts 64: 1677, 1949; J 133: 901, 1947; AmJPubH 37: 860, 1947) complete description; Rose (AnnIntM 31: 871, 1949) clinical; Barker (J 141: 1119, 1949) 12 cases; Pike et al. (NEngJM 242: 913, 1950) case in Bostonian; Franklin et al. (NEngJM 244: 509, 1951) case in Bostonian; LaBoccetta et al. (AmJMed 13: 412, 1952) Philadelphia cases.

An Undescribed Fever Resembling Rickettsialpox and Varicella was reported by Loewenthal (SoAfrMJ 24: 268, 1950) on the basis of 11 cases seen in children in the Transvaal. Malaise of from 3 to 4 days duration preceded the eruption, which was varicelliform, morbilliform, or papular. This appeared first on the oral mucosae, was full-blown in from 24 to 48 hours, and regressed in 8 days. An early symptom was asymmetric enlargement of the occipital and cervical lymph nodes. The disease was self limited and nonfatal.

DERMATOSES DUE TO BACTERIA

STAPHYLOCOCCIC INFECTIONS

Staphylococci are often pathogenic (see Blair BactRev 3 97, 1939) In the skin they can produce (1) epidermal infections such as impetigo (2) intracutaneous and follicular infections such as infectious eczematoid dermatitis and furuncles, and (3) deep infections such as carbuncle cellulitis, erysipelas-like lesions, abscesses and gangrene See Pillsbury (J 132 602, 1946) See Granuloma pyogenicum and Botryomycosis.

Breed et al. (Bergey Manual of Determinative Bacteriology Williams & Wilkins 1948, p. 235) combined the genera *Micrococcus* and *Staphylococcus* and described species of especial dermatologic interest among those which produce nitrites from nitrates but do not utilize $NH_4H_2PO_4$ as the sole source of nitrogen: *Micrococcus (Staphylococcus) pyogenes* var *aureus* liquefies gelatin ferments mannitol and produces abundant orange growth on agar media; *Micrococcus pyogenes* var *albus* differs only in manifesting white growth; and *Micrococcus citreus* manifests yellow growth. *Micrococcus epidermidis* liquefies gelatin very slowly or not at all, does not ferment mannitol and manifests a scant white translucent growth on agar media. These four species are aerobic to facultative anaerobic and do not produce pink or red pigment on agar media.

Staphylococcus pyogenes i the name that Bigger (BMJ : 837 1937) preferred for strains which hitherto have been known as *Staph. pyogenes aureus* and *Staph pyogenes albus* and he did not accept *Staph citreus* as a distinct species It was once thought that the activity of the staphylococcus is due solely to endotoxin but it was shown that a broth filtrate conta ns toxin capable of killing rabbits when given intravenously Necrosis is produced by the subcutaneous injection of the toxin. Hemolysin was demonstrated and its presence in filtrates was recognized in 1901 leukocidin was also discovered early Burnet (1929) studying the cause of death from injections of contaminated diphtheria antitoxin, described the intravenous toxicity dermonecrotic effect and hemolytic action of the exotoxin. Panton et al, discovered that intracutaneous injections of the exotoxin are immunizing Pathogenicity B gger noted is usually associated with the ability of the strain to produce pigment. Defense consists in elimination by leukocytes or prevention of toxic effects by antitoxins. The necrotizing substance causes obstruction to the local lymph flow and so plays an important part in determining the histologic and physiologic aspects of the inflammatory lesion

Staphylococcus toxin was the subject of an illuminating review by Rigdon (AmJMSc 199 41., 1940) There appears to be no relat onship between the quantity of toxin produced nd the irulence of the organism for man. The production of toxin by a given train is not constant. Fractions described include leukocidin, hemolysin, acute killing fraction, dermonecrotizing fraction neph otoxin, coagulase and fibrinolysin. It has not been proved whether these fractions are the same o different substances. The antigenic ty of co jugates of staph lococcus toxin w th other substances, a noted on p. 1°6, phe ome n of unassessed l ut perhaps great clinical sign fica ce The production of coagulase i strongly nd cative of pathogenicity (Moss AmJClinPath 11 857 1941)

The erythrogeni toxin a some strain produces a rash like that of sca let fever (Steven J 95 1957 1027 Aranow and Wood: J 119 1491 1942)

Staphylococcus toxi ha been used therapeutically after alteration to the toxoid by incubation with 0 3% formaldehyde the toxoid does not produce necrosis but does bring about significant, though not great, increase of tibody titer (Dolman CanadPHJ 24 126 1922 JInfectDis 55 172, 1934 Lancet 1 306 1935) Benefits in sycosis a d furunculosis were laimed by Connor and M Kie (BJD 46 20 1934) and i arious conditions due to staphylococci (Connor BMJ 2 1195, 1935 Edit. J 104 502, 1431 1936) It is without alue in acne (Whitby Lancet 1 1464 1936) See Anderson and Stokes (ADS 40 382, 1939) Prior to the introduction of the antibiotics, I used the toxoid commonly in cases of infectious eczematoid dermatitis, especially of the hands. Goodman (ADS 47 841 1943) recommended combination of toxoid and acein Antitoxi neutralizes staphylococcus toxin (Joyner nd Smith SGO 63 1 1936) diminishes the skin reaction t injections of toxin (Kenton AmJP th 16 185, 1939) and i of alue in septicemia (Rigdon and Stookey Surg 12 656, 1942) How er at present the immunologic approach in staphylococcic disease is seemingly obsolescent Little confidence ca be placed in ccines, utogenous or stock. In staphylococcic infection nowadays, reliance is placed on surgery hen ppropriate, control of inoculation, and antibiotics gi en topically or systemically

The unit of peni ili n was originally described in terms of ts capacity to inhibit growth of the Oxford strain of staphylococcus. Experien e with the use of the antibiotic soon showed that some strains either are or become penicillin resistant. Resistance could be creased b ult vati g the organi ms n reasi g c ncentrat on of penicillin, but when they were recultivated in ordinary bouillon the resistance lost (Todd and Turner BMJ 1: 111 1945) Resi tant strai were found t produce pen cillinase and from 100 cases of staph lococcic infect on, 38 resistant stra ns were cult v ted,

28 of which were obtained from patients who had received penicillin (Barber: BMJ 2: 863, 194) Resistant strains may be carried in the nasopharynx of ward nurses (Forbes BMJ : 500 1949) Resistant strains appear to be on the increase, so that the clinical value of penicillin may be decreasing according to Sherris and Florey (Lancet 1: 300 1951) These investigators thought that resistant strains are significantly less often associated with signs of inflammation and suppuration than the sensitive strains.

Aureomycin is usually effective against penicillin-resistant strains (Nichols and Needham: PSEBM 71: 300 1949) Terramycin and Achromycin are also excellent. Strains resistant to these are usually also resistant to penicillin but the reverse is not necessarily true (Finland and Haight AI tM 91: 143, 1953) See Treatment, antibiotics

Clarification of the properties of strains related to the dermatoses caused by staphylococci is by no means complete No epidermonecrotizing agency has been described yet pure cultures of *Staph aureus* are often obtained from purely vesicular or bullous lesions.

STAPHYLOCOCCIC IMPETIGO

Symptoms.—Staphylococcic impetigo is an acute superficial usually primary infectious dermatitis characterized by the rapid development of blisters filled with clear yellowish fluid appearing on normal looking skin or on top of red spots. When the bullae enlarge they become flat sometimes with depressed centers. They vary in size between those of a pea and a dollar piece or larger Differing from the ephemeral blisters of streptococcic impetigo the bullae of staphylococcic impetigo usually persist for a period of days. After they have ruptured the lesions become covered with thin, flat varnishlike crusts of a gray or brown color easily distinguished from the thick crusts of the streptococcic disease In older children and adults, the disease occurs chiefly on the face and neck In babies the folds are preferred neck, axillae and groins and lesions may develop all over the body which may be covered with large readily rupturing bullae a condition designated pemphigus neonatorum. Or staphylococcic impetigo may present circular or reniform lesions consisting of flat blisters and crusts about a zone centrally healed, so simulating circinate tinea (Epstein ADS 42 840 1940 44 317 1941 WiscMJ 40 383 1941 DZtschr 70 328 1935)

Lesions appear singly or in crops. Itching is annoying and scratching leads to autoinoculation The disease is typically a hot weather one and accounted for considerable morbidity in military personnel in humid tropical climates, where flexural (D Avanzo ADS 52 28 1945) as well as facial involvement was common

It is not unusual for impetigo to extend from the skin onto labial mucosae or into the nostrils (Montgomery JCutDis 28 445 1910) Impetiginous stomatitis may affect the inner surface of the lips and cheeks and spread onto the gums and tongue (Cushing Med 21 421 1904)

Impetigo due to an intensely hemolytic strain of staphylococcus may take the form of unusually itchy small superficial strongly erythematous lesions with little vesiculation. Small blebs, fragile and with a bright areola, typify streptococcic disease as a rule (Tachau BJD 50 113 1938) see Streptococcic impetigo

Large bullae sometimes single may occur as the manifestation of impetiginoid staphylococcic disease. This may affect the axillae or groins and is seen often in the Tropics (cf Pemphigus neonatorum and Pemphigus acuta)

BOCKHART'S IMPETIGO is superficial staphylococcic folliculitis, pustular from the onset (Bockhart MonatshPrakD 6 450 1887) Impetigo is a common complication of contact dermatitis, atopic eczema pediculosis capitis and scabies as is also infectious eczematoid dermatitis. Impetigo of the buttocks is usually scabietic Mucous membranes are sometimes affected by extension from the external sites.

ACNE NECROTICA MILIARIS of the scalp is a form of folliculitis which constitutes a typical clinical entity probably due to staphylococci (Lane ADS 28 10 1933) The patients are generally of middle age The lesions are discrete isolated and itchy Pruritus is intense being disproportionate with the visible disease. There may be perhaps 10 to 100 lesions. Before excoriation,

which is their prompt complication they are tiny vesicopustules justifying the name pustular perifolliculitis (Ormsby) Perhaps because of excoriation they leave little scars. If the disease persists and is persistently excoriated the hair may become thin as a result of alopecia cicatrisata. Seborrhea plays no important role in etiology Montgomery (ADS 36 40 1937) demon

Fig. 373 —Impetigo. Early unruptured bleb on helix.
Fig. 374 —Impetigo.

Fig. 375.—Impetigo.

Fig. 376.—Impetigo contagiosa, unusually severe. (Dr L W Ketron)

strated ulceration between adjacent hair follicles with a serosanguineous crust and a moderate infiltration mainly of lymphocytes extending into the mid cutis. Numerous staphylococci were seen at the margins of the ulcer Applications of ammoniated mercury may cure these patients. Staphylococcus toxoid antibiotics, and eradication of foci of infection, especially prostatic are sometimes effective measures. Daily application to the lesions of 10% am

moniated mercury in Carbowax 1500 and the diet appropriate for acne may be recommended. Bichloride of mercury 0.1% in 70% alcohol was approved by Wright (ADS 60: 468 1949) Response to antibiotics has been disappoint

Fig 277.—Impetigo. (Dr J Lama Calloway)

Fig. 278.—Impetigo, staphylococcic.

Fig 279.—Impetigo (Dr J G [illegible])

Fig. 280.—Impetigo

ing for the disease usually relapses when they are discontinued (Stritzler et al. ADS 64 464, 1951) An oxyquinoline antiseptic such as Ung Quinolor is sometimes helpful Pruritus limited to the scalp often responds to cortisone.

Etiology—Both staphylococci and streptococci have been recovered from impetiginoid lesions. Impetigo ' from the Latin an attack, is a clinical name devoid of etiologic connotation. Epstein, culturing 318 cases of im petigo found only staphylococci in 166 only streptococci in 7 both organisms in 143 and none in 2. Carefully reviewing the findings of others he noted that the particular bacteriologic technic influences the results. Mixed infections are common, as exemplified by the report of Cruickshank (Lancet 2 275 1941) who found in 23 cases Lancefield A streptococci in 15 and *Staphylococcus aureus* in 18 Epstein (JID 3 223 1940) fulfilled Koch s postulates by experimentally producing circinate impetigo with staphylococci. See also Bigger et al (BJD 56 55 1944) whose selective cultural methods revealed staphylococci in 97% of 130 patients, streptococci in 32% staphylococci only in 67% and streptococci only in 2%

Pathology—The epidermis is edematous and somewhat thickened. The roof of the bulla is formed by the stratum corneum The cavity is filled with serum in which are found degenerated epithelial cells, leukocytes and a few lymphocytes. Numbers of cocci may be found these are likely to be at the border of the bleb The dermis is inflamed moderately

Fig. 121—Impetigo of the fingers The forefinger lesion has almost healed. The middle-finger lesion has an acti edg The ring finger lesion is fresh.

Diagnosis—In contact dermatitis the vesicles are small, closely grouped and itchy In pemphigus the eruption is not confined to the face bullae develop as such, and the patients are adults. The presence or absence of pediculosis or scabies must be determined.

Prognosis.—Response to treatment is usually good. Fatal cases occur in babies. Reinfection may occur Autoinoculation prolongs the course. If scabies is present it must be treated promptly and vigorously with temporary disregard of cocci. If a case proves unduly rebellious, focal infection should be eradicated In an extremely hot, wet environment, the disease may be practically incurable

Treatment.—One may wipe the lesions gently and anoint them liberally with a 2% ammoniated mercurial paste, which should be reapplied several times daily Too strong an ointment is a mistake to be avoided. Sulfathiazole ointment was highly recommended by Winer and Strakosch (J 118 221 1942) and others it is a hazardous sensitizer A microcrystalline sulfathiazole paste may cure overnight according to Harris (J 121 403 1943) Penicillin oint ment 500 units per gram in a lanolin and petrolatum base was thought to be comparatively tidy and often efficient (Gold BMJ 1 1952 1945) but penicillin is no longer applied topically because of its now well known irritant and sensitizing potentialities.

Figs. 282 and 283.—Impetigo, staphylococcic.

Fig. 284.—Palmar lesion of impetigo, showing excoriation and intense superficial dermatitis.

The ointments in current use are tetracycline neomycin some other antibiotics, and Vioform. When an ointment is prescribed it is to be applied gently and on reapplication grease and débris should be wiped away gently with benzine or mineral oil on a cotton pledget Since without bacteriologic study which takes 24 hours and is more or less expensive one does not know what parasites are present—although an experienced clinician makes a canny guess—I generally combine 0.6% Chloromycetin with Vioform Cream and am only occasionally disappointed

If a case is rebellious, it is good practice to utilize the systemic effects of antibiotics because of the hazard of nephritis. Acute nephritis is a recognized complication of impetigo presumably when it is streptococcic (see p 282) Since tetracycline is so effective and so innocuous when given in modest doses for the few days during which it is needed I give it nowadays to almost every patient

Occlusive treatment, preventing autoinoculation during the few days needed for a given lesion to heal, has been highly recommended (Newman BMJ 1 823 1933) Metaphen 0.2% in collodion may be used for this purpose (*Hollander and Hecht AmJDisChild 48 269 1934*)

Gentian violet is unsightly but often effective (Sutton J 110 1733 1938) The caustic effect of silver nitrate often does more harm than the micrococci. Cool compresses moist with 1:10 000 $HgCl_2$ or 1:6 000 $KMnO_4$, may beneficially be applied for say 15 minutes 5 times a day Patients should be instructed as to the inoculable nature of the disease and the avoidance of autoinoculation a 7 year-old can be induced to keep his fingers off

Pemphigus Neonatorum (Ritter's disease neonatal dermatitis; superficial coccic dermatitis in infants) is an impetiginous, usually staphylococcic dermatitis in infants, in whom the infection is a serious matter It may begin with localized redness, which gradually spreads until the major portion of the body is involved. Or it may begin with wrinkled yellowish, desquamative lesions, or easily ruptured bullae or both, which appear in crops and spread widely Mucous membranes may be attacked. In the cases of Carter and Osborn (BMJ 1: 463 1930) the laundry was the source of the infection, and areas touched by unclean clothing were first affected. The desquamative process may be severe with the development of an oozing eczematoid condition. Folliculitis, furuncles, and deep abscesses may develop. The stools are loose and green and contain *Micrococcus*. Recovery or death generally ensues in from a fortnight to a month.

Cole and Ruh (J 63 1159 1914) are among the many who have confirmed the staphylococcic nature of the disease which has nothing to do with the diet The spread of organisms is subepithelial, a difference from the intraepidermal spread of adult impetigo The absence of papillae in infants skins renders this easier than in adult Streptococci apparently caused the 4 cases of Cannon et al. (ADS 4 834 1940) The pathogenic bacteria reach the infants usually from nasal carriers among the personnel who handle the children (Allison and Hobbs: BMJ 2: 1 194)

PROGNOSIS.—Almost half of v Ritterhsein's patients died. The outlook ultimately depends on the treatment *which must be instituted promptly and must be appropriate* It is possible to inoculate staphylococci so widely by smearing a baby with grease that recovery becomes impossible Epidemics vary in virulence

TREATMENT.—Prevention is possible when the source of infection has been determined. Aseptic noncleansing technic significantly reduced the incidence of impetigo neonatorum at the Philadelphia General Hospital (Ritter UCutRev 45 460, 1951) Oily preparations are worse than useless, but the immediate and early evacuation of blebs and the *careful* injection into them of 20% silver nitrate have been reported effectual. Supportive measures are indicated The % aqueous solution of gentian violet is of great service Hart (BJD 50 118 1938) used mercurochrome permanganate baths and dusting powders; he emphasized the necessity of opening the blisters and keeping the surface dry A cradle with lights to provide radiant warmth, along with good ventilation, is useful. Undermined epidermis should be removed so that the antiseptic may have access to the place where it is needed. Daily inspection is necessary

Penicillin by injection saved the patient of Callaway et al. (JPed 28 39 1946) after other therapy failed. Penicillin ointment succeeded in 14 cases of Kendig and Fiske (J 129 1044 1945) Penicillin resistance accounted for the tragic course of an epidemic reported by Lee et al. (JPediat 41 159 193) in which 1 cases of impetigo were accompanied by 10 cases of severe staphylococcic paronychia, and half of the latter group died. A seemingly trivial infection with an insensitive strain may eventuate in serious complication (Forfar et al BMJ 1 0 1953) The correct antibiotic must be selected by means of sensitivity tests. Tetracycline is usually promptly effective It may be sprayed on a 1% aqueous solution and given by mouth at the same time It should not be overdosed.

Whittle (Lancet 2 1323, 1935), transmission by personnel or impedimenta; Kendall and Aegerter (JPed 15: 733, 1939) Ritter' disease; Flood (AmJDisChild 58 831, 1939) nursing technic Denians (BMJ 1 623 1943) bullous cases, doctors and nurses as carriers Forfar et al. (Lancet 1: 884, 1958) erythromycin with streptomycin effective, same strains of organism in nursing staff and infants; Edmunds et al. (BMJ 1 990 1955) nasal carriers in staff are main source of pathogens in newborns

Desquamative Erythroderma of Infants (Leiner's Disease) is not to be distinguished from the mild form of staphylococcic exfoliative dermatitis of the newborn. It begins on the buttocks in many instances and becomes generalized with lymphadenitis but without vesiculation. It was described as a self limited disease by Lereboullet and Bohn (BSocPédiat 33: 373 1935) and the infant does better when placed on a low fat, high protein diet (Hill: J Pediat 4: 426 1934) Staphylococci were cultivated from the lesions and from the bladder in several cases by Sperk (abs J 7 : 1764, 1914) Gastroenteritis accompanies the disease or precedes it.

See Leiner (BritJChildDis 5 244, 1908 ArDuS 89 65, 1908) Cole et al. (AD& 70: 443 1954) review suggesting Leiner's disease is modified, subacute form of Ritter's, both due to staphylococcus, to be treated with antibiotics and vitamin B complex Crotty (AD 71: 647 1955), 4 cases with protracted diarrhea and secondary anemia, responsive to antibiotics and transfusions of whole blood

INFECTIOUS ECZEMATOID DERMATITIS

Synonyms.—Pustular eczema (many cases) Impetiginous eczema (some cases) Superficial staphylococcic dermatitis.

Symptoms.—Infectious eczematoid dermatitis is characterized by erythematous, vesicular pustular or scaly circumscribed plaques of acute dermatitis which commonly develops from coccic complication of mechanical or

chemical trauma. The exposed parts are those generally first affected. The initial lesion may be a vesicle pustule or an inflammatory scaly or crusted papule The vesicles are not so closely placed and are larger than in an acute vesicular contact dermatitis The lesions are asymmetric as a rule. The eruption spreads by autoinoculation and occurs in circumscribed patches of moderate size which enlarge by peripheral extension. Vesicles soon break to form an oozing patch which extends. New foci begin as clusters of vesicles. The epidermis at the periphery of the lesion is usually undermined, detached or raised by collections of seropurulent fluid which may contain much fibrin so that a thin ridgelike crust forms about the periphery There is no tendency to involute centrally Itching is usually considerable There is usually lymphadenitis, particularly when the disease is widespread as it may be even to the extent of being universal. The disease is often associated with scabies, pediculosis, furunculosis, otitis, or other suppurative disorder such as an infected, ingrowing toenail It is commonest in active adults.

Fig. 191.—Infectious eczematoid dermatitis secondary to scabies. (Sutton J 75 976, 1920)

Etiology — Engman (AmM 4 769 1902) recovered the staphylococcus in pure culture from early lesions and from the surface and crusts of later patches. Experimental autoinoculation can usually be performed then the lesion begins as an erythematous patch which soon becomes moist and crusted.

It is thought that allergy plays some part (Sutton J 75 976 1920 Foerster WiscMJ 34 305 1935) The chronicity and rebelliousness of infectious eczematoid dermatitis distinguish it from ordinary primary staphylococcic infections and convince me that more than a primary infection must be concerned. Contact dermatitis is often the primary disease and contactants may require elimination before antiseptics attain lasting effectiveness. Foci of infection are also frequently concerned. Dermatitis of the hands (q v) an intractable and disappointing disease according to most medical literature has proved usually to be gratifyingly responsive if the aspects of contactants, parasites and foci are eliminated (Lane et al. J 128 987 1945 Sutton and Ayres ADS 68 266 1953)

Sometimes patients apparently fail to heal because of hypoproteinemia, anemia or chronic fatigue from anxiety or overingestion of caffeine The confused status of etiologic understanding was stressed by Kennedy et al (South MJ 46 707 1953) who took into account allergy autosensitization, overtreatment, and psychosomatic causes in an attempt to explain the recalcitrance of some cases.

Pathology —The papillae are swollen and congested There are slight acanthosis and edema of the prickle cells. Destruction is marked in the lowest

Fig. 292.—Infectious eczematoid dermatitis.

Fig. 293.—Infectious eczematoid dermatitis.

Fig. 294.—Dermatitis simulating Paget carcinoma but due to *Micrococcus aureus*.

layers of the stratum corneum which is undermined and detached and its elevated margins are frayed Abscesses are to be found in the upper region of the rete, and groups of cocci can be seen in them. Polymorphonuclear leukocytic infiltration is profuse.

Diagnosis.—In contact dermatitis, the eyelids are usually swollen and itchy and the flexures are involved by predilection; the disease is not primarily pustular but by secondary infection often is complicated by infectious eczematoid dermatitis. The impetigos occur generally in children their lesions are discrete and seldom involve the body and limbs. Staphylococcic impetigo differs little from infectious eczematoid dermatitis. Perhaps one may say that staphylococcic impetigo in the presence of contact dermatitis or focal infection is identical with infectious eczematoid dermatitis. The discrete pea to fingernail size deeply seated, painful not itchy pustules and crusts of ecthyma are distinctive Moniliids and other mycids must also be differentiated. They too may be complicated by staphylococcic parasitism

Treatment.—Greasy preparations are to be avoided, especially irritating ones, such as fungicides. Cole recommended hot 1:5 000 aqueous solution of potassium permanganate 20-minute soaks 3 or 4 times a day for 4 or 5 days. Radiant heat is useful. Gentle débridement is an important part of treatment Crusts must be removed so that antiseptics can reach the bacteria. Baths in bichloride of mercury 1 10 000 (4 Gm. in 10 gallons of tepid water) are useful and comforting but one must be alert to percutaneous absorption and mercurial intoxication (diarrhea) when bichloride baths are used. Wet packs of bichloride may be laid over lesions painted with gentian violet with satisfactory results, especially when both staphylococci and streptococci are present as they often are Foci of infection must be eradicated in resistant cases teeth, gums, sinuses, prostate and running ears are the commonest of these Hospital care is much to be preferred to ambulatory

Penicillin in large intramuscular dosage is quite efficient A common experience is to give penicillin with temporary benefit only to observe relapse soon after it is stopped. When this happens one may be confident that focal infection is significant. Contact irritation must also be eliminated. Chronic pustular dermatitis of hands and feet can often be cured when approached from this standpoint. Hopkins and Burky (ADS 49 124 1944) reported successful desensitization by intracutaneous immunization with staphylococcus toxin. Cooper (PaMJ 46 218 1942) also eliminated foci and used staphylococcus vaccine Bacitracin ointment 480 U per Gm., rarely irritates and often benefits (Miller et al. JID 10 179 1948) Tetracycline orally and topically is effective used in conjunction with potassium permanganate soaks or poultices. Cortisone and high protein diet may also help

X ray therapy is only rarely helpful. When vesicular dermatitis is not responsive to x ray staphylococci are probably causative

Jungle Rot was the G I name for this disease in the tropics, where heat, humidity and staphylococci, along with other factors perhaps, such as hygiene nutrition, and quinacrine produced much morbidity during World War II (Travis: MilSurg 97 224, 1945 Cohen USNMBull 42 1119 1944) When these patients were returned to the zone of the interior in a temperate climate, under conditions conducive to health they generally improved satisfactorily In some the lesions became chronic and lichenified see Lichen Chronicus Simplex.

FURUNCLES AND CARBUNCLES

Furuncles (Boils) are acute circumscribed, follicular phlegmonous inflammatory lesions caused by virulent staphylococci in the skin. Carbuncles are conglomerate furunculoid lesions involving not only skin but also subcutaneous tissue with suppuration, sloughing and the discharge of necrotic material through multiple openings.

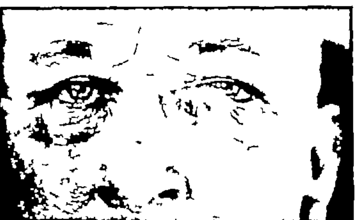

Fig. 296.—Acute staphylococcic cutaneous abscess.

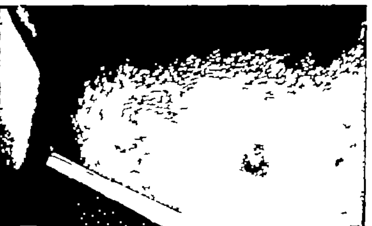

Fig. 294.—Boil on the neck. (Dr Stuart C. Way.)

Fig. 297.—Carbuncle of the nucha.

Fig. 295.—Carbuncle of the back. (Dr Clyde L. Cummer.)

In a furuncle the inflammatory process begins as a rule in the immediate vicinity of a skin gland or hair follicle. Furuncles may number from 1 or 2 to 50 or more and disease may be prolonged almost indefinitely by repetitious development of new lesions. The neck, axillae face buttocks, and legs are sites of predilection although no region is exempt. A lesion begins as an itchy acuminate pustule surrounding a hair As it develops the involved skin becomes smooth, tense and shiny painful and tender In a few days the tumor usually matures, and either comes to a head or becomes boggy and fluctuant. In some cases regression takes place before the occurrence of suppuration, and the lesion a *blind boil* slowly undergoes absorption On reaching maturity a boil generally ruptures spontaneously and a necrotic core is discharged, together with pus and serum Healing speedily ensues. In some boils the center undergoes necrosis but becomes tough stringy and tenacious. Such boils are of relatively small size extremely painful and less responsive to treatment than ordinary ones. They are due to strains of staphylococci which produce necrotizing toxin

Globose lesions developing umbilicated necrotic centers representing bacterial emboli and liquefaction necrosis and resembling acne varioliformis, were described by Balog (JID 5 107 1942) and attributed by him to metastasis from a primary suppurative focus. Compare sweat gland abscesses (p 278)

A stye is a furuncle of a lid margin gland The external type affects the gland of Zeis, the internal affects the Meibomian gland (Dunn WiscMJ 38 117 1939)

Carbuncles resemble furuncles but are larger and more painful and are accompanied by more systemic intoxication When necrosis occurs, their contents are discharged through several openings. The lesions are commonly single. They start with painful localized, erysipelas like induration, which gradually increases in size. The affected skin is dark red tense and shiny Suppuration occurs within from 7 to 14 days, but instead of a single central slough as in a furuncle, the tumor drains through a number of openings and the purplish summit presents a cribriform appearance The central portion of the lesion may undergo necrosis at several different points at the same time and a number of small sloughs form and are cast off or the entire mass may be involved at once with the resulting formation of a deep ragged ulcer This cavity fills up with granulation tissue and ultimately heals with more or less scarring Systemic intoxication may be severe even fatal, and metastasis and septicemia are possible complications. The sites of predilection are the neck shoulders, buttocks, and outer surfaces of the thigh.

Staphylococcic abscesses and cellulitis require mention. They generally fall to the surgeon rather than the dermatologist.

Staphylococcic gangrene is serious but uncommon. Of 5 cases involving the face, resembling erysipelas but becoming gangrenous 2 proved fatal reported by Stookey et al (J 103 1934) The dermonecrotizing toxin is the cause of gangrene (Stookey and Scarpellino SouthMJ 28 148 1935) The facial predilection, the violet color and the probable absence of pustulation were the features stressed by Troisier et al. (PresseMéd 44 801 1936) who estimated mortality at 75% Diabetes predisposes to this condition, which is not to be confused with the streptococcic disease it simulates, wrote Millett (J 112: 1143 1939), giving a bibliography Success in treatment may be obtained with antibiotics and careful control of the diabetes (Millett and Darby NEngJM 235 12, 1946)

Etiology—Pasteur (ComptrendAcadSci 90 1033 1880) described the cultivation of microorganisms from a boil

A puncture was made at the base of the small cone of pus at the apex of a furuncle on the nape of the neck. The fluid obtained was at once sowed. The next day the culture fluid had become cloudy and contained a single organism, consisting of small spherical points arranged in pairs, sometimes in

fours but often in irregular masses.' He demonstrated the pathogenicity of the germ he had cultured and recovered it from lesions produced by cultures in human volunteers.

The appearance of new lesions is not ordinarily due to septicemia, but follicles are infected exogenously. Ointments facilitate autoinoculation.

Certain factors predisposing to microbic invasion are generally recognized. *Of these diabetes mellitus, nephritis, and avitaminosis are the most important.* In every case of furunculosis the patient's urine should be examined. Occupational exposure to grease such as cutting oils also predisposes but furuncles, which multiply, should be distinguished from oil acne which is associated with comedones (Schwartz: PHRpts 56: 1947, 1941). Warmth, humidity and sweating render the skin especially vulnerable to staphylococcic parasitism, for they interfere with self sterilization by drying. In obstinate cases search should always be made for foci of staphylococci in sinuses, tonsils, teeth and urogenital tract. The influence of vitamins is *apparently consequential only in their decided lack,* although vitamins A, D, and C may have some therapeutic usefulness.

The seasonal peak of boils in Great Britain is October or November and most lesions are on the head, face and neck, seemingly the result of contamination by the fingers which transfer organisms from the nose (Whitwell and Sutherland: BJD 62: 109, 1950).

Pathology.—The inflammatory process involves a gland or follicle. The slough is composed of pus, fibrin and necrotic glandular and periglandular tissue. Changes in the dermis are those of acute purulent inflammation. In carbuncles, the infection is deeply seated, and the dermonecrotizing inflammatory process involves dermis and subcutaneous tissue.

Diagnosis.—The staphylococcus is readily found in the pus and may be cultivated easily. Erysipelas is not pustular. Anthrax is characterized by vesicles about a blackish necrotic center. Syphilitic lesions are less acute and painful by far. Iodide and bromide eruptions are distinguished from furuncles by history, culture and blood bromide testing. Acne is often confused with coccic parasitism, which of course can occur secondarily, but acne vulgaris is not a parasitic disease. The itchy acne caused by androgenic substances or ACTH would not confuse an alert observer.

Prognosis.—Recovery generally ensues within a few weeks. Lesions involving the face or scalp are especially dangerous. In elderly and debilitated individuals a virulent infection may prove fatal. The disease usually responds favorably to treatment, although recurrences through autoinoculation are common. Response to antibiotic therapy may be delayed because of resistance, but antibiotic sensitivity tests should dispel this difficulty.

Treatment.—Codeine may be required and should not be withheld. The urine and blood sugar should be tested. The value of vitamin preparations is highly debatable. Thyroid was given by Barnes (JClEndocr 3: 243, 1943) who explained his favorable results on the basis of improved skin temperature, tone and circulation. The only oral medication Sutton, Sr. used to prescribe was sodium citrate. In adequate amounts it tended, he felt, to hasten necrosis and liquefaction.

Limiting the ingestion of carbohydrate may be advisable (Kulchar: JChemother 14: 61, 1937). Dogs on a high starch diet suffered worse effects from experimental inoculation than controls (Lillsbury and Sternberg: ADS 35: 893, 1937).

Sulfonamides have been recommended but chemotherapy alone is inadequate when there exists an accessible collection of pus, which, as John Hunter taught, must be let out (Heling and Abel: AnnSurg 30: 238, 1940). Osgood (JPed 17: 740, 1940) claimed benefit from neoarsphenamine and sulfathiazole. Passive immunization by means of antitoxin has been tried. Stookey and Scarpellino (SouthMJ 32: 173, 1939) investigated dermonecrosis and were

able to help some cases by giving antitoxin, which has value in toxic cases. Bacteriophage was at one time well thought of by some authors it was applied as a moist compress.

Vaccine therapy stock or autogenous, has given me no satisfaction.

Dermonecrotizing toxin produces necrosis quantitatively related to the amount of toxin injected It is neutralized by simultaneous injection of immune serum *Toxoid injections evoke active immunity to toxin without* causing severe reactions. A course of toxoid therapy is often highly efficacious (Zernetol Surg 17 303 1945) although measurement of the staphylococcus antitoxin titer which does not change much has little clinical utility

Antibiotics given by mouth such as Achromycin, are effectual. Penicillin by injection is sometimes eminently satisfactory The dose should be large Some strains of staphylococci are not responsive and some cases of chronic furunculosis improve only temporarily If a given dosage does not yield results, one should increase it greatly before assessing the agent as useless in that case *Since penicillin does not influence immunity toxoid may be ad*visable also in difficult cases of furunculosis. Direct injection of penicillin into and about the infected tissue was thought by Kenney (Surg 21 588 1947) to be especially effective A million units in 5 cc. saline adding 5 cc. procaine solution was injected about the periphery of the carbuncle so as to lay down a barrier of the antibiotic outside the indurated region by Dale and Haug (J 149 527 1952) this treatment along with penicillin intramuscularly bed rest and hot wet packs, was assessed as valuable by these authors. I have never used local injections of penicillin. Penicillin ointment is not satisfactory but an occlusive dressing with Aureomycin or Terramycin ointment may work well Nightly inunction of the whole body with a thin layer of Vioform Cream may cure furunculosis.

Immobilization is important, and this may be accomplished in small lesions by the use of collodion, protective dressings and perhaps a sling Fraser (BMJ 2 894 1935) recommended an elastoplast occlusive dressing which protects, relieves pain and enables a patient to continue his work.

Mild antiseptics applied in the form of blotterlike moist poultices may be employed A good plan is to paint the lesions and their periphery once daily with diluted tincture of iodine or 1% gentian violet in alcohol to prevent autoinoculation then to apply a large gauze pack moistened with half and half glycerol and alcohol Glycerol inhibits by partially destroying the dermonecrotizing toxin (Smith Brit J Exp Path 18 265 1937)

Incandescent lamps, 500 watts, are valuable as sources of radiant heat especially in early stages. Ultraviolet light is worthless in this condition.

Roentgen therapy as it applies to inflammation is discussed in the chapter on Treatment (q v) The effect of electromagnetic energy is not on the organism. It is usual to give small doses. The more acute the lesion the smaller the dose Epstein teaches.

On the back of the neck and in the axilla, MacKee pointed out one suberythema dose may prevent the development of new lesions It may be necessary to depilate the parts in order to effect a cure and this should be accomplished with fractional doses avoiding erythema. Soon after the treatment the patient is likely to be worse, but within 48 hours the pain will have disappeared In some cases the induration is gradually absorbed, while in others the lesion softens and discharges. When the lesion is treated before discharge and while in the indurated stage, x rays cause rapid regression. X ray treatment of lesions of the face is curative painless and safe, with much smaller morbidity and mortality rates than surgery yields (O'Brien NEngJM 220 917 1939) Cannon (SouthMJ 38 106 1945) recommended the following measures 400 to 600 r radiotherapy including a good margin daily irrigation of the region with 5% phenol a thick cotton dressing embodying a paste composed of fluidextract of ergot 6.0 phenol 0.6 and zinc oxide and starch 4.0 of each in cold cream the probing of openings with 50% phenol and intramuscular injections of colloidal manganese or sterile milk.

A boil can perhaps be aborted by the early local application of mercurial plaster or of tincture of iodine. One may hasten its maturity by the aid of hot moist antiseptic dressings.

Many authors have insisted that a boil should never be incised. There are exceptions to this generally wise rule A tiny itchy and painful follicular pustule will progress considerably unless it is aborted. If the point of a scalpel is moved through the undermined epidermis across the follicle mouth so as to penetrate something less than half of the thickness of the dermis, drainage will be made adequate I should then apply *tetracycline ointment* and an occlusive dressing Extraction of the infected hair is an error for this procedure gives the staphylococcus free access to subdermal spaces where an abscess is the least of the prognosticable evils. It is especially dangerous to extract infected vibrissae *Squeezing a lesion accomplishes the same bad effects.*

A surgical attack upon carbuncles is occasionally to be recommended. Prior to penicillin, crucial incision in the early stage was popular a radical *effort being made under gas or pentothal anesthesia (Fantus J 103 1066* 1934) The flaps were laid back the pockets cleaned out and the wound packed with moist iodoform gauze or similar material. Complete and early excision of the infected mass has been advocated but this is rarely necessary Excision of a carbuncle *may stop pain and intoxication dramatically*

The hazards of carbuncles of the face have been stressed by many writers, cavernous sinus thrombosis being a dread complication. This occurred once in 31 cases reported by Totten (WestJSOG 43 609 1935) accounting for *one of the 3 fatalities. Conservative treatment in contrast with surgery led* to lower mortality rates, lower morbidity rates and better cosmetic results (Ayres et al. J 108 858 1937) See Edit (J 109 278 1937) Elliott (IllMJ 72 491 1937) Maes (AnnSurg 106 1 1937) 20 fatal cases, emphasizing avoidance of incision Berman (AmJSurg 40 419 1938)

In recurrent cases find the focus of dissemination of the virulent germs this focus may be inconspicuous. There seems little doubt that susceptibility is variable, for some individuals are infected time after time, and others rarely suffer Guiding principles in the treatment of recurrent furuncles should include attempts to keep the skin dry clean and free from irritation, to eradicate foci of infection, and to raise the general resistance of the patient (Anning BMJ 1 721 1953) The nose is the major source of the pathogen in carriers and should receive attention in recalcitrant staphylococcic infections of the skin (Tulloch BMJ 2 912, 1954) See Edmunds et al. (BMJ 1 *990 1955)*

FOLLICULITIS

Folliculitis is *often staphylococcic differing from furunculosis mainly in* depth and severity of inflammatory reaction about the hair or sebaceous follicles. A solitary lesion, itchy acuminate and pierced by a hair may comprise the whole disease or such lesions may affect a considerable area or may *be widespread over the hairy regions of the body* Sycosis is described elsewhere. It is not remarkable when the infection penetrates to the subcutaneous layer so that an abscess develops. This is often seen on the dorsa of the fingers, and the lesion may have a collar button shape with a small purulent bleb on the surface a tiny hole through the skin and a pocket of pus beneath requiring incision and drainage Folliculitis often results from autoinoculation especially as the result of smearing staphylococci about by the application of greases. When folliculitis is chronic focal infection must be sought out and eradicated. Treatment is as for furunculosis (q v) or for impetigo (q v) compare Bockhart s impetigo

Staphylococcic infection of sweat follicles in infants was described as periporitis staphylogenes by Lubowe and Perlman (ADS 69 543 1954) The lesions consist of minute pinhead to pea-sized, disseminated papules and

pustules, especially over the scalp forehead neck, upper half of the chest, shoulders, upper extremities and back They may be of different sizes and different stages of evolution, tiny firm erythemtous nodules that are deeply situated and capable of becoming pustules or abscesses. Temperate dry surroundings help to bring about cure which is sought in much the same manner as in the treatment of furunculosis (q v) Multiple sweat gland abscesses of infants was the title of the article by Mopper et al. (AD 71 177 1955) in which they described the dome-shaped nodules representative of staphylococcic parasitism inoculated into sweat pores.

Rosacea like Folliculitis is a clinical entity which I have not seen described elsewhere. It closely resembles rosacea, but may be quite itchy which is a difference and the shallow pustules, surrounded by considerable erythema, may be recognized as follicular when examined under magnification. This chronic disease may be discrete or confluent. It responds to antibiotics and to elimination of foci, usually oral, occasionally genitourinary Vioform Cream may be helpful, or 2% salicylic acid in 5% ammoniated mercury ointment as Staley showed me

PYODERMA FACIALE

Pyoderma Faciale was described by O'Leary and Kie land (ADS 41: 451 1940) as an explosive eruption of deep pustules on the face in you g women who have had, or perhaps have not had, preceding acne. Tunneling abscesses, thick greenish pus, pain and tenderness, and disfiguring keloidal scars are characteristic. The patient is often under weight, anemic, and amenorrheic, but tuberculosis has not been found. Antianemic and vitamin therapy appears to be indicated. X ray therapy may be used. Very large doses of penicillin may do the job when modest ones do n t. Compare Hidrade iti axillari suppurati a.

See case reports (ADS 42 1133, 1940; 43 572, 744 1941 50: 418, 1944; 54 349, 573 1946); Reuss (JLabClinM 28 1032, 1943)

Fig. 199 —Pyoderma faciale. (Cole nd Driver: ADS 43: 572, 1941.)

CHANCRIFORM PYODERMA OF THE FACE

Solitary o few in umber the lesions evolv in a few weeks from minute papules into ulcers resembling the syphilitic chancre. The base is indurated, smoothly ulcerated, but superficial, and the bord is not elevated. Staphylococcus aureus was found and sulfathiazole was apparently curative in the case of Kra tz (DWehn 109: 1203, 1939) See Hoffmann (AfDuS 170 403, 1934); Stryker (ADS 4 447 1940); Laymon et al. (AmJSyph 38: 57 1954)

Ulcus Migrans.—A remarkable case with lesions of a spreading and undermining nature, simulating large sores of acne co globata on the chest and shoulder yielded an unusual staphylococcus (Hicks: BJD 62 1 4 1950) There was no lymphadenitis, fever or leukocytosis. Develop g from pustule on n Arab boy's back in a period of 2 years, a bizarre arcuat ulcer prod ct ve of depigmented scarri g was observed by MacDonald (BJD 50: 606, 1938) wh cultivated from the lesion *Staph. aureus.*

GAFFKYA TETRAGENA INFECTION

Pathogenicity of this organism which is one that possesses ordinarily only slight virulence and becomes invasive only when the resistance of the host is reduced, has received consideration from Reimann (JClinInv 14: 311 1935) and Zeligman a d Slesel (ADS 65: 332, 1953) The latter reviewing the literature noted that some 170 cases of *G tetragena* infection have been recorded. They reported a carbuncular lesion caused by it. This was responsive to Terramycin. Infections with *G tetragena* generally resemble the local suppurative or septicemic diseases caused by *M aureus* a closely related organism. Cases have been ascribed to it of septicemia, arthritis, meningitis, endocarditis, pneumonia, prostatitis, empyema and glomerulonephritis.

In a recent year period I had 7 cases in which *G tetragena* was the sole or predominant organism. The lesions were impetiginoid acute and pruritic and in most instances were incited by mechanical or chemical injury followed by secondary infection. *M aureus* wa also present in 3 of the 7 cases. All were promptly responsive to tetracycline oxyt tracycline or chloramphenicol used topically

STREPTOCOCCIC INFECTIONS

A basic serologic classification of *Str pyogenes* (equivalent to group A hemolytic) was made by Griffith (JHyg 34: 54, 1934) See Lancefield and Hare (JExpM 61: 335 1935) regarding classification. The epidemiology of streptococcic infections wa well delineated by Bradley (BMJ 1 733 1938) See Mackie (EdinMJ 47 466 1940) regard ing herd infections. When any part is inf ct d with streptococci pathogens are plentiful as transients on healthy areas (Martin: BMJ 1 45, 194)

Str viridans and nonhemolytic streptococci, apart from rare strains, are f little sig nificance as human pathogens. One strain of *Str pyogenes* may in any given epidemic produce angina, scarlet fever erysipelas, cellulitis, lymphangitis adenitis, otitis stasit tis, meningitis, puerperal fever and septicemia, in accordance with the unitarian hypothesis. Therefore the tendency is to discard specific names for strains which depen l on morphology and cultural characteristics. Most hemolytic streptococci are identifiable by a specific carbohydrate substance and fall into Lancefield Group A. This group was divided into about 30 subtypes by Griffith. Bradley described single-strain epidemics in various semi isolated groups. The rash of scarlet fever is fortuitous, he stated, but each type of the disease streptococcic infection, is an index of the prevalence and an indicator of the ex stence of the pathogen in the community The aggregate of the clinical manifestations probably represents about half of the actual streptococcic morbidity The great bulk of treptococcic disease is probably zymotic and associated with an increased carrier rate enhanced parasitism being at any given time due to one or few serologic types of the organism. Droplet infection is common as well as milk borne but comparatively a timate contact is required; less important is casual contact. The tempo of transmission s slow and is due probably to transference via immune carriers A period of from 5 t 10 days elapses between infection and detection of it. Immune carriers are probably infected for only a brief period, but these are probably more important epidemiologically than persons with chronic foci. A type specific epidemic runs its course and dies out spon taneously Persistence of the in idence of infections and recurrences point to the ntro duct on of a new type of streptococcus.

STREPTOCOCCIC IMPETIGO

Symptoms—Streptococcic impetigo is characterized by superficial lesions covered with thick crusts honeylike and of a yellowish color noted Epstein (WiscMJ 40 383 1041) Compare staphylococcic impetigo The streptococcic disease starts as a red spot, on top of which a thin walled blister develops and this may so rapidly collapse as to be missed In simple cases a few crusted lesions are present In severe cases the lesions become confluent so that the face may be covered by masses of discharging eroded crusts, the original yellow color perhaps changing to a dirty brown from admixture with blood. Regional lymphadenopathy may occur Since the disease is superficial no scar results although circumscribed erythema or brownish staining may persist for some weeks. The favorite location is the face but the neck, hands and scalp are also frequently affected Any location may support the infection, especially when it is secondary to another dermatosis. On the fingers or toes, where the corneum is thick, one finds rapidly enlarging painful bullae which the dermatologic consultant often sees after the patient has erroneously been treated for tinea. The latter itches rather than hurts, and its progress is less precipitate

Ecthyma involves dermonecrosis, and is related to streptococcic impetigo as furuncles are related to staphylococcic impetigo

Fig. 300.—Streptococcic impetigo with "stuck-on crusts."

Fig. 301.—Erysipelas.

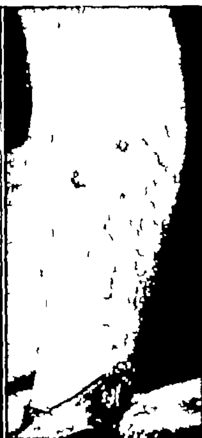

Fig. 302.—Ecthyma.

Etiology.—Streptococcic impetigo occurs either as a primary disease or as secondary infection of any itching dermatosis, such as scabies, dermatitis venenata or infantile eczema. As a primary disease its incidence is seasonal maximal in the fall and parallel with other streptococcic diseases. Comparatively close contact is requisite for transmission. The organism is hemolytic. Mixed infections with both streptococci and staphylococci are common see p 266

Treatment.—The principles involve gentle débridement and isolation of the lesions, the use of suitable antiseptics, and prevention of autoinoculation and spreading. Ammoniated mercury ointment, 2% removed by benzine at the times when it is refreshed, is often effective. Sulfonamide ointments, hazardous with respect to inducing sensitization, have been used effectively but are not recommended nor is penicillin ointment in the light of current views. Aureomycin Bacitracin, Terramycin, Neomycin, dihydrostreptomycin or Chloromycetin ointment is quite satisfactory as a rule. Compare treatment of staphylococcic impetigo and infectious eczematoid dermatitis. Cool compresses, using 1 10 000 bichloride of mercury or 1 5000 $KMnO_4$ are also useful. Tetracycline may well be given orally for a few days.

Impetigo and Nephritis.—Increasing stress has been given the fact that streptococcic dermatoses are followed by nephritis with consequential frequency so that impetigo may not rightly be considered trivial

Stiell (Pract 100: 368 1918) described 5 cases of severe acute nephritis complicating impetigo. In the patient of Cleveland (CanadMAJ 24: 272, 1931) the widespread application o mercurochrome to a neonatal impetigo may have resulted in nephritis from mercury rather than from coccic toxins. Studying cases of acute nephritis in children, Sutton (SouthMJ 27: 708 1934) found that more than one-fourth of them followed severe impetigo. The prognosis of such nephritis is quite good Silvers (NYSJM 39: 1093, 1939) decided after reviewing the literature, yet the kidney injury can be severe. He quoted the experience of Southby and Stanton (MJAustral 13: 127 1926) of whose 103 cases of nephritis, 29 followed tonsillitis, 17 followed impetigo, 15 followed measles, 11 followed pneumonia and 27 were of undetermined cause, while Hill (AmJDisChild 17: 270, 1919) attributed 4 of 51 cases of nephritis to impetigo. Of 1 4 cases of acute nephritis impetigo preceded 34% a higher proportion than was preceded by tonsillitis in the series of McCullough et al. (JPed 38: 346, 1951) and nephritis was fatal in 1.5% of the victims.

In impetigo the white blood cell count e ceeded 10,000 in 24 of 25 patients noted by Towle and Swartz (ADS 9: 551, 1924)

The complication of nephritis is not related to the severity of the dermatitis that induces it, according to Futcher (AIntM 65: 1192, 1940) He recognized it as being more common in children but described its occurrence in 11 adults ranging up to 60 years of age, one of whom had impetigo, the others pyodermas or erysipelas. Edema was the first symptom and appeared within 2 to 6 weeks after the dermatitis appeared. Albuminuria lasted longer 12 months in 7 of these 11 patients. Beta hemolytic streptococci we e cultivated from the skin in 7 of his 11 cases. An epidemic of impetigo has been known to be followed by numerous cases of nephritis. Callaway and O'Rear (ADS 64: 159 1951) observed that 36 of 73 cases were preceded by pyogenic dermatoses, and, confirming other uthorities, stressed th wisdom of treating skin infections early and vigorously in o der to prevent thi serious complication.

Antibiotics given systemically are therefore justified if a case of impetigo does not respond to topical therapy promptly and satisfactorily When penicilli was used in an extensive series of beta hemolytic streptococci infections in children by Breese (J 152 10 1953) the incidence of complicating rheumatic fever or acute glomerulonephritis was exceptionally low

Cortisone is said to be effectual in poststreptococcic states u responsive to antibiotics, just as it is helpful in heumatic fever (Doerner et al.: J 146 641 1951)

ECTHYMA

Symptoms.—Ecthyma is manifested by the formation of small, discrete flat, painful pustules which heal reluctantly and may be followed by slight scarring and pigmentation. A child is the usual patient. The legs and thighs are the sites of predilection, although no region is exempt. The lesions, ranging in number from 1 to 20 or more are irregularly oval sharply defined and have reddish areolae. They begin as small yellowish pustular excavations, which enlarge. The exudate desiccates, forming thick, adherent, brownish

crusts. The bases are raw and tender On healing the crusts drop off but the disease may be continued indefinitely by the development of new lesions. Slight lymph node involvement is usual. The lesions sometimes persist for weeks, unless correctly treated.

Etiology—Streptococci, perhaps secondarily complicated by *Staphylococcus aureus*, are the cause Ecthyma was experimentally produced by inoculation of streptococci into injured skin by Bizzozero and Leone (AfDuS 176 16 1937) Uncleanliness poor hygienic surroundings and inadequate diet are also sometimes concerned. Trauma and insect bites are common exciting causes. The disease is readily autoinoculable.

Pathology—The lesions are shallow abscesses. The dermis is swollen, infiltrated and perhaps necrotized Purulent inflammation and exudation are seen in sections.

Diagnosis.—In flat pustular syphilids lesions are more numerous and disseminated, edges of ulcers are abrupt there is little pain and crusts are bulky and greenish while other signs of syphilis are usually apparent

Ecthymatous lesions have been described under a multitude of names see Ulcer tropical Shallow ulcers of the extremities yielding streptococci and staphylococci were called pyoderma ulcerosum tropicalum by Alpins (MJAustral 1 30 1943) while dermatitis cupuliformis was the title given tropical ecthyma characterized by the evolution of cupuliform nodules which underwent ulceration by Castellani and Chalmers (Tropical Medicine 1929 p 2034)

Treatment.—As a rule the disease responds at once to a sulfonamide given by mouth. Prior to sulfonamides and penicillin these cases were extremely stubborn. Débridement by gentle measures is important with a view to avoidance of autoinoculation. An antiseptic such as Aureomycin or Terramycin ointment may then be applied Bichloride of mercury 1 10,000 in wet applications is excellent. Scratching and picking at the lesions must be prohibited. Penicillin injections, along with permanganate baths, are efficient when sulfonamides are inadvisable

STREPTOCOCCIC DERMATOSES

Included are streptococcic impetiginization subacute and chronic impetigo intertrigo (some cases) streptococcic fissures streptococcic epidermitis pityriasis streptogène seborrheic eczema (some cases)

Symptoms.—The streptococcus can cause persistent scaling and oozing inflammations which tend to undergo fissuring and which are painful and stubborn in response to treatment, especially wherever folds or flexures are involved (Chipman ADS 4 526 1921) Other streptococcic diseases, impetigo ecthyma erysipelas scarlet fever streptococcic gangrene and fissure of the lip are described elsewhere.

Impetiginization may follow impetigo or it may develop as streptococcic infection superimposed on and secondary to dermatitis of various causes. Banal irritation or comparatively inconsequential dermatitis venenata is occasionally so infected, particularly when it is located in a fold or flexure where the skin is moist All stages of dermatitis are seen, ranging from crusted, oozing areas to dry scaly patches. Fissures are especially common behind the ears (spectacle frames and perspiration abet this) at the angles of the mouth and at the anterior angle of the naris. Fissure of the lip (q v) is usually streptococcic

Pityriasis Streptogène, the chronic, dry type is seen usually on the face in the form of furfuraceous patches, practically asymptomatic except the branny desquamation. Behind the ears the dermatitis is likely to present a red and weepy surface glazed and covered with exudation. Dry scaling may involve the ear canal (Williams et al. J 113 641 1939) The whole scalp

and neck may be affected in widespread cases. Circinate, furfuraceous patches of the face in Negroes, producing depigmentation, were called erythema streptogenes by Dobes and Jones (ADS 53 107 1946)

Etiology—While hemolytic streptococci are often found in impetigo nonhemolytic organisms are the ones found in streptococcic intertrigo (Kinnear BMJ 1 291 1935 BJD 48 173 1936 Mitchell ADS 19 659 1929 40 635 1939 J 104 1220 1935 108 361 1937 Barber: Lancet 2 35 1935) It is wise to make smears, cultures and antibiotic sensitivity tests in cases of exudative dermatitis, for the findings affect one's choice of therapy

Prognosis and Treatment.—The duration of these disorders may be prolonged. They are resistant to treatment by ill-chosen or irritating measures. Weak ammoniated mercurial paste (2%) removed with benzine and refreshed twice a day may help Sabouraud used 1% iodine in alcohol Débridement gently performed is essential to success. X ray therapy has only a little value in temporarily diminishing the swelling redness and pain. All involved regions must be treated at the same time for a nostril will not heal if an infected postauricular area is neglected In cases affecting the corners of the mouth the teeth must be freed from calculus, decays repaired, pyorrhea adequately dealt with and dead and abscessed teeth removed. In streptococcic acrodermatitis Mitchell found correct diagnosis the fundamental requirement distinguishing fungous infections and dermatitis venenata and utilizing weak bichloride of mercury soaks and ammoniated mercurial ointment in cases in which streptococci are identified Focal infection must be sought out and eradicated. Sulfonamides by mouth not topically are highly efficacious in streptococcic diseases and so usually is penicillin by injection Many cases however represent mixed infections and topical therapy is also desirable using for example Chloromycetin, 250 mg in an ounce of Vioform Cream or an ointment containing tetracycline neomycin or dihydrostreptomycin. Gentian violet is not useful against streptococci. Injections of dihydrostreptomycin sometimes do a job that penicillin has failed to do

ERYSIPELAS

Symptoms.— St. Anthony's fire is an acute polymorphonuclear cellulitis due to streptococci when they involve skin and subcutaneous tissue. It is characterized by redness, edema and induration, accompanied by intoxication. Cutaneous manifestations are generally preceded by feelings of malaise and chilliness followed by fever The dermatitis begins as a small erythematous patch which gradually enlarges, the involved skin becoming swollen and indurated pinkish or reddish hot and tender with a glazed surface on which bullae occasionally develop Margins of the patch are sharply defined from the first, and lesions usually spread gradually by peripheral extension. Local symptoms are seldom severe but there are some burning and itching Lesions are generally single and seldom involve very extensive areas. Two or more discontinuous regions of activity may be seen in rare cases. The extent and rate of spread are measures of the severity of the disease. In infections of little virulence and slow rate of spread the central zone may clear as the periphery slowly expands. The face is a site of predilection, although no region is exempt There may be considerable swelling and edema particularly in cases involving the face and ears. The mucous membranes sometimes are attacked Occasionally a case is seen in which the inflammatory process is confined almost exclusively to the subcutaneous tissue, edema of the overlying skin being the sole superficial manifestation.

An attack uninfluenced by treatment generally lasts from one to several weeks, and fever is usually present throughout the course Within a few days or a fortnight the process reaches its acme then persists unchanged for a time and finally begins gradually to subside As involution takes place the dusky red color slowly fades to a brownish and then a yellowish hue and ultimately the epidermis regains its normal color There is always more or less desquamation.

Etiology.—Spink and Keefer (JClinInv 15: 17 1 1936) in a study of 30 cases found β hemolytic streptococci in the lesions or in the nasal secretion of all cases. *Streptococcus pyogenes* produces (1) streptococcic hemolysin (2) streptococcic leukocidin (3) an erythrogenic toxin (4) a fibrinolysin and (5) a substance which increases skin permeability and these aggressive substances somehow determine its pathogenicity. Perhaps antitoxic immunity which is the essential factor in resistance to scarlet fever is relatively ineffective as a protection against *Str. pyogenes* invasion of the skin the essential feature of erysipelas. While the erythrotoxin may play a part in the disease it seems that the degree of antitoxic immunity which will protect against scarlet fever will not protect against erysipelas.

Erysipelas like lesions occurring in acute nephrosis (q.v.) were remarked by Aldrich and Boyle (AmJDisChild 50: 1050 1939). Acute edematous cellulitis starts in an area of some 3 to 3 cm. diameter and spread very rapidly migrating especially to the dependent parts. The edges are not raised. The lower half of the body is affected. Favorable response was obtained with large doses of convalescent serum from patients who had recovered from erysipelas or scarlet fever.

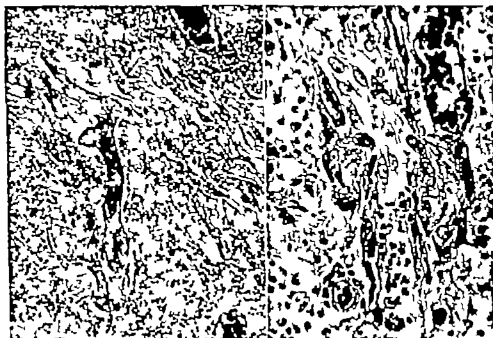

Fig. 303.—Erysipelas, showing polymorphonuclear and plasma cell infiltrate throughout dermis, and swelling of sweat duct. (Dr. Fred Weidman.)

Fig. 304.—Erysipelas showing capillary congestion, swelling of sweat duct epithelium, and polymorphonuclear leukocytic infiltration. (Dr. Fred Weidman.)

Pathology.—There is fibrinous and leukocytic exudation throughout the dermis. Blood and lymph vessels are dilated and congested. There is marked perivascular infiltration consisting mainly of polymorphonuclear leukocytes. The prickle cells are swollen, cloudy and vacuolated. Colliquation necrosis is usual. Streptococci are found chiefly in the lymphatics but are also distributed in the tissues. The inflammation, violent as it is, usually resorbs completely with no cicatricial sequelae but recurrent attacks, while comprising a rare clinical picture, can provoke chronic fibrosis and elephantiasis.

Prognosis.—In 1,193 cases (Hoyne: MRec 141 132 1935) the mortality was highest in the first year of life (39%) and in old age (43% in the 76- to 85-year group). The pregnant patient developing erysipelas is likely to abort within 24 hours (Lynch ADS 26 997 1932). One should note the dates of the studies quoted for sulfonamides and antibiotics have profoundly influenced the prognosis: erysipelas is no longer a disease to be dreaded and in fact, curiously I do not see many cases nowadays.

Acute glomerulonephritis is a possible sequel (see p. 28?).

Mortality rates arranged according to age groups and treatment methods were given by Nelson et al. (J 11 : 1044 1939): on sulfonamide, 1.6% of adults and 18% per

cent of children died; on antitoxin 9.2% of adults and 8.5% of children died; on serum ultraviolet, x ray and topical therapy 7.1% of adults and 10.7% of children died. The mortality rate was 16% in 1400 hospitalized patients reviewed by Keefer and Spink (JClinInv 15: 17 1, 1936). The rate was high in the first two years of life, low until age 60, then rose rapidly. Bacteremia was of grave import as was coincidental debilitating disease also.

Fatal cases according to Toomey (AnnIntM 12: 166, 1938) occurred generally among (1) infants less than 1 year of age, ( ) patients more than 50 years of age, (3) patients with pulmonary disease such as tuberculosis and pneumonia, (4) patients with chronic organic disease such as myocarditis and arteriosclerotic disease, (5) patients with concomitant acute infections, (6) patients who had a severe debilitating illness immediately before their erysipelas, (7) patients with alcoholism and (8) patients who had suffered severe injury. Not all patients in these groups died, but all of Toomey's patients who died belonged in one of these.

In 369 cases seen in Panama (Miller et al.: SMJ 38: 757, 1945) 46 were primary and 2.5% died. Whites were 4 to 5 times as susceptible as natives. In addition to local lesions, other manifestations in order of incidence were chills, local lymphadenitis, vomiting, headache, aching, anorexia, pharyngitis, diarrhea, convulsions, icterus, distention, delirium, toxic psychosis and orbital abscess.

Diagnosis.—Erysipelas is to be distinguished especially from erythematous contact dermatitis. The marginated, indurated lesions perhaps with bullae but not with eczematous vesiculation are distinctive, and the patient with erysipelas has fever and leukocytosis, and is sick. Compare Lupus erythematosus, systemic.

Treatment.—Morphine may be used freely. Good nursing care used to be of great importance. Bed rest, the urging of fluids, and alkaline diuretics are usually ordered. It has become common knowledge (J 108: 32, 1937) that sulfonamides possess remarkable properties in the cure of streptococcic infection and in minimizing its complications.

With their use, lesions of erysipelas become dusky red and purplish within the first 1 to 4 hours and disappear completely within 4 to 10 days. Inflammation resolves, symptoms improve and fever falls almost at once. One should institute treatment early. Sulfanilamide reduced hospitalization time from 11 to 7 days in the experience of Nelson et al. (J 11 1044, 1939). It reduced mortality rates as compared with antitoxin from 9.2% to 1.6 in adults and from 37.5% to 1.9 in children. Treatment other than sulfonamide was adjudged obsolete by Shank et al. (J 117: 2235, 1941) in whose experience no lesion spread after 36 hours of chemotherapy while only 10% of the patients were febrile after 4 days. One may give both penicillin and sulfadiazine.

A dose of from 100 to 300 r of unfiltered x ray therapy may be given over the affected area and a margin of 2 inches of surrounding normal skin as early in the course of the disease as possible followed by the same dose the next day (Bormann: DWchr 100: 131, 1935).

Ultraviolet ray treatment of the lesion and a surrounding zone of uninflamed skin was said to have value. 20 times the erythema dose was advised by Titus (BritJPhysM 9: 160, 1934). Ultraviolet therapy was highly recommended by Nightingale and Starr (J 102: 761, 1934) and Lavender and Goldman (J 105: 401, 1935). It diminished mortality in infants by 20% as compared with antiserum therapy (Starr: APhysTher 18: 772, 1937). It was the best method of treatment at that time according to Knapp (APhysTher 16: 711, 1935; 18: 872, 1937).

Antistreptococcic serum has been proved beneficial and should be given a trial in extremely toxic cases (Eley: AmJDisChild 39: 529, 1930; Foot: SouthMJ 23: 29, 1930). No local medicament reaches the subepithelial region of activity. Continuous cool packs are more or less comforting, the solution being inconsequential if it is nonirritating. Ichthyol ointment is popular but inert.

SULFONAMIDES.—See Domagk (DMedWchr 61: 250, 1935) prontosil; Colebrook and Kenny (Lancet 1: 1279, 1936); Foulis and Barr (BMJ 1: 445, 1937); Snodgrass and Anderson (BMJ 2: 101, 1144, 1937); Long and Bliss (J 108: 32, 1937; SouthMJ 30: 4 9, 1937).

Recurrent Erysipelas.—Relapse may occur within a few hours or days after apparently complete dissipation of the disease or after months or years, Andrews noted (Diseases of the Skin, Saunders, 1954). Antistreptococcic therapy should not be discontinued too early.

Chronic recurrent erysipelas constitutes a characteristic entity resulting in persistent lymphedema and elephantiasis. This rebellious and disfiguring disease to be distinguished from the erysipelas-like dermatophytid (q.v.) may respond to elimination of foci of infection and immunization with streptococcus toxin (Stevens: J 100: 1754, 1933). Andrews recommended also penicillin, plastic surgery and x ray therapy. Penicillin, x ray and solid

CO_2 did not help a case of Ormsby's (ADS 57: 403, 1948) O'Leary discussing this patient, advised a search for portals of entry of infection, the use of rubber bandages, vaccines or sulfonamides prophylactically and perhaps the injection of boiling water into the edematous area, which results in severe reaction occlusion of lymph vessels, and decrease in edema. Corticosteroid therapy is also sometimes beneficial (Andrews)

MELKERSSON'S SYNDROME, an elephantiasic swelling of the face associated with peripheral facial palsy was the name under which Kettel (AOtol 46: 341 1947) described 5 cases occurring in young men and women. The chronic swelling is sometimes bilateral. The onset of cutaneous changes often coincides with an attack of Bell's palsy but facial swelling may not begin until some years after the nerve palsy It is sometimes limited to the upper lip. The chronic recalcitrant edema may be concerned with hypothetical trophic fibers accompanying the seventh cranial nerve. Furrowed tongue is usually also present.

See QMN (J 139 193 1949) Machacek (ADS 61: 912, 1950); Stevens (J 156 323 1954) Hamilton (SouthMJ 47: 778, 1954) comparing erysipelatoid dermatophytid

Fig. 105.—Recurrent erysipelas producing chronic lymphedema. (Dr H C. Baum.)

SCARLET FEVER

Symptoms.—Scarlet fever is an acute febrile streptococcic infection usually of the throat, characterized by a toxic rash which is diffuse, brightly erythematous and productive of desquamation. The incubation period as a rule is short. Headache anorexia and vomiting are frequent early symptoms. High fever and a sore throat, which may present simple inflammation, follicular tonsillitis or a white diphtheroid membrane are typically abrupt in onset. Regional lymphadenitis is painful, and suppuration is not a rare complication. The throat is at first dry but later becomes congested raw and exceedingly tender The buccal mucosa may exhibit punctate redness, similar to that of the skin. The tongue is at first furred but later desquamates and assumes a peculiar strawberry appearance particularly at the border

The eruption at first diffuse and punctiform generally appears on the second day of the disease The neck and chest are usually involved first although the rash rapidly spreads to other parts of the body Only the circumoral region is ordinarily exempt. The eruption when fully developed at the end of the third or fourth day consists of closely aggregated, pinhead-sized or larger reddish macules which give to the skin a distinctly scarlet color Redness disappears on pressure and when the skin is stroked, transient white streaks are formed. Petechiae when present indicate grave intoxication, which may be such that death occurs within a few hours after the onset of the disease In mild and abortive cases the eruption may be slight or even lacking As a rule flaky desquamation commences between the seventh and tenth days and continues for a fortnight. Volar surfaces exfoliate slowly and sheets may come away in the form of casts of the affected parts. Nails are sometimes lost temporarily but hair is seldom shed.

Scarlatiniform eruptions may occur in streptococcic infections of the throat, surgical wounds, burns, *or pelvic and postpartum infections.* These may be considered true scarlet fever which is simply streptococcic infection with a symptomatic rash. Strains of streptococci differ in erythrogenic power and rashes occurred in from 47 to 0% of those infected with various organisms studied by Hamburger et al. (J 124 664, 1944) The rash of scarlet fever accompanied a streptococcic ulcer of the thigh in an old man with pneumonia seen by Kirby and Rantz (AIntM 71 620 1943) cure was obtained with sulfonamide therapy

THE DICK TEST consists in the intradermal injection of toxin; lacking antitoxin the susceptible subject responds with erythema while absence of response indicates relative immunity. Negative reactors got tonsillitis but no rash but Dick positives got scarlet fever as reported by Schwentker et al. (AmJHyg 38: 1943) See Dick and Dick (J 82: 265 1924; Scarlet Fever Year Book Pub., 1938) Rantz et al. (NEngJM 235: 39 1946) however, denied the existence of a relation between the Dick reaction and immunity to infection by hemolytic streptococci.

THE SCHULTZ-CHARLTON REACTION is seen when scarlet fever antitoxin or convalescent serum is injected intradermally into an area bright red with the rash of scarlatina. Blanching *occurs because the streptococcus toxin is neutralized.*

Fig 406.—Postscarlatinal desquamation (Drs Welsh and Schamberg.)
Fig 407.—Postscarlatinal desquamation (Dr Howard Fox.)

Diagnosis.—In drug rashes the history and the usual absence of fever angina and other signs of infection serve as *distinguishing features* atropine however can cause a scarlatiniform rash accompanied by fever and delirium Measles is characterized by its longer period of incubation, the primary involvement of the forehead and face the larger size crescentic arrangement and darker color of its edematous macules and the catarrhal involvement of the respiratory tract.

Treatment.—Prophylactic doses of toxin given to induce active immunity are likely to be followed by fairly severe reactions which may be avoided by giving 7 graduated doses at weekly intervals (Glazier NEngJM 233 204 1945) Nevertheless persons exposed to the disease occupationally should be protected (Anderson and Reinhardt JInfectDis 617 126 1935) *Convalescent serum* given to contacts early seems to abort the disease and even if given later seems to yield symptomatic benefit (Hoyne et al. J 105 783 1935) Human serum provokes no untoward symptoms. During an epidemic, it is

advisable to give sulfonamides to everyone likely to be exposed a gram a day of sulfadiazine brought one epidemic to an end (Watson et al. J 122 730 1943)

Sulfonamides given early in the disease are curative or else reduce markedly the incidence of complications (Sako et al. J 111 995 1938) but cannot be relied upon to the exclusion of other measures (French JHyg 39 581 1945)

Penicillin is probably more efficient for no complications occurred in 118 patients treated with it by Breese et al (AmJMedSci 211 417 1946) High dosage for 8 days is to be preferred, and this tends to reduce the carrier rate Orally 100 000 units q 4 h is effective (Hirsh et al J 133 657 1947) See Pulver (Der Scharlach und Seine Behandlung Huber 1954)

Reporting success with penicillin in 116 cases, Horne and Brown (J 133: 661 1947) adjudged it superior to sulfonamides and as good as convalescent serum. While inadequate doses may relieve symptoms dramatically high dosage is required to eliminate organism completely stated Jennings and DeLamater (AmJMed * 1, 1947) Sore throat subsided in ... days and fever within 4.5 days, as compared with 7 days when using sulfonamides, and the average duration of hospitalization was only 6 days in 1,000 cases reported by Jersild (Lancet 1: 671 1948) Of 56 patients with scarlatinal otitis, only 2 required mastoidectomy an operation which otologists are forgetting how to perform.

Convalescent serum, gamma globulin or antitoxin may do for the severely toxic patient what bactericidal medication cannot do (Fox and Gordon: AIntM 74 1 1944) In the series of Landon and Greenfield (AmJDisChild 76: 280 1948) there were 3½ times as many complications among those treated with penicillin as among those treated with gamma globulin and 5 times as many complications in those treated with convalescent serum. Yet gamma globulin was not highly effective, as penicillin was, in clearing the throat of streptococci.

One may presume it advisable to use gamma globulin, penicillin and sulfonamides together and cases should be recognized and placed under treatment early

Complications and risks are primary toxemia, suppurative cervical nodes, osteitis, especially of the mastoid, middle ear damage, nephritis and arthritis (Edit.: BMJ . 915, 194 ; Hamilton and Togasaki: JPed 14 655, 1939) Streptococcic meningitis occurred in only 19 of over 17,000 cases studied by Gordon and Top (JPed 6 770 1935) but killed 18 of the sufferers, whose purulent leptomeningitis came from the middle ear in 13 instances, from the sinuses in 4 and from the joints in 2. Gangrene of a leg can result from arterial embolism or thrombosis; while rare gangrenous complications were fatal in half of the 16 cases collected by Dick et al. (AmJDisChild 47: 374 1934); See Breen (Lancet 2: 196, 1940)

Topical therapy comforting to the patient includes an ice bag about the neck, cool moist applications such as aluminum acetate 1 500 and mineral oil during the desquamative stage.

RECALCITRANT PUSTULAR ERUPTIONS OF THE EXTREMITIES

One may well follow Andrews (Diseases of the Skin, Saunders, 1954) in the description of this group which includes forms which have so many characteristics in common that it is difficult to divide them definitely into separate entities. Dermatitis repens acrodermatitis perstans and pustular bacterid are diagnoses which excite discussion in any dermatological meeting I use the name dermatitis repens for rare cases of a particular clinical picture where soggy undermining of the epidermis is associated with local parasitism acrodermatitis perstans is put with chronic dermatitis of hands and feet (q v) and not used as a specific diagnosis and pustular psoriasis is applied strictly to clear-cut cases of psoriasis (q v) in which pustulation is present, perhaps as the result of focal infection, such as would occur if recalcitrant pustular acrodermatitis and psoriasis coexisted.

Pustular Bacterid implies that bacterial allergy can cause vesiculopustular lesions analogous with dermatophytids, a concept of dubious acceptability (Sulzberger and Baer YBD 148 p 21) The difficulties involved in using the name are avoided by calling such cases recalcitrant pustular acrodermatitis, which was defined adequately and aptly by Andrews.

Dermatitis Repens *usually follows an injury* small sore or paronychia. It is characterized by progressive and rebellious serous undermining of the epidermis with the formation of numerous minute abscesses. It begins with localized redness and vesiculation or pustulation. The central portion soon

Figs. 208 and 209.—Pustula bacterid. (Dr George C Andrews.)

consists of glazed denuded dermis, and this is surrounded by a ragged border of undermined epidermis. Serum and pus can be squeezed from beneath this marginal collar which ranges from 0 1 to 1 0 cm in width. There is little pain or itching. *The disease spreads slowly usually remaining unilateral. Staph.*

aureus generally can be isolated I look upon the disease as a chronic localized form of infectious eczematoid dermatitis (q v) generally responsive to elimination of foci, toxoid immunization and appropriate antibiotics. The combined parasitism and bacteria can produce the picture *Ps aeruginosa* seemed causative in 2 cases of Post and Hopper (ADS 63 220 1951)

See Barber and Eyre (BJD 39: 485, 1927) Dore (BJD 40: 12, 1928); Barber (BJD 42 500, 1930, 45: 113, 1933) Dore Barber and others (BJD 54 72, 91, 1942); Sachs and Scannone (JID 6 249 1945) Sachs et al. (ADS 56 748, 1947) Sachs, Andrews and others (ADS 65: 101, 1952) Bloom and Loriaux (ADS 70 819 1954) response to balsam of Peru; Murrell and Murrell (SouthMJ 48: 88, 1955) response to Terramycin by mouth, débridement and bacitracin ointment.

Pustular Psoriasis of the Extremities of Barber (see BJD 54 72, 91 1942) is generally bilateral and symmetrical and cultures are usually sterile. Circumscribed lesions of thenar eminences or soles are typical within which occur crops of minute intraepidermal pustules followed by drying crusting exfoliation and recurrence While some of such cases have been cured by elimination of foci, others have seemed incurable. Discussions of the confusing status of various clinically distinguishable manifestations of vesicular and pustular eruptions of the extremities by Dore and by Goldsmith (BJD 54: 72, 91 1942) are interesting My present interpretation of these cases invokes infection secondary infection focal infection, contactant irritation malnutrition, and metabolic imbalances in various combinations and degrees of causative consequentiality

Recalcitrant Pustular Acrodermatitis.—Andrews et al. (ADS 29: 548 1934) reviewed the features of persistent acrodermatitis, early lesions of which are intraepidermal pustules, which by confluence give rise to visible pustules and by peripheral spread produce crusted patches. They emphasized these uniform features of the varying clinical cases (1) failure of bacteriologic and mycologic examination to reveal organisms (2) unresponsiveness to all forms of local treatment including x ray therapy (3) coexistence of foci of infection (4) therapeutic benefit when these foci are eradicated (5) absence of features of psoriasis, with the pustular variety of which these cases have been confused Pustular bacterid includes cases in which the only cure rests on removal of foci of infection. Foci of particular importance are the teeth where pyorrhea and decay as well as abscesses are significant, tonsils, sinuses, kidneys, pelvic organs, vagina, and prostate.

Paronychial disease of this type is described separately by Andrews. A chronic and recurrently active vesiculopustular dermatitis of the terminal phalanges undermines the nails deforming them to a greater or lesser degree. Elimination of foci and contactants, along with penicillin injections, often proves curative. See Chronic dermatitis of the hands.

Etiology—Staphylococci and streptococci have both been found. Any inflammatory lesion such as a traumatic one acts as a filter for whatever circulating organisms may originate from a focal infection (Menkin Dynamics of Inflammation, Macmillan, 1940) See Andrews and Machacek (ADS 32 837 1935); Andrews and Barnes (SouthMJ 34 1260 1941)

Diagnosis.—Infectious eczematoid dermatitis mycotic infections, pustular psoriasis and primary micrococcic lesions of the extremities must be differentiated. Chronicity and rebelliousness to treatment are typical features. In infectious eczematoid dermatitis the eruption is usually of wide distribution and the patches are superficial. Fungi are absent.

Prognosis.—The disease may persist for months or years. A common sequel is x ray injury Response to proper treatment may be gratifying

Treatment.—Of local applications, soaks or poultices with 1:5 000 potassium permanganate may be helpful and I often prescribe 2% sulfur with 1% hydrocortisone in Vioform Cream One must eradicate foci of infection, eliminate contact irritants, and simultaneously attack with suitable chemotherapy

Fig. 310.—Recalcitrant acrodermatitis, psoriasiform.

Fig. 311.—Recalcitrant acrodermatitis. The same streptococcus was cultivated from paronychia and oral focal infection.

any parasites locally present. When the lower extremity is affected due attention must be given to circulatory problems, effort being directed at obtaining optimum conditions of blood flow. Measures corrective of anemia, hypoproteinemia, hormonal imbalance and defective liver function may be helpful. X-ray therapy offers nothing. Large doses of penicillin may yield benefit, likely to be only temporary, and this is true also of the sulfonamides (Sulzberger, ADS 40 843 1019 1939; Lever, ADS 49 273 1944). Immunization with staphylococcus toxoid can be tried. Cases are sometimes well palliated with cortisone, but elimination of foci is the essential measure.

GANGRENOUS DERMATITIS DUE TO INFECTION

Diseases in which considerable necrosis of the skin is a conspicuous feature may be caused by agents working locally or systemically. Gangrenous lesions are described under Bedsore, Burns and Frostbites, Anaphylaxis, Factitious Dermatitis, Occlusive Vascular Disease, Embolism and Thrombosis, Raynaud's Phenomenon, Rickettsial Infections (typhus), Syphilis, Leprosy, Noma, Cancer and Lymphoblastoma; see also Vascular Gangrene and Symptomatic Gangrene.

LOCAL INFECTIONS WITH GANGRENOUS DERMATITIS

Hemolytic Streptococcic Gangrene.—Meleney (ASurg 9 317 1924) pointed out that there is usually an initial lesion, which may be an injury or an operative procedure. Alarming rapidity of spread, swelling, stiffness, pain, fever and prostration characterize the early stages. The skin is first tense, smooth and shiny, but soon portions gradually turn darker, changing from red to purple, then to blue. Bullae may form. By the fourth or fifth day the purple areas become frankly gangrenous. A line of demarcation appears, the dead skin separates and beneath it is revealed extensive necrosis of the subcutaneous tissue. Sometimes the area of skin necrosis is small and subcutaneous loss extensive. Healing comes about slowly by granulation. In severe cases the process continues to advance until several large areas of skin have become gangrenous, the patient becomes more intoxicated, metastatic abscesses may develop and death ensues. The regional lymphatics are relatively little affected. Blood cultures in many cases show a microaerophilic hemolytic streptococcus, as do cultures from the lesions. The synergistic action of streptococci and staphylococci has been indicated by production of the disease in animals.

In treating undermining ulcers zinc peroxide has been recommended. It must be properly prepared to be of service (Meleney and Harvey, AnnSurg 110 1067 1939), mixed with equal parts of sterile water and applied everywhere to the surface of the infected tissue. The dressing must be a daily one carefully done, for direct and moist contact is essential.

Penicillin may halt the progress of the lesion, permitting spontaneous separation of the slough and rendering surgical attack unnecessary, while sulfonamides, strongly recommended a few years ago, have not been wholly successful in controlling the condition, according to Meleney et al. (Surg 18 423 1945). Many cases of chronic dermatitis with recalcitrant ulceration of the lower leg are associated with streptococcic infection and may respond to full doses of sulfonamides (Taylor, J 118 1196 1942). Antibiotic sensitivity tests may be expected to disclose an antibiotic which would cure.

Bacitracin seemed effective to Meleney et al. (AnnSurg 131 129 1950) but Meleney (J 149 1450 1952) was still finding a place for zinc peroxide which he recommended for synergistic gangrene only after excision, for foul ulcers especially cancerous, for diabetic gangrene, radiation burns and ulcerative colitis, and, as a prophylactic, around colostomies and in the sockets left by dental extractions. He thought well of it also in herpes zoster and poison ivy dermatitis. I do not share his enthusiasm.

Chronic Streptococcic Ulcers occur producing cutaneous gangrene which is slowly progressive and resistant to treatment (Goodman J 111 1427 1938) The undermined borders are irregular firm, thickened, ragged, and angry red in color The bases are roughly granular and glazed, discharging a copious serous fluid. Other than mild and transient lymphadenitis, there are no complications A symbiosis of streptococci and staphylococci was postulated as causative of geometric phagedena by Greenbaum (ADS 43 775 1941) See Dostrovsky and Sagher (ADS 54 408 1946) While penicillin by injection is highly effective, the 0 5% wet dressings of cysteine hydrochloride of Hamilton (OklaSMAJ 32 359 1939) deserve mention. Transfusions were highly recommended by Lyons (J 105 1972 1935) A buttock lesion which followed intramuscular injections of penicillin and streptomycin and required excision and grafting was reported by Wooldridge and Hogeboom (ADS 67 56 1953)

See Nixon (TexasSJM 33 216, 1937), 2 cases; Probstein and Helfets (JMoSMA 36 115 1939) infant Traub (ADS 38 94, 1938) correct preparation of zinc peroxide Hamilton (SouthMJ 31 440, 1938) pseudomycosis: injury pustulation, ulceration, brawny cellulitis, slowly spreading, punched-out ulcers, sinuses and undermining Wright and Friedman (ADS 39 554 1939) 3 year duration in old man, helped with sulfonamide Holman (BMJ 1 596, 1939), Lawrence (NEngJM 222 673 1940) cure with sulfonamide, Shallow et al (SGO 79 317, 1944) Marcus (BMJ 2 394 1950) 2 breast cases cured with streptomycin, Marcus (BMJ 1 1218, 1952, leg case requiring excision Ebbeson and Hardy (AnnSurg 123 1112, 1948) case following cold wave.

See also Leg Ulcers, Tropical Ulcers, Chancriform Pyoderma, and Pyoderma Gangrenosum.

Micrococcus mycetoma infections were described by Castellani (JTropM 36 249, 1933) who observed abrupt onset of a cellulitis suggestive of nocardiosis accompanied by fever ulceration and sinus formation, sometimes resulting in elephantiasic fibrotic changes. Similar lesions can be produced by *B typhosus* (Castellani JTropM 38 141 1935)

Progressive Postoperative Gangrene is a rare but clinically typical phenomenon of secondary infection of a surgical wound usually abdominal or thoracic. The lesion begins within 2 weeks as an erythematous induration at the edge of the wound. The inflammatory tumor becomes purplish or purpuric then undergoes central necrosis. Its progress may be extensive, and intoxication, fever and pain feature its course. Streptococci, staphylococci, or both as well as other organisms have been found. Treatment comprised radical excision at one time but one would expect penicillin and antitoxins to accomplish some cures (Touraine and Duperrat AnndeD 10: 237 1939 Dodd et al. ASurg 42 988 1941) Streptomycin by injection cured three cases in which sulfonamides and penicillin failed, according to Karn (NZealandMJ 48 380, 1949)

See Pilot (J 108 1694 1937) Carroll (AmJSurg 2 87 1938) Brodie and Bosch (CanadMAJ 42 133 1940) treatment with zinc peroxide and sulfonamides Lichenstein (ASurg 42 718 1941) Callam and Duff (BMJ 2 801 1941) anaerobic streptococcus and *B proteus* Behrend and Krouse (J 149 1122, 1952) fatal case

Gangrenous Balanitis (Phagedenic Balanitis) is a disease which develops rapidly and may give rise to deep and widespread gangrene The typical cases are apparently the genital manifestation of Vincent s disease for the spirochete and fusiform bacillus can be demonstrated, and the response to arsenical medication may be suggestively prompt. However synergistic coccic gangrene may affect prepucial tissue as well as tissues of the face or legs, the more common location of such lesions. Phagedenic ulcers of the genitalia are characterized by extensive and speedy destruction with comparatively little tissue reaction The slough is greenish gray The odor is putrid and offensive Fever and intoxication are likely to be great The regional lymph nodes are enlarged and tender Death may result. A copious, purulent hemorrhagic discharge characterized the case of v Haam (AmJTropM 18 595 1938)

Necrotic tissues should be cut away in such cases giving free drainage and access to chemicals. Oxidizing agents are used locally hydrogen perox

ide potassium permanganate or chlorine water soaks, or the actual injection into the tissues of oxygen gas. Appropriate antibiotics are of course indicated, and sulfonamides may be given by mouth.

Genital Ulceration in cancer tuberculosis, syphilis, actinomycosis, granuloma inguinale lymphogranuloma inguinale chancroid, paraphimosis, phagedena, gangrenous balanitis, ulcus vulvae acutum and Behçet's syndrome require differential diagnostic consideration (see Carlson JMoSMA 24 147 1937 Speiser AmJOG 43 681 1942 Leider USNMBull 41 278 1943) Biopsy smear culture dark field and intradermal and serologic tests are involved. Penile ulcers simulating chancroid but due to microaerophilic streptococci were seen frequently in southern Japan by Leibovitz (AmJSyph 38 203 1954)

See Campbell (SGO 34 780, 1922), 8 cases, 1 death; Whiting (AnnSurg 41: 841, 1905) 83 cases, 23 deaths; Hanschell (BJVD 20 123, 1944), mixed coccic infection cured with zinc peroxide; Reiter and Wentholt (JID 16 301 1950) primary fusospirochetal gangrene of penis, isolation of anaerobic pleuropneumonia like organism.

Fig. 314.—Gangrenous balanitis. (Dr F O. Harris)

Fig. 315.—Gangrenous balanitis. (Dr J E. Moore.)

Palpebral Gangrene in the Newborn.—Gangrene of the eyelids in infants is extremely rare but has been reported due to diphtheria, purulent ophthalmia and syphilis, and has been invariably progressive and fatal according to Pereira and Conti (ArchOftal 29 503 1954 abs J 157 1057 1955) Their patient, slightly premature and dystrophic developed a little red spot on the lower lid 10 days postnatal Rapid diffusion followed, with gangrene and penicillin was ineffectual. Death occurred after 12 days.

Granulomatous and Ulcerative Gangrene of the Face.—This is a rare, progressive destructive horribly disfiguring disease which has generally proved ultimately fatal Well described by Pardo-Castello et al. (SouthMJ 46 149 1953) it begins with necrotic ulcers in the skin and mucous membranes of the nose and mouth Granulomatous growths evolve and lesions spread to the skeleton of the face producing destructive osteomyelitis, ending in necrosis of the entire center of the face with frightful deformity of mouth nose, eyes and maxillae. The tongue and esophagus usually remain unaffected. The course has extended over a few months to years.

Malignant granuloma of the face was the title chosen by Levan (ADS 68 187 1953) who noted the slow onset and gradual enlargement of the granulomatous tumors. These may arise in the interior of the nose or on the palate and spread to adjacent structures, including the paranasal sinuses, posterior nasopharynx and soft parts of the midface. The patient retains good health until the terminal stages. Levan quoted the early reports of McBride (JLaryng 12 64, 1897) and Woods (BMJ 2: 65, 1921)

While the cause is unknown interesting speculations have evolved concerning the possible relation to systemic lupus erythematosus (Moore et al.: Laryngoscope 61 32 1951) and periarteritis nodosa (Stratton et al BMJ 1 1** 1953) The patient of Moore et al was a woman with rheumatoid arthritis of knees and ankles and erythematous lesions of elbows, hands and feet and cortisone induced healing while it was given. The patients of Stratton et al. showed a low-grade fever and developed albuminuria, renal and cardiac failure, rising blood urea, and necropsy changes of periarteritis nodosa in many organs. Dennie and Hamilton (ADS 4 : 1040 1940) thought *Spirochaeta microdentium* pathogenic in their case The patient of Cole et al. (ADS 43: 943 1941) was a congenital syphilitic and might have suffered ill effects from heavy metal therapy The patient of Astrachan (ADS 49: 7 1944) too, had received antisyphilitic therapy for years. Hargrove et al. (Lancet 2: 596, 1946) queried whether the disease might be sarcoma.

Zinc peroxide helped the patient of Costello (J 121 36 1943) Streptomycin, 3 Gm per day cured Williams (ADS 61 506 1950) Chloromycetin succeeded after penicillin and Aureomycin had failed in the patient of Sneedon and Colquhoun (BMJ 1 298 1952) Encouragement was afforded by the report of success with ACTH in the patient of Hagens et al. (AOtol 57 516 1953) who healed and has remained well (Hagens pers. comm 1955) Unexpected and unexplained cure followed a few small doses of x ray therapy in the case of Ellis (BMJ 1 1251 1955)

Systemic Infections With Gangrenous Dermatitis

Pyoderma Gangrenosum comprises a group of uncommon cases characterized by suppurative destruction of the skin associated with infection of long duration elsewhere in the body Brunsting et al. (ADS 22 655 1930) described 5 patients 4 of whom had ulcerative colitis and the fifth, thoracic empyema. Skin lesions include blebs, ulcers, pustules and abscesses, in which *Staphylococcus aureus* *S albus* and hemolytic *Str pyogenes* were found by Jankelson and Massell (AmJDigDis 3 19 1936) *B proteus* and *B pyocyaneus* may also be cultivated but it is difficult to know to what extent bacterial parasitism is directly responsible for cutaneous lesions.

Ulcers manifest slightly raised jagged, overhanging and undermined edges and bright red bases dotted with granulations and bathed in foul smelling yellowish green pus. They may attain a diameter of several centimeters.

In a review of cutaneous diseases associated with ulcerative colitis Sam tz and Greenberg (Gastroenterol 19 376 1951) noted 93 instances of skin complication in 65 (34%) of 189 cases. They observed oral aphthae and other forms of stomatitis, urticaria, erythema nodosum furunculosis and other lesio and 3 instances of pyoderma gangrenosum. The influence of deficiency with hypochromic anemia and hypoproteinemia, and the relation of skin manifestations to exacerbations accompanied by fever toxicity and purulent diarrhea have been stressed by various observers (Cohen ADS 33: 813, 1936; McClure: ActaDV 1 255 1940 Kiel ADS 56 187 1947)

See Schmidt (PBMMC 11 244 1936), Weiner (ADS 41 711 1940), F len (NYSJM 41 2228, 1941) Russell (BJD 62 114 1940) Brunsting (OhioMJ 30 1131 1934) review

The course of the disease is characteristically chronic Improvement and recrudescence in the internal chronic infectious process are respectively associated with evident trend toward healing and uncontrollable tendency to spread on the part of the skin lesions. At one time the patient may have scars, pustules and large integumentary defects, which may be healing or progressing The total number of ulcers ranges from 1 to a score or more and response to therapy is erratic Amyloidosis was present in the case of Bernstein and Goldberger (ADS 49 76 1944)

Vegetative pyoderma associated with ulcerative colitis is sometimes seen 5 cases difficult to distinguish from pemphigus vegetans were described by Brunsting and Underwood (ADS 60 161 1949)

The outcome is doubtful Some patients have become cachectic and died a majority however have passed through difficult periods with eventual return to health Much depends on the effectiveness of attempts to correct the underlying condition

Treatment.—Locally one may try Meleney's zinc peroxide paste (Brunsting ADS 41: 752, 1940) or sulfanilamide powder (Dostrovsky and Sagher ADS 48: 164, 1943). Wise (ADS 48: 551, 1943) used gramicidin ointment and administered sulfasuxidine, vitamin B complex and vitamin C with benefit.

Fig. 316.—Pyoderma gangrenosum in typhoid fever. (Dr G. B. Lemmon.)

Fig. 317.—Pyoderma gangrenosum. (Dr C. M. Stone.)

fit. Azulfidine, a favorite of Bargen, may be superior to other sulfonamide preparations. Ultraviolet light baths, transfusions, acetarsone by mouth, and various topical antiseptics have been recommended. The correction of inadequacies of nutrition, especially of protein, is a major effort but not easy. The

elimination of focal infection is necessary Antibiotics may or may not prove of much value those which may increase the irritability of the gut should be avoided or used with circumspection.

Gangrenous Dermatitis of Infants (Gangrenous Ecthyma) occurs generally as a rare complication of one of the exanthemata. Vesicular lesions becoming pustular develop into oval sloughs, which result in scars if recovery occurs. Trunk, buttocks and thighs are sites of predilection. A course of weeks o even months is marked by vomiting, chills, fever and intoxication. Such cases are likely to be in fact representative of *Ps. aeruginosa* infection (q.v.). Gangrene of the leg occurred in 2 cases a an embolic complication of scarlet fever (Blumenberger: AfKlinde halik 1936 p. 164). Hemolytic streptococci infecting varicella lesion caused extensive and fatal ulceration in a patient of Banks and McCartner (Lancet : 311 1937). Staphylococcus septicemia was the cause in a boy who wa treated with success by 25% urea wet pack (Blatt et al.: ADS 39: 407 1939). Enteritis preceded the hemorrhagic bullae which underwent gangrene in the two infants, brother and sister reported on by Urnela (abs ADS 39 395, 1939).

Dermatitis Nodularis Necrotica is characterized by a recurrent, polymorphous eruption of vesicles, papules, papulonecrotic lesions and ulcers preferring the back, dorsa of hand and feet knees, elbows and volar skin, with or without constitutional disturbance. Petechiae may occur. Scars and hemosiderin stains result. The hypothesis of tuberculous etiology has been discarded, while that of embolism seems plausible. Bacterial endocarditis brought to autopsy one patient of Duemling (ADS 1: 229 1930, 33: 99 1936) who found hemolytic streptococci in the skin lesions and lymph nodes of another. Reticulum cell sarcoma produced this picture in the report of Nieman and Wise (ADS 40: 560 1939) but Bernstein (NYSJM 40 ?7 1940) could not discover the cause in his 3 patients. Painless red lumps on the buttocks, legs and soles characterized the eruption which was present for 3 years following scarlet fever in a girl studied by Smith (BJD 61: 333, 1949).

A chronic nodular dermatosis, manifested by small, flesh-colored, painless lesions, was observed in a woman 48 years old by Bulter (Dermatologica 102: 139 1951). Minute pustules on the summits of some of the larger lesions yielded only *Staph. aureus*, and penicillin cured the disease although several courses were necessitated by relapses.

Compare Furuncles, globose lesions, p. 79

INTERTRIGO

Symptoms.—Intertrigo is a superficial dermatitis occurring on apposed surfaces characterized by redness, maceration and itching. Localized redness usually accompanied by hyperhidrosis, is the first manifestation. If neglected the skin becomes abraded and raw often with the formation of vesicles and pustules. The gluteal and crurocrotal folds, inframammary region and folds of the neck are common locations. In babies, napkin rash (q.v.) is the diagnosis often made.

Etiology.—Causative factors include friction, warmth perspiration and excretions supportive of floral growth. The usual parasites include the staphylococcus streptococcus, monilia and mycelial fungi, singly or in combination. Cultures from many cases showed in 10% of them pathogenic fungi (Howles AmJTropM 16 77 1936). *The disease is especially common in* obese persons and during the hot months. Leukorrhea urine and other discharges may be instrumental in its production, and diabetic patients are especially subject to the disease. Irritation of the skin by clothing soap or other toilet articles may render it vulnerable. Compare Streptococcic Dermatoses, and Moniliasis.

Treatment.—*In addition to keeping the parts clean the liberal use of a* powder such as zinc stearate or a mixture of zinc oxide and starch, is advisable. Ointments do not act well in these cases. Gentle sponging with a cool nonirritating antiseptic such as *1 10 000 bichloride of mercury or* 1:5 000 $KMnO_4$ is beneficial. The parts are dried by tapping with a soft towel and a bland powder is freely applied. Two per cent sulfur in Vioform Cream may be recommended. See Tulipan (J 116 1518 1941) on tannic acid and brilliant green in treatment. It is helpful to separate the affected parts by means of supportive brassiere or powdered pads. If there is oozing the areas may be painted with 2% aqueous gentian violet. Good ventilation

even an electric fan and drying radiant heat may be utilized along with aluminum acetate baths, half an ounce to 10 gallons of cool water Avoidance of contactants and elimination of focal infection may be necessary in the more difficult cases.

ERYSIPELOID

Erysipeloid is the infection caused by *Erysipelothrix rhusiopathiae* the bacillus of swine erysipelas, which generally reaches the human host through contact with an infected animal cadaver infecting not only butchers but also veterinarian students (Gross JKansMS 41 329 1940) This fine, rod-shaped nonmotile gram positive organism can be cultivated from the deep tissues of infected skin (Watts JPathBact 50: 355 1940) It may be seen in Gram stained sections in the deep capillaries of the dermis, accompanied by inflammation ranging from serous and edematous to leukocytic with or without suppuration, noted Klauder (ADS 50 151 1944) who described the diamond skin disease in hogs and discussed in human beings 3 forms (1) localized occurring at the site of occupational inoculation, exhibiting limited spread central clearing and the formation of marginate figures rarely vesicular often accompanied by periostitis and arthritis (2) diffuse and generalized, exhibiting sharply marginated, extending lesions which heal in older regions, repeated relapses but few or no subjective symptoms and (3) septicemic exhibiting septic fever sometimes endocarditis (Russell and Lamb J 114 1045 1940) with or without cutaneous manifestations which may comprise plaques curiously linear purpuric lesions located at creases and on palms and soles, or hematoma like swellings of the ears. Prolonged arthritis is a common sequel, often affecting wrists elbows, and shoulders (Klauder ADS 49 368 1944)

Treatment.—Solid carbon dioxide in less than vesiculating application relieves pain promptly is rarely required more than 3 times in 3 to 6 days, and cures localized infections in a week or so as a rule, according to Griswold and Bowen (ADS 49 348 1944) Sulfonamides have been used with fairly reliable success (Schoch and Shelmire ADS 41 570 1940) Immune serum may be preferable to sulfonamides and both may be given in resistant cases, stated Klauder and Rule (ADS 49 27 1944) The organism was shown to be penicillin-sensitive by Hellman and Herrell (PSMMC 19: 340 1944) and prompt and excellent results with penicillin by injection have been reported (Costello ADS 52 400 1945; Hodgson BMJ 1 483 1945 Ehrlich AIntM 78: 565 1946 Klauder and Rule JID 7 329 1946) Neomycin ointment topically and penicillin intramuscularly together yielded rapid cures in 90% of the cases reported by Gregory (MaineMAJ 44 1 1953)

The synergism of sulfonamide and penicillin was postulated following animal experiments by Klauder and Rule (JID 12 335 1949) The dose of penicillin must be adequate and may require repetition (Price and Bennett BMJ 2 1060 1951) Antibiotic sensitivity tests indicated effectiveness of penicillin, Aureomycin and Chloromycetin, in that order reported Sneath et al. (BMJ 2 1063 1951)

See Rosenbach (ZfHyg 63 343, 1909) original description; Klauder (DWchr 88 813, 1934) patient developing general disease committed suicide, was autopsied; Karlson and McNutt (JI (Dis 64 49 1939) microscopic aggl tination test; Morrill (JInfDis 65 322, 1939) student cases from horse cada er Greener (BJD 51 372, 1939) infection from peacock; Grinnan and Martin (ADS 41 1037 1940) generalized case with focus in gall bladder Ritchie (TexasSJM 38 226, 1942), case respon[illegible] to sulfonamide; Klauder et al. (J 122 938 1944) fatal case with egetati endocarditi Nicholas (ADS 54 47 1946) case followed crab bite, responded t penicillin Barber et al. (Lancet 1 128, 1946); Mac lay (WisMJ 45 1057 1946) Bush (BMJ 2 984 1949) case in veterinarian from dissection of turkeys; Dereda and Los (BMJ 2 1411 1949) June t October seasonal incidence notabl in British cases, which comprise bout 1 4 of "septic hands," lymphangitis being rare Good win (BMJ 1; 785 1950) Mc Dougall (Lancet 1 1348, 1951) Proctor and Richardson (Brit JIndustMed 11) 175, 1954) 253 Aberdeen cases mong fish workers, seasonal, few cases in cold months. Nelson (RockyMtMJ 52 40 1955) 500 cases among meat handlers, best results with penicillin.

Fig 422.—Erysipeloid The cellular infiltration is haracteristically located deep l the dermis, pa ticularly in and round the f t cells (Dr Stuart C W y)

GONORRHEAL DERMATOSES

Gonorrheal dermatoses are cutaneous manifestations of infection with *Neisseria gonorrhoeae* either direct or metastatic.

Exanthems in acute gonorrhea include erythematous, papular and scarlatiniform rashes and rarely purpura. Annular erythema complicated a case of vulvovaginitis. Purpura and bullae with arthritis and a positive blood culture have been reported.

EXANTHEMA.—See Buschke (AfDuS 48: 181, 385, 1899 Wiedmann (DWchr 81: 541, 1934) bullous and purpuric exanthem Levin and Silvers (NYSJM 37: 1712, 1937) cutaneous eruptions; Kell (QJM 7: 1 1938) bacteremia with skin lesions, f ver arthritis.

Skin Lesions of primary gonococcal infection have been classed as (1) folliculitis, (2) ulcer a simple or serpiginous blenorrhagic chancre, (3) abscess, and (4) circinate balanitis by Kroll et al. (AmJSyph 28 320 1944) Their cases included a fluctuant abscess containing chocolate-colored pus on the shaft of the penis a pustular bleb near the frenum and a painless subcutaneous abscess in the foreskin.

Furunculoid lesions were noted by Lowry and Franks (AmJSyph 27: 4–8, 1943) A pustule with lymphangiitis developed in a laboratory worker accidentally inoculated with a pure culture (Sears: AmJSyph 31: 60 1947) Congenital fistulae of the median raphe were the locale in 4 cases of skin abscess reported by Mee (AmJSyph 33: 152, 1949) Primary cutaneous abscesses involved the dorsum of the penis in 3 cases of Scott and Thomson (AmJSyph 34: 262, 1950) and involved the coronal sulcus in that f Byers and Bradley (ADS 65: 503 1933)

Keratosis Blenorrhagica is a chronic inflammatory dermatosis, occurring in conjunction with gonorrheal infection of the genital tract and of the joints, characterized by a symmetric eruption of horny conical nodules, pustules and crusts on the palms and soles and other parts of the body It is practically invariably associated with multiple arthritic involvement The onset follows specific urethritis by several weeks or months. The disease is rare.

K ratosis blenorrhagica is evidence of grave systemic disease stated Ledany and Hughes (ADS 54: 150 1946) in a review of 165 cases. Its manifest tions are preceded by several days, weeks, or months by gonorrheal urethritis, prostatic and seminal vesicle infection being often present too. Arthritis nearly always ppears before skin lesions do. The exanthem is of sudden onset, associated with chills and fe e Its distribution is symmetric, with predilection for feet soles, ankles, and hands, and it ppears also about the arthritic joints and the genitals. It may be widely disseminated localized to the extremities. Typical les start as pinhead size or slightly larger vesicles firm, surrounded by rythema, becoming pustula with dry caseous contents. These ulcerate and develop dirty hard brown crusts with firm horny collars. Hemorrhagic blisters and erythematous patches may often be found in addition. In later stages there is extensive coalescence of mature lesions forming relief maplik areas perhaps affecti g an entire sole, palm, joint region. Such confluent areas have dusky red, slightly moist base, and sharp slightly raised margins, and are cov red with dry powdery scales, pe haps resembling psoriasis. Toes and fi gers show diffuse, slightly moist, rythematous involvement of the t rm nal phalanges on which tiny tense vesicles re scattered but these do not enlarge o pust late. This may resemble acrodermatitis perstans. Nails become dry and brittle and may be lifted from their bed by heaping up of subjacent horny material. The disease prefers men i the fourth decade who have had gonorrheal urethritis repeatedly Mortality has pproximated 10%. Neisserian organisms ha e bee demonstrated in perhaps 1 % of the cases.

Corneal ulcers complicated keratoderma in cases of Epstein and Chambers (ADS 36: 1044 1937) b t were successfully treated with artificial fever

Etiology—Barrett (ADS 22 627 1930) recorded 2 cases of keratoderma, in 1 of which the gonococcus was found in the vesicles, pustules and abscesses, but such a search has proved fruitless in the experience of many others. Gonorrhea is always present elsewhere however In a review of 83 cases, Downing (J 102 829 1934) noted that some have occurred in patients not having arthritis, and of the 5 reports of finding the organisms, only 1 seemed acceptable

Fig. 323—Gonorrheal abscess on shaft of penis. (Sobel ADS 45 [illegible], 1942.)

Fig. 324—Gonorrheal keratosis. ([illegible] ADS 9 423, 1924.)

Fig. 325.—Gonorrheal keratoderma; note arthritis of right knee. (Haase: JCutD 34: 817 1916.)

Fig. 326.—Gonorrheal keratosis. (Epstein: AmJSyph 21: 148 193[illegible].)

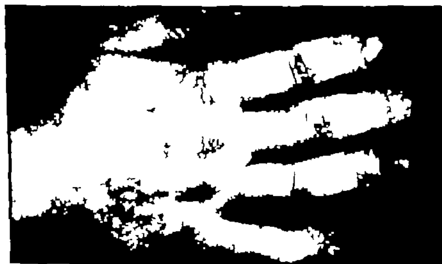

Fig. 327.—Gonorrheal keratosis.

When a moist, aseptic dressing was kept over areas of sound skin in a patient with keratoderma, pustules and keratoses developed under it (Photinos and Relias BSocfrançD 44 1775 1944)

Necropsies were reported by Simpson (J 60 607 1912), Lees and Percival (Lancet 2: 1116 1931) and Friedman (AmJPath 20: 09 1944) with interesting histologic studies. The earliest skin lesion is an abscess with polymorphonuclear leukocytes in the stratum granulosum, followed by dermal infiltration, papillary edema and superficial lymphocytic infiltration. The pustule widens and keratinization develops. A conical crust forms, and it may separate from intact skin beneath or new purulent inflammation may repeat itself under the crust so as to make a large, horny lesion. When death results, the cause is a combination of fever exhaustion and, likely bronchopneumonia.

A skin test i of immunologic interest in gonorrheal i fections. The filtrate of a bouillon culture injected intradermally induces a positive reaction, and reactivity disappears after the infection has been eliminated (Corbus JUrol 35: 11_ 1936) A 0.2 cm. reaction in 48 hours was seen by Conrad (NYSJM 36 1 67 1936), and there were no false positives. The test possesses diagnostic value and becomes negative when the patient is cured (Corbus and Corbus J 116: 113 1941)

Diagnosis—Pustular and arthropathic psoriasis are distinct entities (Epstein ADS 40 547 1939 BJD 51 428 1939 Blumenthal and Sherman Am JSyph 22 176 1938) Reiter's syndrome (q v) is to be distinguished but Ladany and Hughes believed some of these to be gonorrheal.

Fig. 328—Scalp lesions i gonorrheal keratoderma (Dr Harther L. K lm)
Fig 329—Keratosis gonorrhoica. (Dr Marcus Haase.)

Treatment—Elastoplast occlusive dressings and fever therapy were recommended by Taylor (BJD 51 418 1939) Hyperpyrexia has been accepted as effective since reports by Epstein (AmJSyph 21 148 1937) and later by Combes et al (J 114 2078 1940) Penicillin alone is sometimes curative (Emmet ADS 53 278 1946) but failure has been experienced Streptomycin was reported extremely effective a single injection of 0.3 Gm or more being curative (Chinn et al. AmJSyph 31 268 1947) Combs and Behrman (ADS 46 728 1942) *gave massive doses of vitamin A* and penicillin. (See Freireich et al AIntM 79 239 1947 Miale and Singletary ADS 57 151 1948) A case unresponsive to sulfonamides and penicillin was cured by streptomycin by Thompson et al. (ADS 59 284 1949)

ACTH was given with noteworthy benefit by Myerson and Katzenstein (J 149 838 1952) and cortisone in conjunction with penicillin yielded a prompt cure for Schwartz and Kingma (BJD 64 *388 1952) Streptomycin,* penicillin and ACTH together secured a 10-day cure for Shallard and Kanee (CanadMAJ 68 561 1953)

MENINGOCOCCIC DERMATOSES

Symptoms.—*Neisseria intracellularis* the meningococcus, is the infectious agent of epidemic meningitis which particularly in certain epidemics, is associated with petechial and purpuric lesions. If such a lesion of spotted fever is pinched pricked and squeezed and the droplet of blood and tissue juice is prepared with Giemsa, Wright or Gram stain diplococci may be found in perhaps 80% of the cases (McLean and Caffey: AmJDisChild 42: 1053 1931 Tompkins J 123 31 1943 Barnhard and Jordan JCLM 29 273, 1944) Conjunctival exudate herpetic fluid and the urine may likewise yield meningococci for early diagnosis (Sophian J 125 376 1944)

Herpes simplex, commonly of considerable severity accompanies meningococcus infection frequently Toxic erythemas and urticaria may be seen and serum sickness and dermatitis medicamentosa may appear in the meningitic patient

Acute catarrhal conjunctivitis often accompanies the infection and may comprise its sole manifestation (Theodore and Kost AOphth 31 245 1944) Purulent conjunctivitis resembled that caused by the pneumococcus in the case of Reid and Bronstein (J 124 703 1944) Hypopyon of one eye and a papular eruption on the legs were the first symptoms of meningococcemia in the girl reported by Kesteleyn et al (abs J 157 195 1955)

With regard to rashes in the acute disease distinctive is an irregularly round hemorrhage with a gunmetal-colored center composed of pus cells (Appelbaum AmJMSc 193 96 1937) The types of eruption emphasized by Costello (J 134: 518 1947) were (1) those resembling erythema nodosum, (2) petechial puncta interspersed with large hemorrhagic blotches, (3) lesions resembling flea bites with central hemorrhagic punctum and faint erythematous areola and (4) necrotic depressed lesions more or less simulating the papulonecrotic tuberculid. The earliest lesions are ill-defined erythematous macules in a dependent location by predilection, and the rash is multiform variable yet characteristic (Hill and Kinney J 134 513 1947) Petechiae favor the joint regions and pressure areas. The face palms, and soles are rarely affected. Lesions usually appear within 12 to 36 hours after the onset of disease, may develop in crops, and may fade in a few days irrespective of therapy

The rash may be sparse and hard to find. The commonest lesion is purpuric and from 1 to 15 mm. in diameter Sometimes there are only a few faint, pink, evanescent rose spots like those of typhoid Maculopapular lesions are usual, the larger ones being sometimes nodular or plaquelike tender and rarely quite large vesicular or even ulcerative (Daniels et al J 123 1 1943)

A skin test is of immunologic interest and vaccinal immunization can be accomplished. The whole culture produced vigorous skin reaction, the filtration produced less reaction and heating destroyed the capacity of the antigen to provoke any reaction, reported Kuhns (J 107 5 1936)

Chronic Meningococcemia occurs sometimes without meningitis. It may begin suddenly with fever pain in the joints, chilly sensations, and skin lesions. Suppurative arthritis is not found, but arthralgia is without effusion. Cutaneous manifestations appear in the first week and crops come out with each rise in temperature the lesions being various. A characteristic form is a rose-colored macule with a central vesicular pustular or petechial element (Ochs et al. BullUSAMD Sept., 1944) or small faint red macules or papules resembling erythema nodosum, or petechiae of small or considerable size may be seen An apparently insignificant rash is diagnostically as important as purpura, stated Hill and Lever (J 123 9 1943) Tender pea-sized, erythematous nodules appearing in crops were reported by Ingram (BJD 54 228 1942) in patients with positive blood cultures. In addition to macules papules, vesicles, and petechiae Mitchell Heggs (BJD 54 283 1942) described ulcers, sloughs and dermatomyositis.

Migratory arthritis and erythema nodosum may be due to meningococcemia a low grade infection simulating rheumatic fever but proving on

blood culture to be meningococcic (Stott and Copeman Lancet 1: 1116 1940 Copeman BMJ 1 283 1949)

Treatment.—Sulfonamides internally, perhaps given intravenously at first, are extremely efficient The organism is also sensitive to penicillin

Waterhouse-Friderichsen Syndrome.—Fulminating adre al hemorrhage, sometimes meningococcic in etiology and sometimes of unknown cause (see Purpura F lminans) is a catastrophic illness generally fatal, in which the abrupt onset with fever nausea, vague abdominal pains, headache and restlessness are soon followed by lilac cyanosis, shock and ge eralized petechial rash which spreads rapidly Peripheral circulatory failure ensues,

Figs. 330 and 331 —Meningococcemia. (Mitchell-Heggs BJD 54 263, 1942.)

Figs 33 and 333 —Meningococcemia (Dr G B. Mitchell Heggs.)

and the course rr s in from 8 to 24 hours. In 16 cases, the meningococcus was found in every one by Ferguson and Chapman (AmJPath 4: 763, 1948) who thought the deaths due to o rwhelming bacteremia a d to emia rathe tha to drenal destruct on. Pratt Thomas et al. (SouthMJ 38 229 1945) described 4 cases with 1 recovery due to sodium sulfadiazi e given intravenously Oxygen, drenal cortex extract and plasma were also helpful in a patient of Johnson (ADS 53 391 1945)

Cortisone ha changed the outlook remark bly for it rescues the patie t from shock, thereby making ailable the hours necessary fo the sulfonamides to eliminate bacteria (Nelson and Goldstein J 146 1193, 1951 Newman J 146 1229 1051) Alert diagnosis and prompt institut on of treatment are imperati e for cortisone and intravenous sodium sulfadiazi e are lifesaving

In spite of antibiotics ad these chemotherapeutic agents patie ts still die in shock. Treatment of early peripheral vascular collapse a major problem can succeed if Arterenol (norepinephrine) given ntra enously (Muhl NEngJM 49: 229 1953) The Water-

house-Friderichsen syndrome is not necessarily secondary to acute adrenocortical insufficiency; perhaps the ultimate cause of peripheral vascular collapse is extensive vascular damage with capillary hyaline thromboses, and continuous infusion of Arterenol to maintain a normal blood pressure may be a lifesaving measure (Weiner: J 153: 973, 1953)

TULAREMIA

Symptoms.—Tularemia is the disease caused by *Pasteurella tularensis* which commonly infects rabbits from which it is conveyed to man by inoculation usually at the site of a minor abrasion

About 3 to 4 days after infection illness begins suddenly with headache chilliness vomiting fever prostration and aching pains all over the body Such symptoms are readily mistaken for influenza The tularemic chancre when present usually occurs on the hand and develops slowly as a painful papule which soon sloughs, forming a soft flabby painful, punched-out ulcer Regional lymph nodes enlarge first becoming painful tender and centrally necrotic sometimes suppurating through the skin. Lymphadenitis may become general Illness and fever persist perhaps for 3 weeks, but convalescence is slow and is characterized by great weakness and disability which may continue for several months, unless treatment is given.

The ulceroglandular type is the common one but a primary sore is not always present In its absence the case is classed as typhoidal Tularemic pneumonia may develop in either Of 225 cases, among which occurred 17 deaths, 181 were ulceroglandular 7 were oculoglandular (the chancre being about the eye) 14 were typhoidal, and 23 simply glandular (Pullen and Stuart J 129 495 1945) The hands and fingers bore the primary sore in 175 cases. Subcutaneous lymphangiitic nodules were present in 18 cases, and these were firm movable nontender as a rule but attached to the skin and ulcerative in a few instances. Erythema nodosum like lesions were found in 6 cases. A diffuse papular rash occurred in 9 cases, appearing usually in the second or third week lasting usually only a few days. It was prominent on arms and neck was bilateral and symmetric, and included erythematous macules on the palms. Of the deaths, 12 were due to pneumonia and 1 to tularemic meningitis. Hitch and Smith (ADS 38 859 1938) described tularemic eruptions, noting the primary ulceration, which may be mucosal and the generalized rashes, in which macules papules, vesicles, and pustules have all been recorded

Many vectors are recognized, the vertebrates being listed by Burroughs et al. (JInfectDis 76 115, 1945) while insects are occasionally and ticks are often carriers (see PHRpts 55: 667 1940) The organism may be transmitted from animal to animal and from animal to man by wood ticks (epidemic reported by Dvil ld et al.: J 127: 191 1945) dog ticks, and deer flies. The pelts of infected animals also convey the infection. Tularemic infection of a tick does not harm it or its fecundity (Bell JInfectDis 76: 83 1945)

Pulmonary lesions observed by Archer et al. (J 104 895 1935) included pneumonia with *necrosis, pleuritis with effusion nodular and peribronchial* infiltrations, residual fibrosis and perhaps an increase of previous calcification Pericarditis was observed in 2 patients of Meredith (AnnIntM 32 688 1950) While streptomycin helped one of these, it did not prevent constrictive pericarditis, probably because it was given late Tularemia caused miscarriage in a woman who contracted the infection in the eighth month and the dead baby was infected (Lide AIPath 43 165 1947) See Lillie et al. (The Pathology of Tularemia Public Health Service Bull. 167 U.S. Treas. Dept. 1937) a 217 page monograph.

Diagnosis.—Tularemia must be differentiated from typhoid fever glanders, anthrax, actinomycosis, and sporotrichosis. Significantly high or rising titer of the agglutination test is diagnostic (Simpson OhioSMJ 29 35 1933) Positive blood cultures and animal inoculations of aspirated material may also be used in identification The opsonocytophagic reaction parallels the agglutination test and may help to distinguish brucellosis, which cross agglutinates with tularemia.

INTRADERMAL TEST —Foshay considered this to be as reliable as any skin test The few individuals who fail to develop positivity within a few days are persons over 51 years old as a rule Severe reaction occurs with vesiculation and necrosis if ordinary heat killed bacterial suspensions are used therefore Foshay used a test suspension made from virulent strains of *P tularensis*

Fig 334.—Tularemic chancre 19 days after its onset in a market man who dressed rabbits (Brown and Hunter in Stitt's Diagnosis and Treatment of Tropical Diseases, Blakiston's)

Fig. 335.—Tularemic chancre. (Dr Walter M. Simpson)

Fig 336 —Acneiform eruption in tularemia the arms were also involved (Dr Walter M. Simpson)

Fig. 337 —Primary lesion of tularemia, involving right index finger after repeated surgical incisions Nodular lymphangitis overlying metacarpophalangeal articulation. Photographed 6 weeks after onset. (Dr Walter M Simpson)

oxidized for , hours with nascent HNO and then adjusted to a turbidity equivalent to 100 parts per million of fuller's earth The test dose is 0 05 cc and the result is read at 48 hours. Foshay observed failures to respond as late as the sixth day never later There were no false positives. Reactivity remains positive, and the test will not distinguish present infection from ancient. The reaction resembles the positive tuberculin or brucellergin test

taking from 6 to 9 days to resolve and disappear. The skin test seemed highly specific during the first week, perhaps before the agglutination test becomes positive (Friedewald, AmJMSc 197: 493, 1939). Antigen for a skin test was made from necrotic lymph node material by Lawless (ADS 44: 147, 1941).

Prognosis.—Most patients recover fully but mortality ranges about 5%, the development of pneumonia being ominous. The mortality was 4% in 120 cases reported by Kavanaugh (AIntM 55: 61, 1935). The cause of death is septicemia and toxicity rather than pneumonia, believed Foshay (AIntM 60: 23, 1937), who noted that the third week is the dangerous one, most deaths occurring on the sixteenth day. Older patients cannot tolerate the disease as well as hardy young persons.

While it has been thought that no case has suffered reinoculation and that recrudescences were due to persistence of the organism, proof of reinfection was claimed in 2 cases by Green and Eigelsbach (AIntM 85: 777, 1950).

Fig. 331.—Tularemia. Sporotrichosis-like lymphangitis and lymphadenopathy. (Dr Walter M Simpson.)

Fig. 332.—Axillary adenopathy, massive and suppurating, occurring 3 weeks after onset in ulceroglandular tularemia. Spontaneous rupture occurred 2 days later. (Dr Walter M. Simpson.)

Prevention.—Hunters, vacationists, butchers, and housewives are especially exposed. A wild rabbit should never be handled with the bare hands. Infected meat is rendered safe by thorough cooking. The laboratorian working with *P. tularensis* is almost certain to become infected (Lake and Francis, PHRpts 37: 392, 1922).

A vaccine made by Foshay et al. (AmJPH 32: 1131, 1942) by oxidizing virulent strains of the organism with HNO_3 is promising in the prevention of the disease, but 7 persons who had received the vaccine became infected, according to Howe et al. (J 132: 195, 1946). Vaccination which provokes severe reaction in persons already possessing immunity reduces the incidence of laboratory infections by about two-thirds (Kadull et al., JImmunol 65: 425, 1950) and can be recommended to those who expect exposure as an occupational or recreational hazard (Edit., J 144: 1408, 1950).

The therapeutic effectiveness of streptomycin and Aureomycin, especially in cases diagnosed early, makes vaccination less imperative. Streptomycin cured the technician who contracted a tularemic tonsillar ulcer after aspirating a culture from a pipette, reported by Jordan and Downs (JKansMS 50: 390, 1949).

Treatment.—Strict bed rest is indicated for patients who are ill. Surgical interference is useless even dangerous. X ray therapy relieves pain of local lesions. I have seen the antiserum of Foshay (AmJMScl 187 235 1934) yield excellent results. The use of this serum plus neoarsphenamine was recommended by Werling (OklaSMAJ 35 103 1942) or *with 2% sodium bismuth* tartrate 1 cc per 100 pounds daily intravenously reported favorably in 61 cases by Jackson (AmJMSc 209 513 1945) Atabrine yielded results encouraging to Ecke and Ecke (IllMJ 93 318 1949) Penicillin was ineffective in cases of Josey (J 126 496 1944) but Chloromycetin promptly cured 6 patients of Parker et al. (J 143 7 1950)

Streptomycin was found effective in the disease under experimental conditions by Heilman (PSMMC 19 553 1944) *and its superiority to specific* antiserum was recognized by Foshay and Pasternack (J 130 393 1946) and Foshay (IndianaMA 41 207 1948) Streptomycin, 7 000 000 units in 10 days, cured a pneumonic patient in whom penicillin and sulfonamides had proved ineffective (Cohen and Lasser J 131 1126 1946) although sulfonamides have been reported helpful in the past Streptomycin therapy did not alter the immune response for agglutination titers rose as in untreated cases, according to Johnson et al. (AmJMSc 214 645 1947) The excellence of streptomycin is attested by many reports, such as those of Bost et al. (J 137 352, 1948) Burson and Harwell (AmJMSc 215 243 1948) and Corwin and Stubbs (J 149 343 1952) 1.0 to 1.25 Gm. per day, in divided doses each 3 or 4 hours, *to a total of from 5 to 7 Gm suffices, and improvement is conspic*uous within 48 hours.

Aureomycin appeared to do more good than streptomycin or Chloromycetin in experiments with mice and appeared as effective as streptomycin in 3 human patients reported Woodward et al (J 139 830 1949) There are numerous articles on the effectiveness of Aureomycin, which Long et al. (J 141 315 1949) adjudged the first choice see Ransmeier et al (AmJMed 7 *518 1949)*

GLANDERS

Symptoms.—Glanders is due to *Malleomyces mallei*. The infection acute o chron c is characterized by the occurrence of vesicular pustular and ulcerative lesions, long with s t m c symptoms. It a comparati el common disease of horses mules, and donkeys, but it is fortunately a rare d sease in man. The early symptoms are those of mil l sept cemia malaise ague joint pai *fever* of intermittent type and prostration. Profuse cat rrhal purulent nasal discharge is regularly present, particularly in acute cases.

I the cut form the man festation of systemic in olvement grad ally become more ma ked and the pat ent sinks nto a typhoidal state and generally dies. The cute cons mptoms re ried. In cases in which i fection ha occurred through the skin, the nitial lesion *may be* ca buncular *papule or vesicle* More or less induration is *present* however and uperficial sloughing common. Characterist lesions develop in 1 to 4 week a groups of small deep-seated, reddish o yell wish papules which sometimes become es la o bullous, b t whi h invari bl soo e o late f rm ulcers. These may coalesce giv ng rise to l rge, gangre ou areas. L mph node involvement results in the f rmat on of subcutaneous od les f rcy buds. These tumors re lik ly to perforate the overlying kin, *giving rise to foul* suppurating *ulcers*

In the chron c f rm the lesion re fewer i n mbe and less violent in characte Cata rhal symptom develop late if at all. The d sease may persist for months o years Abscesses and lcers are occasionall associated w th metastat c foci subcutaneous and muscular tissues, joi t and lungs.

Glanders occurs mainly in men whose occupations bring them in contact with horses (Hunter Lancet 1 316 1930 Burgess CanadMAJ 34 _39 1936 Mend l+o ; USAFMJ 1 781 1950) The rganism i highly pathogenic nd has caused death of several laboratory workers Strict isolat on is required. *Six cases occurring in laboratory research* wo kers were reco *ded by Howe and Miller (A nIntM 26 93 194) 5 of whom were* infected via the respirat ry tra t a judged by the presence of pulmonary lesions

Diagnosis.—The involvement of th nasal m cosa s the most characteristic feature Thi the k n a d lymphati ol ement and th usually typhoid-like constitut onal symp*toms* should p event co fusion. I trad rmal and compleme t fix tion test re ava lable

Prognosis.—Practically all cases have termi ted f tally

Treatment.—Mallei an endotoxin which correspond with vacci ha been tried with some degree f success. In addition, surgical measures are to be employed Serum and vaccine therapy are ot satisfactory Sulf diazine ma be recommended (Horne and

Miller: AnnI tnM 26: 93, 194) Success with the use of streptomycin has been reported (J 14 : 46, 1950) While all 18 cases that occurred in 1939-1948 in Turkey were f tal (all traced to contact with horses with farcy) a recovery I 1949 followed the use of streptomycin, penicillin and sulfa iiarl and in 1951 a ure was obtained with sulfadiazi alone and in 1953 with Aureomycin and streptomycl (Corresp. from Turkey: J 15 : 143, 1953)

MELIOIDOSIS

Melioidosis is a glanders-like disease which occurs primarily i rodents and also in man Stanton and Fletcher (JHyg 23: 268, 1924; Studies Inst. M. Res. F M S., 21, 1932) having collected 83 cases of human infection with the *Pfeifferella wh tmori (Acti o-bacillus pseudomallei)* Abscesses, pustules, and sinuses are found, although the important lesions are consolidations and abscesses of the lungs li e spleen, sometimes the kidneys. This septicopyemia in man usually is fatal within 3 or 4 weeks. Acute and chro ic forms are seen. In the acute cholera-like vomiting, collapse purgi g and death may occur in 72 hours. In chronic forms, multiple abscesses may develop in all organs except the brain particularly affecting the lu gs, spleen, and live Cutaneous vesicles a d pustules may simulat variola. The essential pathologic lesion is a small area of necrosis developing into an abscess, coalescing with ear by lesions of similar character and forming a honey comb containing creamy or i the liver glairy greenish pus (Edit: BMJ 1: 344 1947) A chronic case from the Western hemisphere was reported by McDowell and Varney (J 134 361, 1947) a d sulfonamides penicillin, and streptomycin were ineffectual; wide ca tery excision helped most. S lf diazine seemed helpful to Mirick et al. (J 130: 1063, 1946) Autoge ou vaccine was used by Peck and Zwanenb rg (BMJ 1: 337 1947) in a patient who did not die. Experimental i fections were not responsive to Aureomyc n (Cruickshank: BMJ 2: 410 1949)

See Whitmore (JHyg 13 1 1913), original description Covi re (Rev d'hyg 57 100 1935) 95 cases reported through 1932, 98% fatal Cox and Arbogast (AmJCP 15 567 1945) cute, fatal case with scattered pustules, palpable spleen and li er pulmonary abscesses Paton et l (BMJ 1 336 1947) f tal case w th pericard tis, effusi pleuritis, purpura.

BRUCELLOSIS

Brucellosis.—Three types of organisms belong to the Brucella group: *Br meli tensis* associated with undulant fever; *Br abortus*, more virulent for human beings than the others; and *Br suis*, perhaps the commonest in humans. A typhoid like roseola appears i about 5% of the cases (Simpson and Frazier: J 93: 1958 1929) An ulcer localized on the face (Michel Béchet, abs BMJ 1: 893 1940) and a case resembling dermatitis herpetiformis (Urbach: DZtschr 64: 230, 1932) have been described. Nodular scrofulous, chronic lesions of th face pai less and subcutaneous at first, late forming craterif rm ulcers and fistulae were seen in the Brazilian patient of Pacheco (abs YBD 1931 p. 89)

Skin Test.—Culture filtrate may be given intradermally as a diagnostic test. The *reaction usu lly ppears promptly showing wide erythema and central edema, which may* even slough along with constit tional symptoms. Reaction may be dela ed (Fla nerv: J 114 1234 1940) The test or repetition of it may be lon of co siderab e therapeut c value. Th test i negative unless the reaction persist for 7 to 10 days; it may persist much longe While the test depends on tissue sensitivity induced by the presence in the body f organisms f the Brucella group diagnosis wants substantiation by the presence of symptoms of the active disease (Ervin and Ho t J 109 1966 1937) The intradermal skin test is nevertheless the most reliable confirmation f a diagnosis of chronic brucellosis (Benning: J 130 320 1946)

Brucella Dermatitis.—Of 50 practicing veterinarians subjected to inquiry by Huddleson and J h son (J 94 1905 1930) 20 per cent admitted developing a rash on the arm when t was inserted into the vagina of cows which in thei opi ion w re infected with *Br abortus*. This manifestation of eczematous eactivity makes its ppearance in 20 min tes, and dependi g on the degree of sensitivity t is (1) light red and blotchy o red and unif rm, d it hy or burning but not edematous, persisting for 4 to 8 ho rs and disappearing w thout desquamatio ; or it is (2) papular the les ons bei g discrete and elev ted, not highly pruritic, lasting 3 4 days, a d hanging to a brown color before disappearing without exudat on or desquamation.

See Thomsen (ArDuS 163 477 1931) original description of llergic dermatitis on forearms of veterinarians Jadassohn (ArDuS 164 657 1931) patch tests.

SKIN TESTS.—Huddleson et l (AmJPH 23 917 1933) kin llergy and immunity Keller et al (J 107 1369, 1936 SouthMJ 31 1 1938) kin tests Gould and Huddleson (J 109 1971 1937), intradermal test with 0.1 cc suspensoid of 1 2,000 nucleoprotein best, read in 48 hours; Angle et l (AnnI M 12 495, 1938), skin test raised serum antibody titer; Gerab nd Black (APath 27 397 1939) histology f tuberculoid skin reaction to test Harris (J 131 1485, 1946) kin test negati in some acti ely infected patients, technic important, read after 96 hours Harris (J 142 161 1950) necrotic skin reactions from intra dermal testing cured by Aureomycin

TREATMENT OF BR CELLOSIS Tisdale and McCullough (J 135 1033, 1947) sulfadiazine and streptomycin Braude et al. (J 141 831 1949) Aureomyci effecti e; Herrell and Barber

(PHMMC 24 138, 1949) Aureomycin and dihydrostreptomycin; Spink et al. (J 138: 1145, 1948 139 352, 1949) Aureomycin best Herrell and Barber (J 144 519 1950) Aureomycin and dihydrostreptomycin with 1 symptomatic relapse in 35 patients.

CHANCROID

Symptoms.—Chancroid, or soft chancre is due to inoculation, usually venereal, with *Hemophilus ducreyi* which soon produces small, autoinoculable painful ulcers of relatively benign character usually located about the genitalia. The earliest manifestation, a minute reddish macule appears at the site of inoculation after an incubation period of 3 to 14 days. It quickly becomes an inflammatory pustule which ruptures and forms a small, shallow circumscribed ulcer The ulcerative lesions may become single through confluence of multiple early lesions although they may remain multiple As a rule they are circular or oval, with soft, nonindurated, slightly undermined edges, and grayish granular floors bathed in pus. A reddened areola is usually present, although there is but little induration except in chronic lesions. Chancroidal ulcers being autoinoculable spread by expansion, inoculation and coalescence The duration ranges from 10 days to several months. Giant and destructive ulcerative lesions are occasionally seen.

Extragenital sores are seen but are rarely primary A primary ulcer on the finger was noted by Brandt et al (VDI 22 89 1941) See Syphilis, mixed chancre (p 388)

The regional lymph nodes are infected and the resultant buboes may suppurate This involvement may be unilateral or bilateral. It is accompanied by pain and fever See Sullivan (AmJSyph 24 482 1940) monographic.

Etiology—*H ducreyi* is a small slender nonmotile nonspore-bearing non acid fast gram negative bacillus which generally forms chains. It can be grown with difficulty but the technic of Beeson and Heyman (AmJSyph 29 633 1945) enabled them to obtain diagnosis by cultures in three-fourths of their cases. There is evidence that the bacillus of chancroid sometimes exists in the female genital tract as a saprophyte In smears from the ulcer the organisms may be found as small ovoid rods arranged in pairs, groups or chains lying parallel to one another They may be intracellular or extracellular Human volunteers were successfully inoculated with pure cultures by Tomaszewski (ZtschrHyg 42 327 1903) The experimental disease in monkeys and rabbits was described by Reenstierna (ActaD-V 2 1 1921)

Qualitative chemical analysis of the organisms revealed nitrogenous constituents consisting of simple and degenerated proteins, amino acid derivatives and nucleoproteins polysaccharides and glucosides, which like the nucleoproteins, were specifically antigenic (Ronzani abs YBD 1939 p. 137)

Pathology—Superficial necrosis pervaded with polymorphonuclear leukocytes, and a peripheral zone rich in plasma cells lymphocytes, and perithelial and endothelial leukocytes characterize the lesion (Torpin and Dienst AmJSyph 22 634 1938)

Diagnosis.—In syphilitic chancre the period of incubation is long from 3 to 6 weeks the lesion is comparatively painless erosion but not ulceration is typical lymph node involvement is characteristic, the nodes being firmly elastic nutlike painless and freely movable and *Spirochaeta pallida* can usually be found in the lesion. Mucous patches of the genitalia are always accompanied by other evidence of syphilis. Cancer usually develops after the fourth decade of life chancroids before that period In cancer there is often a history of long-continued irritation and the lesions develop slowly and are always indurated

Biopsy yields specific diagnosis in some 90% of cases cultures in 75% smears in only 50% according to Heyman et al (J 129 835 1945) The skin test alone is inadequate Diagnosis by autoinoculation may be considered (Strakosch et al JID 6 95 1945)

Fig. 340.—Chancroid.

Fig. 342.—Penile chancroid and digital lesion due to autoinoculation. (Dr O. G. Costa.)

Fig. 343.—Chancroid, chronic and grossly deforming. (Dr Harold N Cole.)
Fig. 344.—Chancroid, 6 months duration. (Dr Harold N Cole.)

Mixed Infections.—In lesions caused by conjointly inoculated syphilis and chancroid prolonged observation is required to diagnose syphilitic infection. Dark field examinations help These should be performed on several successive days during which treatment is limited to saline dressings. Serologic tests for syphilis should be made monthly for 6 months (see J 116 2405 1941) Penicillin sufficient to cure early syphilis, 2 doses of 1,200 000 units each, may as well be given in doubtful cases.

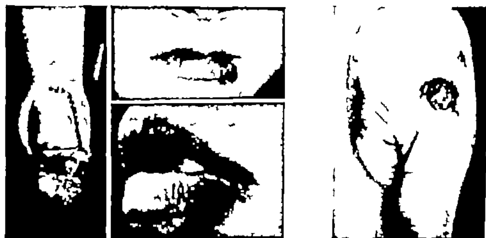
Skin Test.—The vaccine may be used by intradermal injection as a specific diagnostic test the Ito-Reenstierna reaction (Saunders et al NYSJM 39 447 1939) Cole and Levin (J 105 2040 1935) found that sterile pus from the chancroidal bubo will serve in lieu of vaccine There is an interval of about 5 weeks from the appearance of the sore until the development of demonstrable skin allergy to the specific antigen Sensitization does not develop unless considerable regional lymphadenitis occurs (Dienst and Gilkerson AmJSyph 31 65 1947) A positive test may be obtained even 30 years after infection. Positive reaction means only a past or present infection.

Skin Test.—Ito (AfDuS 116 241 1913); Reenstierna (MunchMWchn 1920, p. 893 AfDuS 147 362, 1924), Frei (HandbHcwl 21 1 1937) Dulaney (AmJSyph 21 667 1937) Hunt (PSExpB 33 252, 1936), vaccine from pure culture for skin test, cultural methods Greenblatt and Sanderson (ADS 36 486 1937), preference for bacillary [illegible] Sanderson and Greenblatt (SouthMJ 30 147 1937) culture method of preparing [illegible] Dienst (AmJSyph 32 [illegible] 1948) antigen as good from avirulent as from virulent culture Willcox (AmJSyph 36 284 1952) question of transplacental transmission of skin reactivity

Prophylaxis.—A 10% aqueous solution of Zephiran chloride and a 2% solution in propylene glycol were 100% effective in preventing experimental inoculations if applied within one hour (Combs and Canizares ADS 51 237 1945) while mild mercurous chloride and 15% sulfathiazole emulsion were 85% effective if applied within 6 hours. Soap alone was not effective Penicillin yields no prophylactic effect but streptomycin does (Willcox AmJ Syph 34 378 1950) *Sulfathiazole Aureomycin and Chloromycetin* protected from heteroinoculation experimentally performed but penicillin was a poor prophylactic, and antimony bismuth and neoarsphenamine were ineffectual (Willcox ADS 62 533 1950 BJVD 26 131 1950 BMJ 1 509 1951)

Prognosis.—Chancroids heal readily as a rule Occasionally ulceration is extensive Complication with phagedenic coccic or Vincent's infection may lead to serious fulminating destruction. If the ulcer is excised or is adequately drained by circumcision before the bubo has developed the bubo fails to develop Modern treatment has simplified the disease so that it has become relatively trivial, and the sulfonamides have rendered surgical measures obsolescent (Kornblith et al. J 117 2150 1941)

Treatment.—Simple cleanliness is requisite Violent chemical measures are harmful rather than beneficial, although cauterization with nitric acid was a time-honored procedure If phimosis complicates, mild astringent applications such as 1 500 aqueous solution of aluminum acetate may be employed until the inflammation subsides.



A popular presulfonamide method consisted in moist antiseptic soaks, alternated with drying, o[illegible] nde the influence of radiant heat and a dusting powder such as iodoform Beneficial soaks are hydrogen peroxide warm 1 5 000 potassium permanganate and 1 10,000 bichloride of mercury Specific vaccine treatment has been especially successful in chronic serpiginous ulcers. Injections were given intrav[illegible]ously at intervals of 3 days. The dose must be conservat[illegible]ve and fever was expected. Prior to sulfonamides, the bubo, if fluctuant wa[illegible] punctured, pushing the knife through normal ti[illegible]ue at the periph[illegible]ry The content was expressed an antiseptic injected, and a pressure bandage applied. Circumcision diminished the average hospital sta[illegible] by 4 days reported Rauschkolb (ADS 39 319 1939)

Sulfanilamide yields remarkably beneficial effects, a dose of 1 Gm each 6 hours being recommended. In the absence of bubo 21 Gm. of sulfathiazole in 5 days cures as efficiently as larger doses while in the presence of bubo 7 days of treatment do as well as 14 and experimental infections are cured in 3 days stated Combs et al. (AmJSyph 27 700 1943) Sulfonamides will not cure all phagedenic cases (Canizares and Cohen ADS 42 640 1940) Sulfanilamide powder may be applied locally and it may be packed into an

abscessed bubo when this is opened. Uncomplicated cases respond to bed rest and sulfathiazole 21 Gm in 5 days if simple, 29 Gm. in 7 days if bubo is present the drug being given 2 Gm. to start with and 1 Gm four times a day (Combes NYSJM 46 1700 1946) More is not necessary

The effectiveness of sulfonamide medication is attested by articles by Batchelor and Lees (BMJ 1: 1100 1938) by Hutchinson (Lancet 1: 1033, 1088) who found that sulfanilamide resulted in 15 days of hospital care in cases of bubo as compared with 42 days with surgery or with Dmelcos vaccine by Henschell (Lancet 1: 836 1938); Greenblatt and Sanderson (AmJSyph 23: 603, 1939); Schwartz and Freeman (J 114 946, 1940); by Culp (AmJSyph 4: 622 1940) who found buboes disappearing without incision; by Trautman and Emeshieer (abs VDI 23: 763, 1942); by Satulsky (J 127: 259 1945) who in 1,533 cases found dorsal slit needed in only 6 occasionally punctured a fluctuant node and injected 1 cc of 7% tincture of iodine and calculated average hospital stay at 11.2 days.

Antibiotic sensitivity tests on *H ducreyi* in vitro showed moderate sensitivity to streptomycin, *none to polymyxin and little to* penicillin bacitracin or Aureomycin (Wetherbee et al AmJSyph 33 462 1949) Penicillin is without value in chancroidal infection (Pereyra and Landy USNMBull 43 *189* 1944) *despite the fact that the organism is susceptible to penicillin in vitro* (Tung and Frazier AmJSyph 29 620 1945) *Streptomycin cures* chancroid in rabbits (Mortara et al *AmJSyph 31 20* 1947) and 15 human cases, proved by culture were cured by streptomycin by Hirsch and Taggart (JVDI 29 47 1948) Jawetz (ADS 57 916 1948) cured 15 cases *with 10 Gm given in 5 days.* Streptomycin cured *the sulfonamide-resistant* case of Weber et al (AmJSyph 33 58 1949) In *a dose of 2 Gm daily for* 5 days it cured 61 cases reported by Taggart et al. (AmJSyph 33 160 1949)

spread infiltration mainly of connective-tissue cells with a few leukocytes intermixed round cells plasma cells and mast cells. Clumps of staphylococci are scattered through the growth Gross section of a lesion widely excised shows its bulging elastic translucent whitish composition, arranged as a cone-shaped mass lying within the skin the apex at least as deep as the level of the sweat glands this explains the failure of clipping off at skin level as a method of treatment

Fig. 353.—Granuloma pyogenicum of chin, unusual lesion (Ayres ADS 69 331, 1949)

Fig. 354.—Granuloma pyogenicum, showing resemblance to hemangioma.

The lesions seem to bear the same relation to granulation tissue that keloid bears to cicatrix (Berger et al. APath 21 273 1936) and they are not related to botryomycosis.

Treatment.—The lesions are harmless but persistent Excision followed by cauterization is successful if adequately destructive Radiotherapy can be used (Eisen CanadMAJ 42 628 1940) the dose must be rather large comparable with the dosage used in treating keloid. I give 500 r once a week for from 3 to 6 doses. A cure was reported by injecting the base of a lesion with 300 000 units of penicillin dissolved in 1.5 cc. of procaine solution (Spilz inger abs J 151: 1456 1953)

See Hatzell (JCutDis 22 520, 1904) Wile (JCutDis 28: 662, 1910) Sutton (J 66 1012, 1916) Armstrong (ADS 2 128 1920) Hoffmann (HandbHuG 8 I 397 1929), Thoma (Clinical Pathology of the J ws, Thomas, 1934 p. 344) epuli gra ulomatosa Kelly (ADS 31 884 1935), lingual tonsil involved; Maury et al (BsocfrancD 46 493 1939) gia t case on leg ulcer Frank and Blahd (AOtol 31 919 1940) 5 nasal fossa cases; Allison (ADS 45 679 1942) upper lip case cured with sulfathiazol

Staphylococcic Actinophytosis (Botryomycosis) is a rarely recognized entity distinct from granuloma pyogenicum (Berger et al.: APath 1: *"3, 1936) The lesion is a small tumor containing a granular sanguinopurulent exudate within which are microscopic granules simulating those of actinomycosis. Crushed or cultured these bodies are found to be composed of masses of nonhemolytic but coagulase positive *Staph aureus* (Drake et al.: J 1-3: 330 1943) In at least 7 of the reported cases foreign bodies have been discovered in the lesions.

VERRUGA PERUANA

Symptoms.—Verruga peruana (Peruvian warts Oroya fever Carrió s disease) is a disease e demi w th n certain inland portions of Peru due to infection with *Barton lla bacill formis.* It is characterized b fe e of a l termitte t remitte t or irregular type, followed o ccompanied by rapid and progressive anemia and the eruptio of pinhead t pea size red w rty inflammat ry tumors. The disease i limited in it geographical dis tribution to the region between lat tu les 8 and 13 S in Peru between altitudes of ,500 and 9,000 ft. on th west slope of the A des It e pecially likely to be contracted in hot ravines which are heltered from high wi d (Fox J 104 045 1035) Lactescent plants and the insects on them are n olved n its tran mi sio The sandfly transmits th d sease *Phlebot m rrucarum* be g the pri cipal spec es invol ed (Edit.: J 122 153, 1943) See Ed t, (J 113 35, 1939) and (lo l t (Hases d l control sol re la ve ruga, Lima, 194)

Benign an l mal gn t form of the disease re seen the malignant var ety bei g se re acute and prod ct ve of profound anemia.

The period of cubat on ranges from to 6 week o l ger a d i haracterized by fe e of rregul t pe jo t pa ns, heada h and ba k h nd a em a of se re grade On the ppeara ce of th erupt on these mptom graduall subside and may disappear Earl cut neous manifest tion re usually purely eryth matous The d s tribution is roughl mmetric a d more o less ge eral although the face neck, and

extensor surfaces of the arms and legs are the sites of predilection. The mucous membranes are early involved Within a few hours or days groups of papules many of which later become nodules, develop in the erythematous spot These lesions are of various sizes, from 0.5 to 4.0 cm in diameter, bright or dark red in color and sensitive to touch They may be sessile, cylindric or pedunculated. Their capsules are thin and fragile, and readily rupture giving rise to hemorrhages which tend further to debilitate the already weakened patient. In addition to surface lesions, nodular masses commonly develop in the subcutaneous regions, particularly about the joints. In time many of these break down *to form deep, foul ulcers, which are likely to give rise to hemorrhages of greater or less* severity Some superficial warty growths may shrivel up and disappear, and many larger ones undergo absorption but the course of the disease may be prolonged over a period of many months by the development of new groups or crops of lesions, each outbreak usually being preceded by recrudescence of fever and anemia.

Etiology—Barton's bacillus is found in the local lesions, as well as in the red blood cells during the febrile period of the disease These small, pleomorphic, motile aerobic, Gram negative organisms, 0.2 to 0.5 μ by 0.3 to 1.5 μ, dumbbell shaped and coccoid, occur singly and in masses.

Diagnosis.—The symptoms are suggestive and the eruption is pathognomonic. The agglutinin titer is maximum just prior to the appearance of the eruption when positive blood cultures may be obtained (Howe: AIntM 72: 147 429 1943)

Prognosis.—The mortality averages about 15% Sluggish cases may drag along for months, and the patient finally recovers while in those with hyperpyrexia, severe anemia and great prostration death may occur within a few days. One attack yields lasting immunity

Treatment.—Change of climate particularly removal to the seashore, often proves beneficial. Treatment prior to the advent of antibiotics was largely symptomatic, though arsphenamine has been thought to be sometimes helpful. Howe (1943) tried hyperimmune rabbit serum in 3 cases, but results were not dramatic. Streptomycin appears to be curative (Aldana et al.: ArchDerm J 139: 605, 1949), while penicillin and Chloromycetin do not affect the course of the eruption, although they induced disappearance of Bartonella from the peripheral blood (Krumdieck: ArchDerm J 143: 1 19 1951)

Prevention is readily accomplished: it consists in staying away from infected regions and in avoiding them particularly at night DDT affords promise in control efforts.

RHINOSCLEROMA

Symptoms.—Rhinoscleroma is a chronic granulomatous disease which affects the nose and upper respiratory tract. Women are attacked more commonly than men Persons who live in poorer hygienic conditions appear to be more susceptible The first stage is characterized by rhinitis, fetid nasal secretion and dryness of the throat the second stage by localization of the infiltration, obstruction of the nose and damage to the larynx and the third stage by nodule formation and heavy invasion (Reyes ADS 54 531 1946) *A fourth stage of cicatricial evolution was added by Kline and Brody* (ADS 59 606 1949) who spoke of the symptoms as being largely mechanical and preferred the name Scleroma

The disease begins insidiously with nasal symptoms comprising at first crusts and foul discharge then obstruction and epistaxis. Diffusely or discretely there develop hard, insensitive cartilaginoid plaques which are subcutaneous and later extend superficially (Cunning and Guerry AOtol 36: 662 194) The overlying skin gradually assumes a peculiar reddish or brownish glistening hue and may become scaly and crusted. Within several months or years, the tumors tend to grow irregular or lobulated, with smooth or slightly wrinkled telangiectatic surfaces, and they are firmly embedded in the skin.

Ultimately the masses diminish in size and become dense and hard. The resulting deformity depends on the location and extent of involvement. The disorder generally affects the anterior nares, upper lip and contiguous structures, but cases have been reported in which the pharynx, larynx, trachea, tongue and even the lacrimal passages and the lobe of the ear were involved, either primarily or secondarily In the nasal cases the nostrils are thickened and stiffened, and the tip of the nose is enlarged and elevated. Infiltration may be so great as to close the area entirely Mobility of the lips may be impaired so as to interfere with speech. The mucosa of the nose and pharynx becomes puckered and shrunken. The gums are involved in rare instances, and the teeth become loose and may fall out. Ulceration is rare but may occur as a result of accidental injury or infection. The course of the disease is extremely tedious, extending perhaps over a period of many years. There is lymphadenopathy.

Etiology and Pathology—It is possible that rhinoscleroma is due to a short, encapsulated, gram-negative bacillus isolated by von Frisch (1882) which is morphologically almost identical with the pneumococcus of Friedländer although the results of animal inoculation experiments have been negative There is little evidence to show that the organism of v Frisch is primarily responsible for rhinoscleroma. There is no means by

Fig. 357 —Rhinoscleroma (Novy and Tauscig ADS 39 1058, 1939)
Figs. 358 and 359 —Rhinoscleroma. (Dr W S Gottheil.)

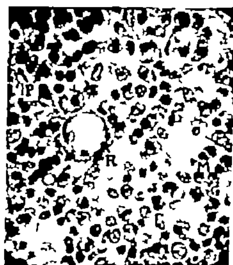

Fig. 360.—Rhinoscleroma (Dr Robert Andrade)

Fig. 361 —Rhinoscleroma. *M* Mikulicz cell *R* Russell body which is a plasma cell showing eosinophilic hyaline degeneration *P* plasma cells. (Dr Stuart C. Way)

which it can be distinguished with certainty from other members of the encapsulated group, which are found in healthy noses (Topley and Wilson: Principles of Bacteriology 1937). Nonpathogenic to mice. 10 strains investigated by Morris and Julianelle (J Infect Dis 55: 150 1934) absorbed agglutinins identically with type C Friedländer bacilli.

The tumor mass consists mainly of plasma cells, collections of which are irregularly scattered in all layers of the skin and subcutaneous tissue. The collagenous tissue is thickened and increased at many points in the tumor and it is this unyielding, fibrous material which accounts for the pathognomonic hardness of rhinoscleroma. Large, oval, dropsical cells first described by Mikulicz, and hyaline degenerated cells of Pellizari (Russell bodies) are characteristic regressive changes. Mikulicz's cells are probably degenerated plasma cells, each containing 0 to 8 of v. Frisch organisms. The hyaline degenerated cells are spherical in shape and, like the dropsical cells, are 4 or 5 times as great in diameter as the surrounding plasma cells.

Diagnosis.—The characteristic location of the lesions, their hardness, and the absence of ulceration are suggestive. Syphilis, carcinoma, other granulomas and keloid are to be excluded by biopsy.

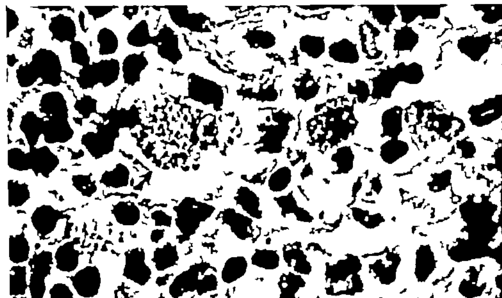

Fig 182.—Rhinoscleroma. Granulomatous tissue, showing Mikulicz cell designated by arrows. (Simpson and Ellis, ADS 39 681 1939.)

Prognosis and Treatment.—The disease is steadily progressive and remarkably resistant to treatment. Surgical interference is usually followed by recurrence. Radiotherapy given early has proved palliative. A case was cured by streptomycin, 250 mg each 3 hours to a total of 97 Gm. given because the Klebsiella group of organisms have been shown by Heilman (PSMMC 20 33 1945) to be sensitive to this agent (Devine et al PSMMC 22 597 1947). Streptomycin induced marked improvement within 5 days, during which cultures became negative, and recurrence did not take place in a period of 3 years in a patient of Russell et al. (J 148 642, 1952)

See Ireland (CanadMAJ 34 149 1936); Chamberlin (AOtol 23 285, 1936); Alderson (ADS 36 1012, 1937) Novy (ADS 39 1058, 1939) Gadomski (AOtol 29 681 1939) Quevedo (AnnOtol 58 612, 1949) 102 cases in Guatemala. New et al. (AnnOtol 57 416, 1948) streptomycin cure. Levine and Hoyt (AOtol 47 438, 1948) diagnosis.

ANTHRAX INFECTION OF THE SKIN

Symptoms.—Anthrax infection in the skin is manifested in a circumscribed, carbuncle-like inflammatory lesion due to *Bacillus anthracis*. Anthrax in man may be septicemic or localized. The septicemic form generally is a result of spread from local infection of the skin. The infection may be immediate from a domestic animal or its hide or hair (shaving brushes, J 117 115 1941) or mediate through the bites of fleas, flies, and other insects. The

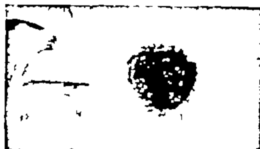

Fig. 363.—Anthrax. Tense vesicles around black ulcer. (Dr. Herman Gold.)

Fig. 364.—Anthrax pustule on neck, no longer edematous after treatment with specific antiserum, showing now only collar of vesicles about central ulcer. (Gold: J.Lab.Clin.M. 21: 134, 1935.)

Fig. 365.—Anthrax pustule on knuckle on fifth day of infection. (Dr. Herman Gold.)

Fig. 366.—Anthrax involving proximal aspects of forearm near elbow in a veterinarian.

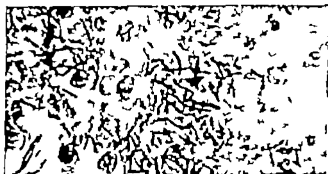

Fig. 367.—Anthrax bacilli in tissue. (Dr. Arthur St. Clair Brumbaugh.)

period of incubation ranges from 1 to 3 days. A small, pruritic reddish macule resembling a flea bite develops, to be followed in the course of from 12 to 24 hours by a red indurated papule which soon becomes vesicular or pustular. The lesion often contains blood and soon ruptures leaving a dark red base which dries and blackens within a few days. The sore is then a typical eschar surrounded by a vesicular zone. The disease may proceed to recovery or satellite vesicles may develop. The lesions are not necessarily of *the textbook description. It may resemble a smallpox vaccination or a streptococcic or staphylococcic sore and it may or may not show vesiculation* or eschar (Enrich BMJ 2 50 1933). Multiple lesions are uncommon.

Etiology and Diagnosis.—*B anthracis* may be found on apparently healthy animals. It causes disease in animals however as well as in man. Anthrax is an occupational disease among handlers of hides. Microscopic examination of smears suffices for diagnosis. *B anthracis* is easy to cultivate (Lebowich et al AmJClPath 13: 505 1943). The disease has been acquired in the laboratory by accidental inoculation (Soltys JlPathBact 60 253 1948). At least 30 such cases have been reported (Sulkin and Pike AmJPubH 41 769 1951) but only 1 of them was fatal. Wool and hair used in the carpet industry may harbor the parasite (Lloyd AIndustHyg 6 421 1952). Bone meal imported for fertilizer from the Far East has been the source of infection in a number of cases in Great Britain (Davies and Harvey Lancet 2 880 1953 Jamieson and Green Lancet 1 560 1954). An insect bite may have inoculated the patient of Hunt and Cook (BMJ 1 87 1955).

Treatment.—While early and radical excision of the lesions was at one time advocated expectant treatment combined with specific serum gave better results (Hodgson Lancet 1 811 1941 Gold AnnIntM 70 785 1942). Immobilization, as in the treatment of carbuncle, is an important measure. Antianthrax serum can be obtained from the Bureau of Animal Husbandry at Washington, D C., and it should be administered repeatedly until edema begins to subside. Sulfonamides have some value (Bonnar BMJ 1 389 1940) but *penicillin is now known to be paramount (Murphy et al. J 126 948* 1944 Ellingson et al J 131 1105 1946) rendering other efforts, excepting isolation unnecessary. The organism is also sensitive to streptomycin (Holgate and Holman BMJ 2 575 1949) and Aureomycin which protected guinea pigs from inoculation and cured 2 cases of Sanchez (MedMex 29 211 1949). Aureomycin was considered as effective as penicillin by Gold (AmJMed 8 31 1950). Chloromycetin and Terramycin are likewise curative reported Gold and Bogar (NEngJM 244 391 1951). Chloromycetin was entirely satisfactory in 4 cases of Clarke (BMJ 1 86 1952). Streptomycin and neomycin are also effective antibiotics, according to the in vitro tests of Boger (ADS 67: 541 1953). Recovery from anthrax meningitis followed the use of antianthrax serum sulfadiazine by mouth and penicillin by injection in the case of Kindler (IndustM&S 21 487 1952). See Gold (AIntM 96 387 1955).

See Para-anthrax. Leo Smythe and Bricker (JIndustHyg 4 53, 1922) 123 cases in Pennsylvania in leather industry 1916-1921 mortality exceeding 31% cut ½ by hospital care, rest, immobilization. Regan and Regan (AmJMSci 167 388, 1924) antiserum given locally round lesion also I M and I V avoid surgery, 14 cures, 2 deaths. Pinkerton (J 112 1148, 1939) horse t 55 miles to rancher who pelted them. Wyatt and Epstein (VetMJ 40 101 1941) 3 cases from dead cattle, cured with antiserum and sulfonamide. Lockwood and Gilderslee (J 116 1606 1941) neoarsphenamine and "hands off". Bendeman and Wheeler (J 135 837, 1947), case ivory worker from elephant tusk, fatal. Weinstein and Colliver (AmPract 2: 332, 1948) 3 cures with penicillin. LaRocetta (AmJMSci 216 407 1948) 36 cures with penicillin; Harasha and Lovett (AmJOphth 32 106, 1949) ocular. Griffin et al. (NYStJM 48 1718, 1948) 17 carpet factory workers 3 with meningitis, all cured with penicillin, some supplemented with sulfonamide. Cole (BMJ 1 1124 1951), 61 cases in Dar-es-Salaam, penicillin superior to sulfonamide. Wolff and Heimann (AmJHyg 53 80, 1951) industrial control measures. Wilson et al (JFlaMA 39 404, 1952) case in cowhand, review. Beaton and Strange (BritJExpPath 35 144, 1954) effective antigen for immunization from cultures.

DIPHTHERIA OF THE SKIN

Cutaneous Infection With *Corynebacterium diphtheriae*.—This may result from autoinoculation contact with an infected individual, or the use of contaminated articles. Cross infection of 16 of 18 patients on a ward was re

ported by Tauber and Goldman (ADS 4: 757 1942) Nasopharyngeal carriers are usually the source.

The eruption often comprises gray sloughing ulcerating patches which *develop around a swollen* inflamed wound. In many instances foci have been multiple and polymorphous, eczematoid or pustular in character Genital lesions are not rare especially in girls. Penile infection leads to sloughing *sores of the glans* (Crowther BMJ 2 646 1943) Umbilical infection in the newborn was reviewed with a collection of 66 cases by Thompson (BJChildDis 36 171 1939) Dermal lesions are usually ulcerative but may resemble impetigo intertrigo or varicella When impetigo is associated with conjunctivitis, diphtheria must be suspected for toxemia is not marked as a rule (Rogers IrishJMSc 150 283 1938) Impetiginous, purpuric pyodermic and ulcerative lesions in several instances accompanying diphtheritic conjunctivitis, were studied by Williams (BMJ 2 416 1943) who demonstrated virulence of the organisms in 12 of the 16 cases so tested.

Fig. 268—Pseudomembranous diphtheria of ankle seen 6 days after a minor injury (Gill ADS 49 408, 1944)
Fig. 269—Pseudomembranous diphtheritic ulcer of 7 days' duration. (Dr S. Gill)
Figs. 270A and 270B—Chronic diphtheritic ulcers of 10 months' duration (Dr S. Gill)

Diphtheria of the Lips was seen in 46 British prisoners of war in the Far East by Biddell (BMJ 818 1950) The pearly white or slightly yellowish, raised, glistening membrane was firmly adherent and covered usually the outer third of the upper and lower lips on both sides. The clinical appearance was quite distinctive Toxemia was generally insignificant After serum was given, the membrane separated within 48 hours.

Ulcerative Lesions occurring in Palestine were intensively studied by Gill (ADS 49: 408 1944 51 43, 1945) Occurring usually on the legs the sores may be solitary or multiple They follow insect bites or minor trauma. A serosanguineous pustule may develop with a wide areola, pain and regional lymphadenopathy Or a pseudomembrane appears, beneath which necrosis and sloughing produce a punched-out ulcer This loses its painful character in some 6 weeks, and cases are seen in which diphtheria is justly suspected as the original cause but only cocci can be found. Or proliferation of tender tissue follows rupture of the pustule and a deep central cavity without membrane formation ensues Erythema and pigmentation along with anesthesia about the ulcer are typical.

Multiple indolent ulcers, jungle sores in Indian troops were followed by weakness of the extremities loss of reflexes, blurring of vision and paresthesias (Ward and Mc... BMJ ... 1945) To demonstrate the organism in ulcers Cameron and Muir (Lancet 770 194..) removed the membrane applied saline compresses for 4 hours, then scraped *the surface at the margin to obtain material for cultures* They described acute primary infections as small follicular blisters or pustules becoming flat sores while as a secondary invader *C diphtheriae* caused the rapid development of a blackish membrane *Of their* 66 cases with cutaneous lesions, 4 were limited to the skin and 1 developed paralyses. Deep punched-out ulcers seen in the South Pacific region were diphtheritic in many instances reported Liebow et al. (AIntM 8: 255, 1946) Trauma or an insect bite predisposed to the infection, and the granulations at the bottoms of the ulcers constantly underwent necrosis *Slightly alkaline blood agar* was good in bacteriologic identification, and penicillin in saline locally helped healing. The Schick test was twice as frequently positive in patients with such ulcers as in controls. The ulcerative diphtherial lesions seen by Stern (CalifM 69 ..4 1948) were generally painless and the scars they produced were hypoesthetic.

Fig. 378.—Scar of diphtheritic ulcer which has been healed for a year.
(Figs. 371-378 courtesy of Dr. R. Gill. ADR 48: 408, 1944.)

Recalcitrant ulcers of the leg due to diphtheroid organisms were the result of rapidly progressive necrosis following initial necrotic pustules in the cases of Barber et al. (BJD 49 260 1937)

Toxic Erythema appearing as a rash on the trunk and extremities is a transient occurrence in some cases and annular erythematous lesions may be seen (Robinson: JCutDis 1: 193, 1933)

The Guillain Barré Syndrome of upper respiratory infection followed by diplopia paresthesias, disability of the lower extremities, high protein content but no other abnormality of the spinal fluid, and myocardial damage, is perhaps diphtheritic and skin diphtheria may produce it according to Delp (AnnIntM 24 618 1946) Myocardial involvement was better detected by electrocardiogram than by clinical examination the more striking abnormalities occurring in the T waves; palpitation was not a symptom, but dyspnea and dizziness when erect, and abdominal pain, nausea and breathlessness were noted by Kay and Livingood (BullUSAMD 4: 462, 1946) Heart damage following cutaneous diphtheria was reviewed in an editorial (BMJ 1: 338 1947)

Multiple Neuritis caused by cutaneous diphtheria was of especial interest to Gaskill and Korb (ANeurPsych 55 559 1946) The onset was late, averaging some 70 days after the initial skin infection. It occurred in only 14% of patients who received antitoxin during the first month, but appeared in 30% of those given antitoxin later than this. Cranial nerve palsies and peripheral paresthesias were observed, and, once they had developed, were unresponsive to treatment. Twenty cases of late polyneuritis were reported by Sampson (AmJMSc 1 433 1946)

The Schick Test is a means of distinguishing between the susceptible and resistant members of the human herd. It is performed by the intracutaneous injection of toxin, to which a positive reaction, an erythematous wheal, means antitoxin is absent or inadequate. The Schick test may not be relied upon as a definitive measure of immunity and repeated doses of toxoid should be given in prophylaxis (Sandesson et al. J 112: 1919 1939) The test is followed in rare instances by an immediate allergic reaction (Beck: DelaSMJ 13 96 1941) The site may show reactivation if toxoid is given 9 days later (Chesney: BMJ 1: 911, 1936) Peripheral to a strongly positive Schick test reaction an area of anesthesia may be found 10 days later and this slowly diminishes during the subsequent 3 months (Toleman BMJ 1 1061 1935)

A scratch test using diphtheria toxin, 30 flocculating units per cc., seemed as reliable as, and easier to perform than, the intradermal test, wrote Groxin (AmJDisChild 57: 564 1939)

Diagnosis depends on suspicion, suggestive clinical features, and in the end cultural identification of the organism and tests of its virulence. A test of dubious value consists in applying 2% potassium tellurite to the lesion blackening which develops in 5 to 10 minutes indicates the presence of diphtheria or diphtheroids (Manzullo BMJ 1 1291 1939) Virulence of the organism may be tested by inoculation of the chick chorioallantois (Evans Sci 113 39 1951) Toxigenic strains kill the embryo in 96 hrs. in almost all cases, while nontoxigenic strains permit survival

Treatment requires isolation, penicillin locally and by injection and antitoxin, 20 000 units intramuscularly with careful precautions against anaphylaxis (BullUSAMD March, 1945) Antitoxin does not hasten healing While C diphtheriae is penicillin sensitive and the antibiotic should be given, antitoxin is equally necessary (Dodds BMJ 2 8 1946) Penicillin is effective in treating both the acute infection and the carrier state of which it terminated 87% of the 52 cases of Crawford (NEngJM 238 220 1948) Aureomycin is of considerable but not invariable value (Karelitz et al JPediat 39 544 1951) Terramycin seemed satisfactory both in diphtheria patients and in carriers reported Lall and Karelitz (JPediat 43 35 1953) Danger is great to both the patient and his associates because of the likelihood of delay in diagnosis. Antitoxin given early and in adequate amounts is curative Powdered methylene blue is a suitable topical application.

PSEUDOMONAS AERUGINOSA INFECTION

Symptoms.—*Pseudomonas aeruginosa (B pyocyaneus)* has occasionally caused an ecthymatous or gangrenous dermatosis. A patient with septicemic symptoms and abscesses which became gangrenous lesions simulating glanders was described by Carter (Lancet 1 437 1924) Infants and children rarely adults, are affected and undernutrition or cachectic states are predisposing factors. The lesions are livid, indolent abscesses measuring up to an inch in diameter They are multiple develop rapidly and are capped by a vesicle or bleb which ruptures to form a superficial ulcer with a necrotic center *Ps. aeruginosa* may cause middle-ear suppuration ecthyma gangrenosum, necrotic and ulcerative lesions of the alimentary mucosa perhaps infantile diarrhea. It is usually however merely saprophytic and occurs in feces and on the skin about the axillae and anus, commonly contaminating eczematous dermatoses and ulcers. It cannot grow in an acidic medium. No reason is known to explain its occasional pathogenicity but ear canal infections with this organism are common and difficult to cure The dermatitis produced is exudative and itchy but clinically nondescript

Septicemia cases especially were studied by Hand (SouthMJ 47 1049 1954) who secured 3 recoveries in 5 cases by the use of polymyxin B Skin lesions in such cases are important because they may be recognized sufficiently early for therapy to be of value. They begin as minute ecchymoses or blebs at a time when the blood culture is usually already positive, although the infant s temperature may still be normal (Geppert et al. JPediat 41 555 1952) The blebs persist or enlarge and undergo crusting or produce weeping lesions. Large areas become dry dark and necrotic suggestive of thrombotic necrosis. The extremities and buttocks are the sites of predilection. Many cases have been reported as ecthyma gangrenosum (McCurdy and Noter Pediat 9 572, 1952) but the lesions were recognized as characteristic manifestations of *Ps aeruginosa* sepsis almost 40 years ago by Fraenkel (ZtschrHyg 84 369 1917) Good clinical photographs were presented by Geppert et al. (1952) who noted the peculiarity of the histologic findings in that vascular thromboses are common while the inflammatory tissue reaction is minimal perhaps as a result of the potent proteolytic enzymes produced by the organism (Yow and Townsend AmJMed 14 762 1953)

Diagnosis.—The presence of the organisms is proved by culture, although a putrid odor of the exudate is strongly suspicious. When *Ps. aeruginosa* infects the ear there are usually other pathogenic bacteria also present see Dermatitis of the External Ear Infections with this organism are becoming more frequent, it would seem, because of the suppression of other organisms with the commonly used antibiotics (Clement and Milland: PresseMéd 61 661 1953)

Treatment.—Supportive measures are recommended, keeping the skin dry with alcohol and powders, and the ulcers dry also with boric acid or other mild antiseptic preferably in powder form while ultraviolet light and foreign protein therapy may be helpful. Weak solutions of acetic or citric acid or 0.5% phosphoric acid are beneficial for local application (Weidman Appleton s System of Medicine 1937) Streptomycin sensitivity of *Ps. aeruginosa* was demonstrated by Bellows and Farmer (J 135 491 1947) in experimental eye infections where instillations of a solution of 10 000 micrograms per cc. were safe and effective In dermatitis of the ears compresses and instillations of 2,500 units per cc cured a case of Calloway (ADS 55 257 1947) Recalcitrant exudative dermatitis of the foot followed trauma and was unresponsive to many therapeutic agents until zinc peroxide was used by Post and Hopper (ADS 63 220 1951) Proteus may thrive during therapy with an antibiotic

which depresses other organisms, according to Yow (J 140 1184 1952) who recommended polymyxin B Chloromycetin 0 6% in Vioform Cream, is an effective topical application.

See Hitschmann and Kreibich (WienKlinWchn 10: 1093 1897) ecthyma gangrenosum; Dudden (JahrbKinderh 99: 257 1922) 4 fatal gangrenous cases, Carter (Lancet 1: 447 1924) septicemia and baccemia, resembling glanders Yap (ArDuS 178 687 1939) multiple ulcers cured with $KMnO_4$, H_2O_2 and zinc peroxide.

NECROBACILLOSIS

An acute infectious disease has been described in the human being caused by B necrophorus a non-spore-bearing elongated gram variable filamentous anaerobe to which are attributed calf-diphtheria, necrotic stomatitis of cattle, foot rot of sheep gangrenous dermatitis of horses and mules, and hepatic necrosis of cattle, pigs and sheep (Beveridge: JPathBact 39 467 1934) *Bullae and erysipelas-like disease developed following a scratch* of a meat inspector s hand, but recovery ensued after a stormy week, in the case of Stemen and Shaw (JKansaMS 10: 405, 1910) No lymphangiitis or constitutional symptoms occurred in the case of Bamber (BJD 53: 351, 1941) Subcutaneous abscesses of 8 years duration with gas formation characterized the case *of Reuter (Trans. ADA 1948, unpublished)*

Fig. 379 —Necrobacillosis of the hand. (Dr F W Shaw)

TUBERCULOSIS OF THE SKIN

Cutaneous infection with *Mycobacterium tuberculosis* may be primary or secondary the skin being involved by inoculation directly or from an internal focus. Manifestations of tuberculosis in the skin depend on the presence and activity of *Myco tuberculosis* or its products, and on the reactivity of the tissues of the host. This reactivity is a significant variable involving the newness of the infection or its superimposition on a background of previous infection which has altered immunity and sensitivity Immunity and sensitization are perhaps independent phenomena although the independence may be only partial as is shown by the fact that hyposensitization by injections of tuberculin does not necessarily alter immunity (Selter and Weiland ZtschrfTuberk 74 161 1935) Clinical appearances vary according to the predominance and histologic location of the tubercles, the inflammatory process, *the granulation tissue or the secondary changes such as hypertrophy* or hyperplasia of the epidermis, or degeneration necrosis or ulceration of the affected parts (Sulzberger and Wise MCNAm 14 1555 1931)

CLASSIFICATION OF TUBERCULOUS LESIONS OF THE SKIN

Localized types of cutaneous tuberculosis extending from an infected spot, progressive in the absence of adequate immunity

1 Primary tuberculous complex in the skin (Ghon tubercle; inoculation into virgin soil)
2 Tuberculosis verrucosa cutis (inoculation into partly immune soil)
3. *Tuberculosis cutis orificialis (secondary by implantation from disease of internal organs)*
4 Scrofuloderma (secondary t subjacent glandular or osseous involvement)
5. Lupus vulgaris

Hematogenous types of cutaneous tuberculosis

1. Acute miliary tuberculosis (not limited to the skin occurs usually in children, is ge eralized and fatal; immunity lacking)

2. Multiple disseminated tuberculosis of the skin (immunity inadequate to prevent caseation)
   a. Disseminated miliary lupus of the face
   b. Rosacea like tuberculosis
   c. Tuberculosis cutis indurativa: erythema induratum; tuberculous gumma
3. Tuberculid with hyperergic immunity
   a. Lichen scrofulosorum
   b. Papulonecrotic tuberculid
4. Tuberculid with hypoergic immunity: sarcoid (questionably tuberculous)

See Gans (Histologie der Hautkrankheiten, Springer 1928, p. 416); Volk (Handb HuG 10: 1-686, 1931), McCarthy (Histopathology of Skin Diseases, Mosby 1931 p. 239); Schmidt (AfDuS 176 639 1937) Montgomery (ADS 35: 698 1937); Blumenthal (ADS 35: 1027, 1937), relation of type of lesion element to allergy and immunity Cipollaro (NYSJM 44: 1557 1944); Michelson and Laymon (ADS 52 108, 1945); Riehl and Kopf (Hauttuberkulose und ihre Therapie, Vienna, 1950)

Localized Tuberculosis Extending From an Infected Site

The Primary Tuberculous Complex is characterized by the development of an ulcer at the site of inoculation accompanied by lymphangiitis and lymphadenitis. Bacilli are present in the tuberculous chancre as well as in its satellite gland which may or may not undergo caseation and ulceration. This syndrome occurs when tuberculosis is inoculated into virgin soil. The 3 cases I have seen occurred in physicians who were inoculated while performing autopsies, a hazardous task in tuberculous deaths. Two of them healed after extremely tedious courses while one died following dissemination of the disease after the axillary nodes became scrofulous. Records of 28 primary inoculations of the skin and mucous membranes were presented by Miller (Lancet 1 5 1953) who noted that erythema nodosum followed the infection and calcification of the regional nodes developed in every one

Cases of inoculation seemingly with *M tuberculosis* have followed minor injuries incurred in swimming pools, and have been described by Cleveland (ActaD-V 31: 147, 1951) and Tolmach and Frank (J 151: 7?4 1953) An acid fast organism, *M. balnei* was originally identified from biopsies as well as the water and walls of a pool where a number of patients remembered having scratched the inoculation site, reported Linell and Norden (ActaTuberc Scand Supp. 33, 1954 also BJD 67: 39 1955) These authors studied cases involving 61 girls and 19 boys who in 1949-1951 acquired the localized granulomatous lesions in one town in Sweden. The incubation period was about 3 weeks. A small, red papule came first, usually on the outer aspect of the elbow It increased gradually for weeks or so becoming soft, spongy and eventually crusted over a central crater Spontaneous healing, followed by scarring took place after several months. Adenopathy usually absent was inconspicuous when present. In many cases the lesions were trivial, but in a few, suppuration occurred and lasted as long as 3 years. Several patients were infected twice at intervals of 1 to 6 months. Linell and Norden inoculated human volunteers and succeeded in reproducing the disease. Their bacteriologic studies indicated that their *M balnei* is not a form of *M tuberculosis* In vivo it was sensitive to streptomycin, tyrothricin and isoniazide. The histologically tuberculoid lesions it produced were not responsive to Finsen light calciferol or PAS. In 1952 another epidemic in a different Swedish town provided 24 more cases, and these patients underwent contemporary Mantoux conversion seemingly due to the swimming pool infection and indicative of immunologic similarities between *M balnei* and *M tuberculosis*.

See Ghon (BeitrPathAnat 69 66 1921) primary complex; Stokes (AmJMSci 169 722, 1925) earliest U.S. report of skin inoculation Brunsgaard (BJD 46 112, 1934); Michelson (ADS 32 889 1935) tuberculous chancre; Montgomery (PSMMQ 11 407 1936), Sulzberger (J 106 314, 1936), Schachmann (AfKinderh 116 31, 1939) 4 cases in infants Laymon (Jour Lancet 59 124, 1939), 2 cases, O'Leary and Harrison (ADS 44 371 1941) good description Scott (AmJDisChild 62 596, 1941) petellar inoculation in child causing verrucose tuberculosis; Vero (ADS 44 736, 1941) lesion in physician contracted at autopsy, Pitcherska and Bedam (AOphth 30 198, 1944), conjunctival primary Epstein (ADS 91 317 1948) Grady (AmRevTuberc 63 576, 1951) comprehensive review Russell (BJD 65: 33, 1953) Miller (Lancet 1 5, 1953) cases, 16 of skin, 6 of eye, 3 of mouth Zschunke and Irmscher (Hautarzt 6: 118, 1955) occupational, in a milk tester case

Tuberculosis Verrucosa Cutis.—Infection occurs from without as a result of an ulcer at the site of inoculation accompanied by lymphangiitis and tuberculous sputum. Sites of predilection are the exposed parts of the body The lesions begin with small wartlike papules which gradually increase in number and coalesce to form small verrucose rounded reddish-brown patches. The lesions may heal spontaneously first centrally leaving thin atrophic, whitish cicatrices. Streptomycin injections cured cases of Allison et al. (JID 13 ?07 1949) and Kern (ADS 63 378 1951)

Fig. 380.—Tuberculosis verrucosa cutis, antecubital location, 9 years' duration, in a 13-year-old boy. (Dr. Glover Wende.)

Fig. 385.—Tuberculosis verrucosa cutis.

Verruca Necrogenica or prosector s wart is a form of tuberculosis due to inoculation. Lesions are seen most frequently on the dorsal surface of the thumb and fingers. They are usually indurated, and always keratotic The growths are persistent but benign, and disappear spontaneously with but slight scarring if immunity is high

Tuberculosis Cutis Orificialis attacks the integument contiguous with mucosal orifices. It begins with the formation of yellowish miliary tubercles, which usually ulcerate to form sluggish, granulating painful sores. The progress of the disorder is slow The lesion is usually superficial with soft irregularly outlined edges, and a raw uneven floor covered with purulent fluid When the tongue is attacked the patient suffers great pain and discommodation (Schugt Laryng 51 284 1941)

See Morrow and Miller (J 83 1482, 1924) 10 tongue cases Rautschkolb (ADS 29: 308, 1924) Stahler (AmJSurg 43: 419 1938), 11 rare lip cases Bryant (AmRevTuberc 39 38, 1939) 17 oral cases in 7 000 patients with advanced tuberculosis, good description, tooth socket is not infected after extractions Farber et al. (AmRevTuberc 42 766, 1940) tongue cases rare may occur as extension from larynx Ikes and Redding (J 117 1148 1941) anal case Lewis (JUrol 50 737, 1940) penile involvement of 110 cases, 73 resulted from circumcision, usually primary; Wolfer et al. (J 136 249 1948) improvement on streptomycin; Butaille and others (abs JID 62: 237 1950) oral cases including oral primary; Wallner et al. (J 146 1252, 1951) 10 laryngeal cases treated with streptomycin, some with PAS, too, with marked improvement and usually relief from pain, Kidd et al. (AmJSurg 82 884, 1951) anorectal streptomycin an adjunct to surgical treatment.

Fig. 336.—Tuberculous ulcer of tongue (Dr George M. MacKee.)
Fig. 337.—Tuberculosis of the tongue. (Farber et al: AmRevTuberc 42 766, 1940.)

Lupus Vulgaris is characterized by plaques of small, soft, apple-butter like tubercles. The malady progresses by the formation of satellite nodules, which coalesce to form irregular groups of various sizes. The face is the common site although no part of the body is exempt. The course is slow but progressive Regressions with subsequent atrophy may take place, but as a rule the tubercles become small, crusted ulcers, ultimately to be replaced by fibrous tissue Deformity resulting from ulceration, cicatrization and contraction may be great The disease develops slowly and insidiously and the chronic course is characterized by periods of retrogression and exacerbation for many years (Michelson JID 7 261 1946) The extent of the disease may become extreme and serpiginous and ulcerative cases sometimes with elephantiasis, have been described (Volavsek AfDuS 178 288 1938 Hamann: abs J 114 1603 1940) Traub (ADS 42 1152 1940) presented such a patient, who obtained a remarkable cure with plastic surgery Lupus vulgaris has in rare instances developed at the site of BCG vaccination (Marcussen: BJD 66 121 1954) Even if BCG vaccine does occasionally incite lupus vulgaris, this is rare and the harm it does is outweighed by the good (Edit BMJ 2 1095 1954); see Letter from Norway (J 155 61 1954)

Scrofuloderma comprises cases in which the skin is involved secondarily by direct extension from subcutaneous lymph nodes or bones which are tuberculous. Cervical lymph nodes are those most commonly affected. Infected nodes become swollen, firm and adherent to the overlying skin They

are at first nodular and elastic but later as a result of caseation may become doughy and ultimately fluctuant. Overlying skin becomes thinned, purplish and depressed and sloughs at one or more points. The resultant ulcers serve as mouths of sinuses from which purulent matter discharges. The sinus walls are soft, reddish and granular and bleed readily. Symptoms and constitutional manifestations are slight. The lesions may heal spontaneously with the formation of rough, corded cicatrices, or the disease may persist for years with little change. Most patients are children and young adults.

Fig. 332.—Lupus vulgaris, papillomatous and elephantiasic. (Dr Gusta Riehl.)

Figs. 333 and 334.—Lupus tumidus. (Dr Gusta Riehl.)

Pathology.—*Mycobacterium tuberculosis* gives rise to histologic changes in the dermis which do not differ from those resulting from its presence in other tissues of the body. The essential lesion is the tubercle or tuberculous nodule. The epidermis is not involved primarily but is usually stretched and

thinned as a result of pressure from below Bacilli are numerous in lesions associated with low immunity and scarce in those with hyperergy They may be undemonstrable in hypoergic individuals whose immunity is high.

Chemical fractions of dead tubercle bacteria were used in investigations by Sabin and Joyner (JExperM 68: 659 837 1938) who showed that specific fractions evoke typical responses. The phosphatid substance injected subcutaneously provokes an epithelioid and giant-cell reaction; the waxes, proliferation of fibroblasts the acetone-soluble lipid, proliferation of all connective tissue cells including those of the vessels, even causing hemorrhage; the polysaccharides are chemotactic and toxic to leukocytes; the protein produces plasma cell proliferation and fever

Tissue responses depend also on factors of sensitization and immunity that are incompletely understood (see Rich: Pathogenesis of Tuberculosis, Thomas, 1944 Friedman: AmJ Path 23: 621 1944 asteroid bodies in giant cells of sarcoid) Explants from an immune donor retain acquired immunity which appears to be concerned with fixed tissue cells, mononuclears and phagocytes but no circulating antibody is demonstrable (Edit.: J 119: 1508, 194.) Acquired tuberculin hypersensitivity is not transmitted by serum from a hypersensitive guinea pig (Chase: PSExpBiol 59: 134 1945) but leukocytes obtained from peritoneal exudate of the donor do convey hypersensitivity when injected intradermally into the recipient animal (Kirchheimer and Weiser: PSExpBiol 66: 166, 1947) This kind of phenomenon was demonstrated in human beings by Lawrence (PSExpBiol 71: 516, 1949) who found that hypersensitivity so acquired persisted for as long as three months. See Edit. (J 138: 833 1948 141: 1301 1949)

Fig 402—Tuberculous tissue from a miliary sarcoidal lesion, showing giant cells and epithelioid cells, but no caseation

Fig. 401.—Lichen scrofulosorum, showing tuberculous inflammation superficially located in the dermis. (Dr Stuart Way)

A carbohydrate-lipid component of dead bacteria, obtained by paraffin oil extraction, was claimed to provoke antibody formation just as Old Tuberculin does, by Choucroun (Sci 106 46 1947)

Clinical tuberculosis must be recognized a a struggle between the tubercle bacillus and the tissues of an immunized host, wrote Pottenger (AmRevTuberc 68: 933 1953) in his essay correlating immune mechanisms, pathologic changes, symptoms and treatment. It may be described as a metastasizing inflammatory, destructive and curative process. The patient kills himself or cures himself according to the metastases which take place the number and virulence of the bacilli which cause them, and the state of his resistance natural and immunologic, at the time the metastases form or that he is able to develop in response t their stimulation. While the immunity reaction is the cause of destruction of tissues, at the same time it is the most important aid in the cure of the disease and one without which there would be no recovery

See Jadassohn (BJD 41 481, 1922) tuberculoid structure develops when immunity is high so that organisms are few Dienes and Mallory (AmJPath 13 897 1937) responses to injection of tubercl bact ria differ as early a the 4th day in infected as compared with previously noninfected animals Kahn (AmRevTuberc 20 150, 1929) dust-fine particles of H37 strain of tubercle bacteria sprout rods which grow int mature organisms Sabin et al (JExpM 52 suppl. 3 1930) results of injecting chemical fractions of M t berculosis Smithburn and Sabin (JExpM 56 867 1932) tissue reactions to chemical fractions; Anderson (PhysiolRev 12 166, 1932) chemical fractions Wells and Long (The Chemistry of Tuberculosis, Baillière, Tindall & Cox, 1932)

Prognosis of Tuberculosis Cutis.—Lupus vulgaris is extremely chronic rebellious to treatment and prone to relapse and recur Systemic tuberculosis is present or develops in a considerable proportion of the cases. The outlook in miliary and disseminated tuberculosis is even graver Tuberculids are benign in themselves, but they may signify an awakening of the systemic disease

The mortality rate for pulmonary tuberculosis in some 3,500 cases of lupus vulgaris was from 5 to 10 times as high as among the normal population the rate was significantly higher for males than for females (Kalkoff AfDuS 186 144, 1947) Modern treatment is highly effective

LUPUS CARCINOMA is a recognized hazard squamous carcinoma developing in the scars, especially when x ray therapy has been used. The lesion may histologically resemble spindle cell sarcoma, yet is of epithelial derivation. Cancer developed in 3% of 2 725 cases of lupus and caused 1.2% of the deaths, reported Mayr (DWchn 104 51 1937) See Spindle Cell Carcinoma also Schock (DWchn 97 1723 1933) Guell (abs J 148 152, 1952) If early lesions are recognized and treated effectually the precancerous proclivity of the tuberculous scar can be counteracted with success.

Diagnosis of Tuberculosis Cutis.—So various are the clinical configurations under which tuberculosis may appear that as in syphilis, suspicion of its possible existence and broad knowledge of its manifestations are required for diagnosis. Biopsy and animal inoculations are two reliable means for diminishing equivocation. Tuberculous lesions are to be differentiated from those of carcinoma, syphilis, lupus erythematosus and blastomycosis. In lupus vulgaris the nodules develop in previously sound skin and are always soft and compressible. Under a pressure glass outlying tubercles appear as yellowish apple-butter-colored puncta surrounded by exsanguinated sound skin. Tuberculous ulcers have soft, nonelevated margins, and their bases are usually granulating and pliable

TUBERCULIN TESTS.—Negative test may signify positive or negative anergy Quantitative intradermal testing has significance (Bonnevie and Björnstad ActaD-V 21 9 1940) Tuberculin patch tests are simple harmless and fairly reliable (*Vollmer and Goldberger AmJDisChild 57 1272, 1939*)

That tuberculous lesions can *always* be found in bodies of persons who during life had no evidence of disease except reactivity to tuberculin was demonstrated by Ghon the tuberculin test demonstrates the presence of tubercle bacilli in the body of the patient as surely as though they were seen through a microscope or were grown in culture media or in animals, according to Myers et al. (J 158 1 1955) Sensitization develops within 3 to 7 weeks after invasion, so that tests frequently repeated will determine the date of invasion promptly and accurately

Reaction to a tuberculin test, patch or intradermal, signifies that at least primary lesions are present, and they probably contain living tubercle bacilli (J 139 69 1949) After the bacilli first invade the body there is an interval of from 3 to 12 weeks before the tissues are so sensitized that reactivity can be elicited by tuberculin (Sweany: AmRevTuberc 56 125, 1947) When allergy first appears, it soon reaches a high level, but if no exogenous or endogenous reinfection occurs, sensitivity wanes until it can be elicited only by a large dose of tuberculin, such as 1 mg Reactivity may sink even below this level, and, if all tubercle bacilli die in the body which probably happens more frequently than used t be believed, allergy completely disappears so that there is o response even to 10 mg. of tuberculin.

Every reactor, child or adult, should be examined at once to determine whether lesions can be detected. If none is found, he should be re-examined periodically The adult who reacts to tuberculin should have the test repeated periodically to determine whether sensitivity wanes or disappears. Tuberculous disease may become evident at any time as long as allergy persists. The old belief, once a reactor al ays a reactor, must be abandoned, although it is not known how long allergy lingers after all tubercle bacilli have died. The belief that all adults have had primary tuberculous infection and therefore react to tuberculin is now obsolete in most parts f the United States. It is as important to test adults as to test children, and the significance of the results is the same.

Atypical tuberculin reactions attracted the attention of Arany (J 15_1 491 1953) In 6 instances, there appeared a large area of marked erythema and a small area of infiltra

tion at 24 hours, completely waning at 48 hours usually following a large dose of intracutaneously administered tuberculin. These are false positive reactions as a rule, Arany thought, but may rarely occur during certain phases of active tuberculosis. Therefore if this type of reaction is encountered in a patient with pulmonary lesions of undetermined nature, it should not be interpreted as definite evidence against the diagnosis of active pulmonary tuberculosis.

The histology of the intradermal tuberculin reaction in human beings was investigated by Hinshaw and Feldman (JID 43 1939). They did not find such obliterative endarteritis as is seen in these lesions in cattle.

See Sulzberger and Wise (MClinNAm 14 1555, 1931) quantitative reactions, relation of reactivity to clinical forms, positive and negative anergy; Martenstein (AfDuS 158: 409, 1929) clinical forms and tuberculin reactivity. Sulzberger (AmRevTuberc 28 734 1933), in sarcoid. Sutherland (The Tuberculin Handbook, Oxford Univ Press, 1936). Moro and Doganoff (WienklinWchr 20 933, 1907) O T in wool fat for patch testing. Wolff and Hurwitz (J 109: 2042, 1937) patch tests. Hays et al. (AmJMedSci 194 220 1937) monthly tests in tuberculous patients showing no correlation of sensitivity and clinical course, though dying patient was insensitive. Harrington et al. (J 108 1309, 1937), incidence of positive reaction by age groups, worthless in treatment. Puente (abs YBD 1937 p. 79) patch test. Nelson et al. (JPediat 12, 26, 1938) tuberculin test does not sensitize. Corper and Cohn (J 112 403, 1939) specific immunity not producible with vaccinal preparations. Thomas (ADS 45 544, 1942), purified protein derivative (PPD) as good as O T; Pascher and Sulzberger (ADS 49 258, 1944) agreement between O T and Vollmer patch test. Lowenthal (ADS 52 240, 1945) Vollmer negatives should be retested with 0.01 O T. Kalkoff and Huck (AfDuS 186 374, 1947), threshold sensitivity in various forms of disease. Leider and Sulzberger (JID 13: 249, 1949) O T reactions in city dwellers by age groups, BCG vaccination effects. Stilwell (PSMMC 25 436, 1950) tuberculin testing and evaluation.

Treatment of Tuberculosis Cutis.—Hygienic measures are important in this form of the disease as in systemic infections. Fresh air sunlight, ample nourishing food and moderate exercise are helpful.

Vitamin D_2 was reported to yield remarkable improvement in lupus vulgaris and was usually tolerated in a dose of from 200 000 to 400 000 units per day (Dowling and Thomas BJD 58 45 1946). Its use entails hazard of metastatic calcification of kidneys and vessel walls, as well as less consequential symptoms of intoxication.

Macrea (BJD 59: 38 1947) obtained excellent improvement in most of the 70 cases of lupus vulgaris so treated. Michelson and Steves (ADS 56 317 1947) helped 6 cases, obtaining scarring fibrotic healing with a dose of 150 000 units of viosterol in oil per day.

The use of vitamin D_2 was initially tried in 1940 by Charpy (BJD 60 121 1948) and independently by Dowling and Thomas (see BJD 60 1?7 1948; BMJ 1 430 1948 Lancet 1: 919 1946). Its action appears to be concerned with mineralization of the skin, with biochemical changes comparable with those promoted by the salt free diet. Its helpfulness is not reliable, and it does not replace Finsen light treatment, wrote Ingram and Anning (BJD 60: 159 1948).

Toxic reactions from overdosage of vitamin D (q.v. under Avitaminosis) include nausea, anorexia, vomiting cramps, diarrhea, urinary frequency tenderness of gums and teeth, arthralgia and myalgia, dizziness, weakness headache haziness of memory and paresthesias of the extremities (Bills: PhysiolRev 15 1 1935). Some 111 cases of hypervitaminosis were reviewed by Chaplin et al. (AmJMedSci 21: 369 1951) who listed, in addition to the above depression mild psychosis and stupor normocytic, normochromic anemia albuminuria, red blood cells and casts in the urine, with progressive impairment in concentrating ability frequency and nocturia band keratitis elevated serum calcium and phosphorus with normal or slightly elevated alkaline phosphatase progressive nitrogen retention diffuse demineralization of the bones in advanced cases, and periarticular soft tissue calcification. Depending on the severity of intoxication all or only a few of these findings may be present. Six of their patients exhibited band keratitis, a lesion commonly associated with disturbed calcium metabolism. The 2 most serious of their 7 cases showed remarkable calcium-containing cysts, located largely in the periarticular areas and in the vicinity of the bursae. These cysts were fluctuant, did not transilluminate and ranged from 1.5 to 8 cm. in diameter. The calcium phosphorus ratio of the sediments centrifuged from the aspirated fluid of the cysts was more than twice that present in bone. Treatment of the patients consisted of cessation of vitamin D intake a strict low-calcium diet, avoidance of undue exposure to sunlight, avoidance of alkali, maximum mobilization of the patient and sufficient fluid intake for a daily urinary output of at least 2,000 cc. Some of the patients were given diethylstilbestrol.

Vitamin D is a potentially dangerous drug and should be used only in diseases in which there is a reasonable rationale for usage. If it is used in massive doses, careful follow up is obligatory for early detection of signs of intoxication. A rise in serum calcium follows D_2 treatment and is a good indication of incipient toxicity (Dawson BJD 60: 164 1948). Constipation is an early toxic symptom (Gauvain BJD 60: 1?4 1948). D_2 may cause conjunctivitis and ulcerative necrosis of lupus tissues, and it is not well tolerated by hyper

tensive patients (Lomholt: BJD 60: 13., 1948) Cysteine 1 mg. by injection daily, inhibiting the action of alkaline phosphatase seemed an effective antidote in intoxication from D_2 (Charpy and Pichat: also Lancet 1: 433, 1948)

Inactivated ergosterol is nontoxic and is as beneficial in a dose of 300 to 600 mg per day intramuscularly as vitamin D_2, wrote Raab (Sci 106: 546, 1947)

Yet the remarkable improvements on D_2 treatment are most marked during the toxic phase of the administration of the drug (Edit. BMJ 1: 453, 1948) During healing, the tuberculous tissue diminishes and is replaced by young connective tissue (Freudenthal: BJD 60: 178, 1948) Comparing clinical results with histologic changes, tuberculosis histologically active in lesions seemingly cured was found by Ruiter and Groen (BJD 62: 15, 1950) who warned against overrating the results. Histologic changes during treatment, with evolution to sarcoidal structure followed by scar were observed by Kovacs (also YBD 1949 p. 471)

See Anderson (EdinMJ 54: 552, 1947) 71 cases; Feeny et al. (Lancet 1: 433, 1947) 150 cases. Riehl (WienKlinWschr 60 525, 1948) 150 cases, Edit. (J 141 726, 1949) Anning et al. (QuartJM 17 203 1948) D_2 intoxication Pascher et al. (JID 13, 89, 1949) utility of D_2; Jeans (J 143 177 1950) hypervitaminosis Hyd and Richmond (AmJDisChild 80: 379 1950) chronic intoxication.

Streptomycin will usually induce fairly prompt apparent cures of skin lesions but histologic tuberculous changes persist and disconcerting disseminations of tuberculous disease such as meningitis and peritonitis, have followed its administration.

If streptomycin is given, the minimum dose should be 2 Gm. per day said O'Leary et al. (ADS 55 222, 1947) and most benefit accrues in scrofuloderma. See Council Rpts (J 135: 634 1947; 138: 584, 1948 14.: 650 1950; 147: 253 1951: Veterans Administration hospitals experience) one Gm. per day suffices.

Toxic manifestations, especially labyrinthitis, necessitated stopping the antibiotic in 6% of the series. One gram a day or even only twice a week reduces toxicity without impairing therapeutic efficiency While the organism develops resistance to streptomycin in about 30% of the cases, the concomitant administration of para-aminosalicylic acid delays or prevents this (Bailey: AmJClinPath 21: 241 1951) Best responses occur in fresh lesions rich in bacilli, and the antibiotic is without virtue in tuberculids (Adorni: ADS 68: 378, 1953) Tuberculous sinus tracts reacted favorably and promptly to streptomycin injections, reported Brock (AmRevTuberc 58: 33 1948) Oral lesions respond well (Oppenheim et al.: AOtol 5 : 910 1950) Combining calciferol and streptomycin in the treatment of 5 patients with lupus vulgaris, Cornbleet (J 138: 1150 1948) thought the two drugs worked in synergism. Local intracutaneous injection of streptomycin was tried by Foster (ADS 63: 597 1951) with apparent success.

Para-aminosalicylic acid 8 Gm per day yielded gratifying results in 7 cases of Linros (ActaD V 31 217 1951)

The hydrazides of isonicotinic acid, iproniazide and isoniazide exert an important therapeutic effect in tuberculosis in a daily dose of 4 mg per kg body weight (Selikoff et al. J 150 973 1952) All cases of cutaneous tuberculosis treated with isoniazide in doses of from 3 to 8 mg/kg daily were benefited reported Latapi et al. (ADS 69 678 1954) Given alone or in combination with dihydrostreptomycin, isoniazide produced good effects in true tuberculosis of the skin in the experience of Holsinger and Dalton (J 154 475 1954)

Lingual and laryngeal lesions he responded well. Various forms of cutaneous lesions so treated by Grutz (MedWchr 94: 1297 195.) were helped. Lupus vulgaris unresponsive to calciferol and other measures did well on isoniazide (Goldberg and Simon: J 131 640 1953) The drug cured in 15 weeks a case of 40 years duration according to Obermayer et al. (JID 19 311, 1952) Good results in lupus vulgaris have been reported by Russell et al. (Lancet 1 964, 1953) Leider and Sawicky (JID 21: 49, 1953) reported notable benefit in 12 cases of lupus vulgaris, 7 of indurative tuberculosis of the skin, and 1 of ulcerative disease; and they saw some benefit from its use in 2 cases of leprosy It did no good in lupus erythematosus sarcoid or tuberculid. Striking improvements were obtained in several patients within 1 month, while toxicity was relatively minor, being manifested by vertigo and tremor in 1 patient, who could not tolerate 50 mg per day reported Dowling et al. (BJD 65 314 1953) The worst cases did well according to Brett and Braun-Falco (DWch 127: 1 1953) whose series included 4 cases of l pus, 1 of erythema nodosum and 2 of scrofula. Mucosal as well as skin tuberculosis was gratifyingly responsive observed Grutz (DWchr 1°7: 160 1953), who saw one instance of purpuric intolerance of the drug In most cases treated by Chakraborty et al. (BJD 65 310 1953) improvement was dramatic and was evident within a fortnight of therapy The response of tuberculids and tuberculoid leprosy was usually disappointing but l pus, scrofula and lepromatous leprosy responded well, reported Cornbleet et al. (ADS 68 536, 1953) although sarcoid was not helped. Large doses were not more effective than modest ones. All forms of tuberculosis of the skin re-

sponded favorably in the experience of Goldberg and Simon (ADS 68: 656 1953). Isoniazide in a daily dose of 4 to 6 mg./kg. body weight continued for 3 or 4 months after clinical cure did not fail to improve every patient of Paulus and Serin (Medizin. Jan. 22 1955) and no serious by-effect occurred. Peripheral neuritis accompanying isoniazide therapy is prevented by giving pyridoxine simultaneously for according to Biehl and Vilter (J 156: 1549 1954) isoniazide induces excessive excretion of vitamin B_6.

Some authorities have made use of a salt free diet (Haldin-Davis BMJ 2 539 1930). It was alleged to have produced results that surpassed those of any other method of therapy (Blumenthal and Funk Strahlenther 45 49 1932). Tuberculin capable of doing much harm was once discarded as being of no use. MacKee (JCutDis 29 307 1911) found it valuable in nonulcerating lupus and tuberculosis verrucosa cutis and least effective in the ulcerating forms. The dose was increased progressively but not to the extent of producing fever. Gold sodium thiosulfate or other salts may be given intravenously. Gold is beneficial in some cases, but intoxication must be carefully avoided (Neuber WienKlinWchn 53 1021 1940).

Roentgen therapy heliotherapy and phototherapy were among the physical agents used. Phototherapy by means of the Finsen lamp gave the best cosmetic results but was extremely tedious. It required great patience and a staff of trained specialists (Lomholt BMJ 2 291 1934; abs J 114 2345 1940. Edit BMJ 2 366 1943). Aitken (BMJ 1 160 1937) used carbon arc light baths with especially good effect in the glandular cases. Radiant heat was commended by Rusten et al. (AmRevTuberc 34 383, 1936). X ray therapy approved if expertly used by Koch and Birkenmaier (DWchn 96 210 1934) entails the hazard of inciting lupus carcinoma. Modest doses in the treatment of fresh, small foci were recommended by Uhlmann (ActaDV 21 529 1940).

Destructive agents of many kinds have a place in the treatment of lupus vulgaris. Acid nitrate of mercury applied to the nodule by means of a small swab produces necrosis, crusting superficial chemical ulceration and sloughing of the tubercle, which eventually heals with scar (Adamson BMJ 2 123 1920). Trichloroacetic acid, lactic acid, potassium permanganate crystals and electrocoagulation are among the agents that have been used (Cipollaro APhysTh 18 415 1937). Plastic surgery certainly has a place in the treatment especially of lupus vulgaris but the removal of a lesion may not prevent the appearance of new ones (Butterworth and Freed ADS 46 242, 1942. Robinson and Tasker ADS 57 293 1948).

Cortisone and corticotropin appear to have no place in the treatment of active tuberculosis as such, and in the presence of active tuberculosis the use of these drugs should be regarded as potentially dangerous (Edit J 149 1474 1952). Careful examination before during and after the use of these drugs is indicated even in the absence of known tuberculous infection, for there may occur exacerbation of an unsuspected lesion. See Treatment cortisone.

Hematogenous Types of Tuberculosis of the Skin

Acute Miliary Tuberculosis.—Eruptions may or may not be present. Purpura may occur. *The infection is overwhelming* and the tuberculin reactivity is likely to be anergic (Rubin AmRevTuberc 39 567 1937). Dusky erythematous crusted papules and subcutaneous gummatous nodules were seen in patients with skin lesions accompanying acute dissemination of tuberculosis reported Lees and Munro (BMJ 1 496 1934).

Multiple Disseminated Tuberculosis of the Skin.—The lesions are small, circumscribed collections of brownish scale-covered nodules which appear suddenly and are irregularly distributed over the face, trunk and extremities. They may undergo central caseation necrosis so as to form ulcers which heal slowly

Fig. 404.—Lupus miliaris disseminatus. (Dr Gusta Riehl)
Fig. 405.—Lupus miliaris disseminatus. (Wise and Satenstein ADS 4 [illegible], 1931)

Fig. 406.—Rosacea-like tuberculosis. (Division of Dermatology Dept. of Med Uni of Chicago, from Weiner Skin Manifestations of Internal Disorders, Mosby 1947)

Miliary Lupus of the Face is a disseminated form in which tubercles, scattered more or less *symmetrically on the face are manifest as small, yellow* ish discrete papules. They make their appearance sometimes coincidentally with an exacerbation of pulmonic tuberculosis. The eruption is chronic, un sightly but asymptomatic It favors the periorbital regions. Histologically the lesions show caseous tuberculosis. The *patients react to tuberculin* with moderate hyperergy Animals have been successfully inoculated with material from the lesions (Wise and Satenstein ADS 4 586 1921)

Disseminated follicular lupus (Fox) and acnitis (Barthélemy) are de scriptive *names more or less synonymous with miliary lupus,* and representa tive of the same phenomena see Ketron (BullJHH 26 111 1915) Malony (ADS 15 285 1927)

Figs 40 408 and 409—Hematogenous, noncaseating tuberculosis in a Negress

Rosacea-like Tuberculosis is characterized by minute discrete brownish or dusky red flattened papular lesions on the face They make their ap pearance suddenly and in crops and persist over a considerable period of time They differ from the lesions of rosacea in being not centrally located upon the face not usually pustular and not accompanied by seborrhea Intra venously administered gold sodium thiosulfate may yield prompt therapeutic effects in this disease Sensitivity to tuberculin is usually high, though Lay mon (ADS 54 232, 1946) found such variation of reactivity *in Minnesota* cases that he judged the test of little diagnostic importance

See Lewandowsky (Cor Bl f schw Ärzt 47 1280 1917), original description Wile and Gruner (ADS 31 174 1935) Machee and Sulzberger (ADS 31 159 1935) Rothstein (KyMJ 38 417 1940) Laymon and Michelson (ADS 42 625, 1940) Machacek (ADS 44 387 1940) Rothman (ADS 54 231 1946) Snapp (JID 13 175, 1949)

Figs 411 and 412—Lichenoid tuberculid Hematogenous distribution of epithelioid tubercles d pic ted the histologic structure of sarcoid, although in some places caseation necrosis was observed. (Ockuly and Montgomery JID 14 415, 1950.)

Lichenoid Tuberculid.—Representative of the hematogenous forms of cutaneous tuber culosis this uncommon variety named by Ockuly and Montgomery (JID 14: 415, 1950) appears predominantly on the extremities, with symmetry of distribution, sometimes quite extensive, and not on mucous membranes. A case was reported by Crawford (ADS 40 950 1939) Ockuly and Montgomery referred to similar cases of Pick (AfDuS 69 411, 1904) and Civatte (AnndeD 37: 709 1906) Resemblance to parapsoriasis has been noted. A nonpruritic flat topped or slightly umbilicated papule f split pea size violet or brownish in color with overlying and adjacent telangiectasis, capped by a fine adherent scale, is typical. Similar lesion were among those present the prototypic instance f Boeck's sarcoid (q.v) Such lesions are discrete and grouped, often with an ular configuration. They involute to form brow ish macules without scarring Histologic changes are those of typical tubercle formation together with various degrees f caseation necrosis. The structure is largely sar coidal and centers about the horizontal network of blood vessels in the superficial cutis. Tuberculin reactivity is generally negative unless lymph node o systemic tuberculosis is also present. On the basi of 15 cases, Ockuly and Montgomery delineated a form of tuberculosis they believed to be distinct from miliary disseminated tuberculosis and from sarcoid, to be differentiated clinically from lichen planus, lichen nitidus and purpura. While frequently associated with lymph node or systemic disease, the cutaneous condition is essentially benign and pparently responds well to treatment with gold sodium thiosulfate and to isoniazide.

Hematogenous Tuberculosis in the Negro often takes a characteristic configuration, with groups of elastic miliary lesions symmetrically disposed on the eyelids about the eyes, and on the lips chin and ears (Bloom and Mendelsohn ADS 36 937 1937) The trunk buttocks and arms are also likely to show these papules Some cases manifest necrosis and high sensitivity to tuberculin (Irgang ADS 47 627 1943) An occasional patient shows micropapules first appearing on the face but becoming generalized except on volar skin and about the mouth (Irgang ADS 53 372 1946) The facial lesions, when papulonecrotic may closely simulate acne (Irgang ADS 49 351 1944) Various manifestations of skin tuberculosis in the Negro were described by Kennedy et al (SouthMJ 35 449 1942)

See Irgang (ADS 57: 184, 1948); Bernstein (AmJDisChild 57 1260 1939); Alden and Jones (SouthMJ 32 256 1939) dynamic concept of variations of skin tuberculosis.

Tuberculosis Cutis Indurativa includes erythema induratum and similar clinical groups of tuberculous disease in which occur scattered nodular lesions, sometimes ulcerative, the microscope revealing caseating tuberculosis.

Nodular Tuberculosis of the Hypoderm.—Painful subcutaneous nodules of from pea to walnut size were observed in the tissues of the face where they underwent spontaneous involution and caused deeply seated scars, reported Wende (JCutDis 29 1 1911) Animal inoculations from the lesions proved positive.

Erythema Induratum (Bazin s Disease) is characterized by the development of symmetrical indurated cutaneous nodules which terminate in absorption or necrosis. The patients are often girls or women with chilblain circulation. The lesions develop insidiously They are usually confined to the legs, particularly the calves, and the lower third of the thighs. The nodules develop in the panniculus adiposus and first become apparent to the touch as rounded or oval, pea to cherry size, indurated masses which are slightly tender on pressure *and tightly adherent to the overlying skin which* assumes a reddish or purplish hue Many undergo spontaneous involution, leaving discolored, reddish or brownish spots which persist. The mass may ulcerate but necrosis is circumscribed as a rule, and the process is comparatively superficial Tuberculous erythema nodosum (q v) seems to represent more successful immunologic reactivity to bacteria than erythema induratum does.

Nodular Vasculitis.—O Leary (ADS 50 212 1944) described an erythema *induratum like disease productive of scarring* lesions in 3 middle-aged women. Montgomery et al. (J 128 335 1945) reviewed 175 cases of nodular sometimes ulcerative lesions of the legs and 40 cases of recurrent idiopathic thrombophlebitis. While histologic structure suggesting tuberculosis may prove a false suggestion, yet tuberculous disease proved by animal inoculation may manifest only nonspecific inflammatory reaction they pointed out. Diagnosis of tuberculous nodules was accepted if guinea pig inoculation was positive, histologic structure was classic tuberculosis elsewhere in the body was demonstrable by roentgenologic findings or strongly positive tuberculin reaction, and the clinical *appearance and course after prolonged* observation were typical. Among their distinctions, which were argued as not valid by Anderson (J 128 1249 1945) they thought nodular vasculitis more painful than erythema induratum, which occurs in younger women. One of their patients originally said to have a case of nodular vasculitis, did develop tuberculous cervical adenitis illustrating the diagnostic difficulty

The syndrome was accepted by Woodburne and Philpott (ADS 60 294 1949) who thought it may be related to periarteritis nodosa or possibly to panniculitis. The poor circulation in thrombophlebitis leads to enhancement of allergic reaction *within the ill nourished* inflamed tissues, setting up a

vicious cycle explained Nakle (AIntM 80 388 1947) A relation to idiopathic thrombophlebitis as described by Barker (AIntM 58 147 1936) can be imagined.

Fig. 413.—Erythema induratum. (Dr Gustav Riehl.)
Fig. 414.—Erythema induratum. (Drs. Fordyce and MacKee.)

Fig 415.—Sarcoid of Darier Roussy d ... ulcerated, necrotic lesions (Drs. Fordyce and MacKee.)

The debatable status of nodular vasculitis serves to emphasize the facts that some lumps in legs are not tuberculosis and that diagnosis should be critical even if difficult. The condition was considered to be a nontuberculous

type of erythema induratum by Irgang whose 2 cases involved the lower extremities of Negro women with high blood pressure His histologic findings were typical, revealing fat necrosis fibrosis and inflammatory infiltration which included some giant cells.

The scrofulous association of Bazin s syndrome was questioned because of failure to recover the bacillus, not achieved until long after Bazin s first description (in 1858) by Audry in 1898 and by Galloway (BJD 11 206 1899 25 217 1913) noted Wilkinson (BJD 66 201 1954) who preferred the name Whitfield s erythema induratum also championed by Bettley (ProcRoySocM 43 391, 1950) Wilkinson discussed 42 patients with nodular eruptions of the legs showing histologically predominantly vascular changes. They occurred in association with the action of cold in (a) young women who tended to obesity but were otherwise healthy (b) young to middle-aged women with legs affected by poliomyelitis, rheumatoid arthritis or other immobilizing disease and (c) women, not necessarily obese at menopausal age who previously suffered from chilblains, acrocyanosis or Raynaud s phenomenon. Cold alone appeared to be the only cause in 15 of Wilkinson s patients and these he regarded as a nodular form of erythrocyanosis. A few cases mostly males, had nodular eruptions associated with thrombophlebitis or erythema nodosum like eruptions over a number of years and eventually developed arterial disease

Granulomatosis Disciformis Chronica et Progressiva.—Lesions of dubious classification but seeming to possess some relation with erythema induratum were given this name by Miescher and Leder (Dermatologica 9 : 25, 1948) Anterior leg lesions were seen gradually to enlarge with shallow infiltration, raised borders central atrophy and tuberose surfaces. The histologic structure resembled tuberculosis without necrosis. A similar case was described by Wells and Goldsmith (BJD 63: 364, 1951), who referred to 9 cases of Mali (Dermatologica 101: 84, 1950) and a curious morphealike lesio microscopically tuberculous, seen by Goldsmith (BJD 41 226 1929) Nine cases were reviewed by Arzt (Hautarzt 3: 488 1952), who described the disease as occurring usually on the legs but sometimes on the forehead and dorsa of hands and consisting of slightly elevated nummular or annular patches surrounded by an erythematous halo. Histologically he described the dermal infiltrate consisting of circumscribed masses of lymphocytes, rare plasma and giant cells and some epithelioid fibroblasts, and he noted thickening of the walls of the small vessels. In differential diagnosis, one must consider necrobiosis lipoidica, granuloma an ulare morphea and atypical tuberculosis, of which this may be one variant.

Tuberculous Gumma.—Subcutaneous, caseating tuberculosis in the cutis or subcutis develops independently of underlying lymph nodes invades the superjacent skin and eventually ulcerates The names *scrofuloderma gummosa* and *tuberculosis cutis colliquativa* are descriptive (Michelson ADS 10 565 1924) The breast was the site in the case of Garb (ADS 58 308 1948) and Promin jelly cured by local application. Ulceration of the lesions of erythema induratum relapsing after calciferol treatment, produced analogous ulcers (Meer BJD 62 19 1950) Subcutaneous abscesses were featured in a patient of Montgomery (MClinNoAm 19 611 1935)

Unusual Tuberculodermas occur and mixed cases are common. Both the usual forms and the unusual are fairly well comprehended if one keeps in mind the possibilities which may result from variations in virulence of organisms and in responsiveness of the tissues of the host. Sarcoidal structure results from comparatively good immunity (positive hypoergy) and necrosis results from high reactivity (allergy) or from damage by virulent bacteria (negative hypoergy) The multiformity of syphilis scarcely exceeds that of tuberculosis (Montgomery MCNAm 19 611 1935; Blumenthal ADS 35 1037 1937)

Treatment of Disseminated Tuberculosis of the Skin is simply the treatment of active tuberculous disease. Streptomycin yielded dramatic cures in 2 cases of erythema induratum reported by Witherspoon and Hamilton (ADS 64 49 1951) and the effects of streptomycin and isoniazide together in 10

cases were gratifying to Pasleczny (ADS 70 514 1954) One may use vitamin D and isoniazide as discussed under treatment of lupus vulgaris.

Tuberculids.—The term tuberculid indicates, and should be restricted to an eruption due to a shower of tubercle bacilli reaching the skin by embo-

Figs 416 and 417—Tuberculous gummas. (Dr D E. H. Cleveland.)

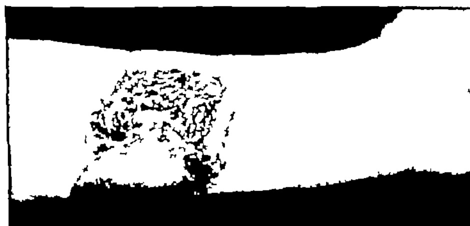

Fig. 418—Tuberculous gumma of forearm. (Dr Sam D. [illegible])

lism in persons with high tuberculous allergy said Rothman (ADS 54 231 1946) Lichen scrofulosus, papulonecrotic tuberculid, and erythema induratum conform with this definition. I see no cogent semantic reason for excluding other eruptions, including those which are sarcoidal presumably

because of positive anergy if they are due to showers of tubercle bacilli also The following descriptions fit certain varieties of tuberculous manifestations.

Hyperergic Tuberculids.—Such doses as 0 1 cc. of 1 1 000 000 dilution of tuberculin result in reactions when injected intracutaneously in certain persons. The conception of hyperergic tuberculids is based on the existence of such sensitivity (Low EdinMJ 39 154 1932)

Fig. 419 —Papulonecrotic tuberculid active lesions and scars. (Drs. Fordyce and MacKee.)

Fig. 420 —Papulonecrotic tuberculid atrophic scarring. (Drs. Fordyce and MacKee.)

Fig. 421 —Lichen scrofulosorum. (Dr T C. Gilchrist.)

These eruptions are thought to be due to multiple emboli of bacilli of low virulence which rapidly succumb in the tissues. Clinical manifestations depend on amount and distribution of the antigen and reactivity of the skin. *Eruptions are better called true tuberculosis if organisms are demonstrable* in the lesions microscopically or by animal inoculation. Tuberculid implies absence of demonstrable organisms occurrence in phthisical subjects *histologic* resemblance to the histopathology of tuberculosis and perhaps, as in lichen scrofulosorum experimental production of the disease by injection of tuberculin. Tuberculous disease in the skin may be divided into (1) true *tuberculosis* (2) tuberculids, and (3) sarcoid forms. In true tuberculosis,

there is classic tubercle formation, caseation occurs, organisms are present and reactivity is hyperergic In tuberculids, there is typical tubercle formation histologically and reactivity is hyperergic but organisms are not present. In sarcoid forms, the tubercle is naked (epithelioid structure) organisms are lacking and the reactivity is hypoergic even anergic.

Lichen Scrofulosorum is characterized by the occurrence of asymptomatic groups of pinhead size pinkish or reddish desquamating papules. The lesions are little, conical papules, which tend to form rounded, superficial plaques, which ultimately disappear without scar The site of predilection is the trunk. The lesions have appeared following injections of tuberculin. Reactivity to tuberculin is high. Demonstrable bacteria are absent. The lesions generally disappear under appropriate treatment Phlyctenular keratitis is an occasional complication. Lichen scrofulosus appeared in conjunction with calciferol intoxication in a case of lupus vulgaris reported by Laden (ADS 57 302, 1948) Cod liver oil is the time-honored medication for this eruption.

Papulonecrotic Tuberculid is manifested with small, discrete lesions of widespread, generally symmetric distribution. They appear in crops and are apparently due to the dissemination of tuberculous antigen via the blood stream Since animal inoculations are regularly negative, the antigenic substance may be either enfeebled circulating bacteria or bacteria killed in the tissues, where they are not to be found microscopically The tuberculin test is positive in extreme dilution. The individual lesions are of various sizes, but are always small. They begin as tiny papules, which enlarge slightly become somewhat tender undergo central necrosis with sloughing or crusting and eventually heal with the production of circular, sharply demarcated scars, which are white, atrophic and slightly depressed. Extensor surfaces of the extremities are the sites of predilection. Itching is absent a distinction from prurigo Compare multiple disseminated tuberculosis of the skin, with reference especially to hematogenous tuberculosis in the Negro.

See Wlassics (DMtsch 76 201 1937), Poor' type, red papules, necrotic centers, healing with central depigmentation; Krantz (ArDuS 178 668, 1938), lesions of remarkable size Parkin (ADS 65 610 1952) appearance during calciferol treatment of lupus vulgaris Pautrier and Weringer (BSocfrançD 46: 412, 1939)

SARCOID

The lesions of sarcoid are typically composed of epithelioid cells, but giant cells, caseation and tubercle bacilli are wanting Since organisms are not ordinarily demonstrable doubt exists as to the specificity of the cause and there is justification for believing that several etiologic agents are capable of provoking sarcoidal tissue reaction. Lesions resembling sarcoid can be caused by leprosy syphilis actinomycosis, trichophytosis, leishmaniasis, lymphoblastoma, and the intradermal injection of foreign bodies, wrote Irgang (ADS 40 35 1939) A sarcoidal rash on the arm of a woman who had previously had *pleurisy with effusion was cured with penicillin*, reported Bernstein and Leider (JID 15 75 1950)

The term sarcoid has been applied rather loosely to a number of chronic granulomatous lesions, wrote Jordan and Osborne (ADS 25 663 1937) They gave a clinical classification (1) miliary lupoid type with small, disseminated nodules, frequently associated with lymph node enlargement often undergoing necrosis and commonly associated with demonstrable tuberculosis elsewhere (2) the deeply seated type of Darier and Roussy and (3) the type to be called Besnier Boeck s disease characterized in its dermatologic aspects by lesions of Boeck s sarcoid or of lupus pernio (q v) and representative of a generalized reticuloendotheliosis characterized by lymphadenopathy and lesions of the same histologic structure in lungs, bone marrow nasal mucosa ocular lacrimal and salivary tissues, liver and spleen.

Boeck s Sarcoid.—Boeck (JCutDis 17 543 1899) described a policeman aged 36 in 1894 whose eruption began on the brow spread t other parts of the face thence to the scalp, trunk and limbs. He was a pale, thin man with groups of lymph nodes much swollen and a

slight increase of wh te blood cells, showing a widespread, somewhat symmetric eruption of firm nodules of varying size on the head and extensor surfaces of the trunk and extremities. The early nodules were red becoming darker and finally yellowish or brown. There was a tendency to peripheral spread and central depression and while some atrophy attended their involution, exudation and ulceration never took place Some lesions on the thigh resembled lichen planus (compare lichenoid tuberculid) This man died from metastases of hyper nephroma in 1940 when he showed only slight, spotty scarlike alteration of the skin of the forehead and temples No sarcoidosis was demonstrable at autopsy but the Kveim test was positive when done in 1940 many years after the disappearance of his sarcoidal skin lesions (Danbolt: SchweizMWehn 77: 1149 1947)

Lupus Pernio of Tenneson (BsocfrançD 3: 4 1 1892) and Besnier (Anndel) 10: 333, 1889) may be considered a variant of Boeck's sarcoid. It was included with cases of multiple benign sarcoid by Jordon and Osborne (ADS 35: 663 1937) and by others, as comprising simply a part of the connotation of Besnier Boeck's disease.

Fig. 422.—Lupus pernio Boeck disease. (Dr Gusta Riehl.)
Fig. 423.—Boeck sarcoid. (Dr J Lamar Callowa.)

As originally described, there occur livid red or purplish, congested lesions on the face nose ears, hands and feet symmetric in distribution infiltrative fairly soft more or less sharply demarcated and differing from true chilblain, persisting throughout the summer Telangiectases are often present Diascopy may reveal minute tubercles Swelling may cause the fingers to become misshapen and ulceration may take place The histologic structure is sarcoidal, yet the disease often associated with lupus vulgaris. Chilblain lupus of Hutchinson (BMJ 1 6, 58, 113 1888) is actually lupus erythematosus and should be distinguished from perniolike tuberculosis of the skin.

See Martenstein (AfDuS 147 70, 1924) Low (EdinMJ 39 189 1932) Kissmeyer and Nielsen (ActaD-V 14 283, 1933), similarity of sarcoid to leprosy review of 200 cases Sulzberger (AmRevTuberc 28 734 1933) classification and quantitative tuberculin tests, Pautrier (PresseMéd 43 148, 1935) multiple benign sarcoid as a systemic reticuloendothelial disease Fulbo (J 105 1205, 1935), simulation by leprosy Ellit (BMJ 2 514, 193), review of enlarging concept of Besnier Boeck Schaumann disease Kreibech in 1904 observed ray changes in hands and feet in lupus pernio, and Jüngling (FortschrGebRoentg 2 375 1920 Delt klin Chl 143 401 1928) recognized osteitis tuberculosa multiplex cystica as being the same.

Subcutaneous Sarcoid of Darier and Roussy (AmédExper 18 1 1906) is rare lial cal form. The lesions are few in number and gradual in evolution, becoming rounded or

ovoid tumors of from 1 to 3 or 4 cm. in diameter Painless, nonulcerative, and located usually in the extremities of women, they resemble the lesions of erythema induratum. Finnerud (ADS 4: 34-, 1921) studied with care a female with mixed manifestations, finding sarcoidal bone involvement but not tuberculous disease. Nodular tuberculosis of the hypoderm is distinguished from sarcoid of Darier-Roussy by the fact that tubercle bacilli are readily demonstrable in the former according to Maloney and Combes (ADS 33: 709 1936) The syndrome may properly be included within the connotation of sarcoid as now understood.

Angiolupoid of Brocq and Pautrier (AnndD 4: 1 1913) has occurred in middle-aged women with sarcoidal lesions sparse in number sometimes solitary on the face, especially on the sides of the nose near the inner canthus The tumors are softly infiltrated, reddish violet in color sometimes streaked with yellow with smooth and telangiectatic surfaces. The distinction of this form from Boeck's sarcoid and miliary lupoid is said to be clear by Auckland (BJD 62: 78 1930) who reported 2 cases and reviewed the literature The lesions are noncaseating tuberculin reactivity is usually present and may be highly sensitive animal inoculations fail and organisms are not demonstrable. The course is chronic, benign and recalcitrant. Local destruction may be required but one of Auckland patients responded well to calciferol.

Sarcoidal Osteitis.—See p. 141.

Figs. 424 425 and 426.—Schaumann disease. A woman from Missouri, whose family lost several members with tuberculosis In the neck were nodules, cystic abscesses and sinuses The skin showed discrete, coppery scaling, infiltrated lesions forming large plaques, resembling the lichenoid tuberculid Photomicrograph illustrates noncaseating epitheloid structure of biopsy from the leg.

Sarcoid in the Skin is characterized by the presence of few or several sharply defined elastic brownish, intracutaneous and subcutaneous nodules which are asymmetrically distributed over the face or extremities or both. The tumors are benign. When they undergo involution, either spontaneously or as a result of therapy they may leave no trace or a pigmented spot or a thinned atrophic, macular cicatrix Clinical varieties are large nodular small nodular or papular and diffusely infiltrating Cases may be atypical or mixed. The skin tumors may range in number from 1 or 2 to 100 or more. The face is the site of predilection. The lesions usually begin as minute firm

rounded nodules which may appear in crops but develop slowly The surface is covered by a fine network of capillaries. After attaining a size from that of a split pea to that of a walnut and persisting for months or years the growths may undergo regression. They almost never ulcerate. Verrucous and papillomatous lesions were seen in a Negro whose unusual lesions perhaps resulted from the admixture of sarcoid and keloid (Irgang ADS 62 105 1950)

Sarcoid a Systemic Disease.—Schaumann (ActaD-V 2 409, 1922 BJD 48 399 1936) collated evidence that sarcoid may be and generally is a disease of wide dissemination in the lymphohematopoietic system. He applied the name lymphogranulomatosis benigna to cases characterized by (1) lymphadenitis in the neck, axillae or groin, (2) epithelioid tubercles in the tonsils, (3) fusiform swellings of the fingers and toes due to sarcoid within the bone marrow and demonstrable radiographically as cavernliform and osteoporotic lesions and (4) skin lesions at first of the type described above later becoming more like those of lupus pernio but with (5) a possibility that skin lesions might not be present at all

Involvement of internal organs is part of the disease, at times the entirety of it, while the complete syndrome with cutaneous osseous lymphatic and visceral lesions is found in comparatively few patients, the majority of whom manifest pulmonic and lymphatic lesions. A review of 35 cases with 4 necropsies by Reisner (AmRevTuberc 49: 289 1944) is worthy of study Mainly young adults, 30 were Negro and 5 white The lungs were affected at least to some extent in 33 with mild nonproductive cough and minimal physical signs. Chest films revealed (1) diffuse, disseminated small nodules as in hematogenous tuberculosis, or (2) diffuse or local strandlike changes following the bronchovascular markings, or (3) patchy coalescent densities suggestive of conglomerate fibrotic induration, usually associated with types 1 and 2. Lymph nodes were usually discrete, movable nontender and moderate in size. Mediastinal and tracheobronchial enlargement was present in 30 cases, typically with widening of the superior mediastinal shadow and prominence of the root areas, usually bilateral and often symmetric, generally without symptoms o signs.

Thoracic studies of value were recorded by Bernstein and Sussman (Radiol 44 37 1945) Pulmonary changes usually started with diffuse infiltration accompanying or soon following bilateral hilar lymph node enlargement. This ranged from a fine miliary type to a coarse, irregular mottling and in half the cases cleared completely eventually When infiltration was progressive, coarse strands in the middle zones evolved, and secondary emphysema often developed (Scadding: BMJ 1: 745 1950) An intensive study of 212 primarily pulmonary cases of sarcoid was presented by Lofgren and Lundback (ActaMScand 14.: 424 1952) The lesions in their patients generally regressed within a year Extrapulmonary lesions were observed in 12% of the cases, those in the skin in 6 instances apparently localized by trauma. Only 1 patient had demonstrable tuberculosis.

Reviewing the Army Institute of Pathology material with 300 cases diagnosed during life and 22 in which sarcoid was found at autopsy Ricker and Clark (AmJCP 19 725 1949) found that the peak age incidence was 20 24 years and Negroes were 17 times as frequently affected as whites. Lymph node enlargement cough, weight loss, skin lesions, low fever malaise and weakness were, in that order of frequency the presenting symptoms. The organs i volved were, in order of frequency lymph nodes, lungs skin, bone, eyes, liver and spleen. Of 88 tuberculin tests, 83 were negative. Hyperproteinemia in excess of 8.0 gm. per 100 cc. was present in only one-third of the cases. See Nelson (AmJMedSci 226: 131 1953)

Infants and children are subject to the disease, although uncommonly A child of 3 months came to autopsy (Nauman ZtschrKinderh 60 1 1938) The course in children is the same as in adults, with widespread systemic involvement, eosinophilia, monocytosis, increase of globulin and reversal of the A/G ratio (Reeves et al. SouthMJ 41: 295, 1948)

Osseous changes, demonstrable in th smaller long bones, particularly the digits and ribs, are sometimes those of osteitis fibrosa cystica, and are found in perhaps a fourth of the cases (Connolly BJRadiol 11 25 1938) Of 63 patients with sarcoidosis, only 11 had bony lesions in the series of H lt and Owens (Radiol 53 11 1949) Diffuse coarse, reticular bone destruct on resulted in a lacelike appeara ce which was more characteristic, they thought, than the circumscribed, punched out foci f Jüngling Differentiation from cystic tuberculous osteitis was discussed by Ellis (InternatCli 4 155 1935)

Myocardial lesions occurred in the patient of Cotter (AIntM 64: 286, 1939) Six cases with cardiac involvement were reported by Longcope and Fisher (ActaM 108: 529 1941) and 15 were collated by Sales (FlaMAJ 40 27 1953) whose original patient died as a direct result of sarcoidal heart disease See Gilg (ActaD V 33 318 1953)

Renal and retinal damage featured the unusual case f Klinefelter and Salley (BullJHH 79 333 1946) Albuminuria, reduced kidney function, and normal blood pressure were noted in 2 cases with renal lesions reported by Ustvedt (abs J 113 1084, 1939)

That uveoparotid fever is a manifestation of Boeck sarcoid was convincingly argued by Longcope and Pierson (BullJHH 60 223 1937) and confirmed by others, including With (AOphth 15 104 1937) and Thompson (AIntM 59 646 1937) Compare Cat scratch d sease.

Uveoparotitis and Mikulicz syndrome are sometimes sarcoidal, believed Pinner (Am RevTuberc 3 : 690 1938) In uveoparotid fever inflammation of the iris and of the parotid glands may develop quickly or slowly Sometimes the onset is febrile with malaise and a toxic rash perhaps resembling erythema nodosum or urticaria is found especially on the lower extremities. The parotid glands generally enlarge at about the same time, causing swelling in the preauricular region with uneven, nodular induration but with little tenderness or pain Other salivary glands may be affected, and dryness of the mouth is a feature Parotid swelling last fo several months and recedes without suppuration. Facial nerve palsy resolving in a few months or a year complicates in about a third of the cases.

Lymphadenopathy is likely to accompany the disease and chest films may yield diagnostically important findings.

Neural symptoms are mostly of the peripheral neuritic type but the central nervous system sometimes suffers from sarcoid (Jefferson: BMJ 2: 916 1932) Pituitary damage in the patient of Barber (BJD 58: 70 1946) caused changes simulating Simmonds's disease and was alleviated by implants of desoxycorticoste one and testosterone. Neural involvement caused Adie s syndrome in a woman who later devel ped uveoparotitis (Lewis BMJ 1: 552, 1941)

Ocular lesions may appear at any time in the course of the parotil anl lymph node manifestations and may undergo resolutions and relapses (Walsh: AOphth 21: 4 1, 1939) Ocular symptoms are generally bilateral and not pathognomonic. Burning, photophobia and misty vision are the complaints, and iridocyclitis is the commonest symptom (Michelson: ADS 39 329 1939) Irregula pupils, keratitis, vitreous opacities and optic neuritis may occur (Cohen and Rabinowitz: J 105: 496, 1935) Eyelids may display millet seed lesions; the lacrimal gland may undergo painless swelling; small sarcoidal lesions may rarely occur in the conjunctiva and episclera; the corneal lesions are generally associated with uveal sarcoid; the most frequent and serious manifestation is nodular iritis and the retina is only occasionally affected (Woods: TransAmAcadOphth 53: 333, 1949)

Etiology.—The cause of sarcoid is not known (Rostenberg ADS 64 385 1951) The relationship to tuberculosis is suggestive but dubious. The tuberculin test in sarcoid is generally negative despite failure to escape tuberculous infection (Bjornstad abs J 144 1130 1950) and this has been thought to signify positive anergy

Tuberculin reactivity was transferred passively using viable leukocytes, as successfully to patients with sarcoid as to tuberculin-negative controls ly Urba h et al. (NEngJM 247 794 1952) Anergy of the sarcoid patients was judged therefore to be nonspecific, since their skins exhibited no inhibition to the transfer Inoculations with living BCG organisms and other antigens were made in 13 patient with sarcoidosis and 11 controls by Rostenberg et al. (ADS 67: 306, 1953) who found no differences in reactivity between patients w th sarcoid and without it. They judged the hypothesis of positive anergy erroneous and that of tuberculous etiology unlikely to be correct.

The problematic coexistence f sarcoid, tuberculin negativity and calcified hilar nodes was explained on the basis of variations in virulence by Kalkoff (abs J 144: 966, 1950) who pointed to the fact that clinical transition of sarcoid into tuberculosis with positive sputum sometimes appears to take place.

Guinea pig inoculations are almost invariably negative until late when the patient may eventually succumb to active tuberculosis. Schaumann (1936) despite extensive inoculation experiments was unable to cultivate the tubercle bacillus from his patients, although 4 of them came to autopsy Schaumann and Hallberg (abs YBD 1941, p. 487) were able to find tubercle bacteria in the tissues w th Hallberg's staining method. Cameron and Dawson (Edin MJ 53: 465 1946) supported the theory of tuberculous etiology with their case. Of 27 cases long watched by Reimer 13 regressed, 9 progressed, and 5 remained stationary He believed the outlook dependent largely on the extent of permanent functional damage of the organs involved, while frank tuberculosis accounts for most of the fatal ties. Efforts to demonstrate *M. tuberculosis* in 17 Mayo Clinic cases failed (Kelman et al: MinnM 32 989 1949) nor could it be found by Doepfmer (DeutschMWchs 78 873 1953) The relationship to erythema nodosum, which occurs in about one-fourth of sarcoid patients, seemed significant to Kerley (BJRadiol 16 199 1943)

A virus resembling that which causes mumps has been isolated from several cases of sarcoid by Lofgren and Lundback (ActaM 138 71, 1950 WienklinWchs 63: 398, 1951)

Pathology.—The nodules consist of sharply defined collections of epithelioid cells with pale-staining nuclei the masses being separated by connective tissue septa within the meshes of which there may occur few giant cells and lymphocytes. The nodules contain vessels, but no elastic tissue The epitheli oid infiltration is the same in the skin tracheobronchial nodes, lungs, bones and viscera. In the giant cells one may find curious asteroid bodies (Lever and Freiman ADS 57 639 1948)

Fig. 427.—Sarcoid, bone changes: cystic lesions as of Jüngling's disease, occurring in patient with cutaneous tuberculosis. Cystic tuberculous osteitis is easily confused with sarcoidal osteitis. (Dr. F. A. Ellis, Univ. of Maryland. Internat. Clin. series 48, 4: 186, 1938.)

Fig. 428.—Sarcoid of Boeck. Classic multiple, loose-set, discrete collections of epithelioid cells. Giant cells scarce. No caseation. (Dr. Fred Weidman.)

Plasma globulin is often increased in sarcoid (Salvesen, 1935 confirmed by Longcope J 117 1321 1941) Hyperproteinemia due to increase of globulin returns toward normal as the patient improves, and is of prognostic significance (Fisher and Davis BullJHH 71 364 1942)

Blood chemical studies showed significant changes in the serum calcium, phosphorus nitrogen and globulin reported Grekin and Curtl (JID 11: 299 1948) Blood changes were reviewed by Jirsebl and Howe (Blood 5 478, 1950) In their study of a patient who had thrombocytopenic purpura due to sarcoid and recovered following splenectomy Anemia, they concluded, is uncommon; polycythemia has occurred; the leukocyte count is generally normal or not far from normal but leukopenia is more frequently found than leukocytosis.

Diagnosis.—As a diagnostic problem the multiformity of sarcoid is such that the patient may present symptoms in almost any specialty the pathologist holding the final decision (Gifford and Krause AOphth 41 667 1949) Diagnosis by needle biopsy of the spleen was reported by Block (J 149 748 1952) Examination of the eyes is indicated in all cases of sarcoid (Dressler and Wagner ActaDV 22 511 1942) for they are involved in about a third of the cases. Confusion is possible with tuberculosis syphilis leprosy lymphoblastomas and other neoplasms, silicosis and berylliosis. Hyperparathyroidism causes general not local decalcification while in sarcoid the serum phosphatase is usually normal and serum protein raised (Salmon and Mynell BMJ 2 1440 1951)

THE KVEIM TEST (REACTION).—Sarcoidal lymph node tissue, crushed under aseptic conditions, mixed with saline diluted 1:10 and filtered through gauze sterilized at 60° C. for 2 hours and tested for sterility by aerobic and anaerobic culture and guinea pig inoculation, is phenolated (0.5%) and serves as the antigen (Danbolt: ActaMScand 114 143 1943) One inject 0.1 to 0.2 cc intracutaneously and observes the test site for several months. Positive reaction is indicated by the development after about two weeks, of persisting erythema and induration, reaching its maximum in two months then fading slowly (Leider: JID 10 377 1948) The positive test site shows sarcoidal structure histologically The test is usually positive in persons with active sarcoidal disease and negative in healed or inactive cases (Nelson: JID 10: 15, 1948) It may have prognostic as well as diagnostic value. Patients with positive Kveim reactions showed a sarcoidal response to intradermal injections of normal splenic tissue (Nelson: ADS 60: 377 1949) The Kveim test is negative in leprosy and the lepromin test is negative in sarcoid according to Wade (JID 17 337 1951)

See Kveim (NordiskM 9 169 1941); Putkonen (ActaDV 23 Suppl 10, 1943 23 391, 1943); Danbolt (ActaDV 28 151 1948) antigen serum protein-linked, heat-stable, destroyed by NaOH Id. (ActaDV 31 184, 1951) specificity Siltzbach and Ehrlich (AmJMed 16: 790, 1954) the Nickerson Kveim reaction a useful confirmatory diagnostic tool, Rogers and Haserick (JID 23 389, 1954) reliable, practical diagnostic aid, Jones and Thomson (QuartJM 24 49 1955) Kveim test provides histologic proof of sarcoidosis, indices of activity progress and value of treatment.

Treatment.—X ray therapy will bring about resolution of the skin lesions as a rule small doses suffice. X ray did not help the lymph node involvement in cases of McCort et al. (AIntM 80 293 1947) Old reports recommended arsenicals intravenously and cod-liver oil was given. Chaulmoogra oil, 3 to 9 cc. intramuscularly each week was recommended by Ormsby (ADS 50 61 1944) Old tuberculin may help when started with 0 1 cc. of 1 1 000 000 gradually increasing the dose at 2 to 3 week intervals.

Calciferol therapy given as for other forms of tuberculosis, induced marked improvement in 2 cases of Curtis et al. (JID 9 131 1947) increased excretion of phosphorus was noted and toxic symptoms developed. Similarly a patient of Robertson (BMJ 2 1059 1948) given vitamin D did not show much improvement until severe intoxication developed but Nelson (JID 13 81, 1949) thought calciferol of little virtue. BCG vaccination helped the 4 patients in whom it took, reported Cornbleet (ADS 62 697 1950)

The influence of hormones was observed by Berman (J 147 246 1951) whose patient was much better during each of 2 pregnancies. Cortisone yields remarkable results (Ronchese and Schiff ADS 64 806 1951); see Siltzbach et al., Lovelock and Stone and Small (J 147 927 930 932, 1951) whose patients collectively had ocular pulmonary cutaneous and lymph node involvement, all of which showed dramatic improvement on cortisone Some patients hold their remission and others relapse more or less promptly after with

drawal of the drug (Shulman et al. BullJHH 91 371 1952) An ocular case exhibited remarkable recovery of vision, and 12 other patients with sarcoid made various degrees of recovery on doses of from 100 to 150 mg per day given by Siltzbach (AmJM 12 139 1952) In ocular cases, it must be given early if vision is to be saved (Dolphin and Heathfield Lancet 2 1160, 1952) The benefits from cortisone are most striking upon extrapulmonary *manifestations and in patients with symptoms of brief* duration, the effects being less in pulmonary infiltration and little in mediastinal lymphadenopathy according to Israel and Harrell (J 156 461 1954) They felt that the course of the disease over the long term was favorably influenced in only the minority of cases and 4 of their 36 patients died of sarcoidosis in spite of cortisone therapy

Local infiltration of the individual skin lesions with hydrocortisone acetate produced nearly complete resolution with subsequent partial relapse observed Sullivan et al. (J 152 308 1953) They found that cortisone by mouth was likewise palliative *only while it was given. Palliation may be most gratifying to a patient* who without cortisone would be desperately ill (Dent et al BMJ 2 808 1953) That cortisone aggravates the process was denied by Lovelock and Stone (AmJMed 15 468 477 1953 J 169 69 1955)

Isoniazide may produce some benefit and being almost harmless is worth a trial It helped 2 of the 6 patients of Edelson (JID 21 71 1953), p 339

See Salvesen (ActaM 86 127, 1935) 4 systemic cases, Hunter (NEngJM 214 346, 1936), systemic manifestations Mellon and Helmhauer (ADS 36 315, 1937 37 451, 1938) etiology in avirulent dissociated forms of tubercle bacillus Nickerson (APath 24 19 1937) 8 autopsies, reticulum not destroyed as it is by tuberculosis Lomholt (ActaD-V 18 131 1937) 40 cases reviewed, half with bone lesions, 90% with intrathoracic Scott (BMJ 2 777 1938), 8 cases, including Heerfordt's uveoparotid syndrome, Spencer and Warren (AIntM 62 285, 1938) autopsy showing myocardial, renal and thyroid lesions Cornbleet and Rattner (ADS 40 211, 1939) 3 cases, Negro Leder (Dermatologica 80, 142, 1939), 13 cases followed for from 3 to 15 years without developing active tuberculosis, Saenz and Palomino (ADS 39 456, 1939) tuberculoid leprosy Lambie (MJAustral 1 815 1940) review Pautrier (La Maladie de Besnier Boeck Schaumann, Masson, 1940) Vorbein and Bonnevi (ActaD-V 21 408, 1940), 34 cases Herrell (AIntM 65 1003, 1940) 11 cases Cameron and Dawson (EdinMJ 49 727 1942) case and review doubts on tuberculous etiology Pakov and Taylor (JLCM 27 1284 1942) histology, Ronchese (ADS 46 800 1942) case, autopsy miliary tuberculosis of lungs, Thornhill (AmJDisChild 64 262, 1942) ocular lesions in child Fletcher (AOtol 39 470, 1944) 4 cases involving septum and turbinates, mechanical symptoms, Bates and Walsh (AnnIntM 29 306, 1948) 7 cases, 1 autopsy Michelson (J 136 1034 1948), review Leitner (Der Morbus Besnier Boeck-Schaumann, Basel, 1949) 318 p. monograph (abs ADS 61 171 1950) favoring tuberculous etiology, Curran and Curran (Surg 28 874, 1950) pancreatic involvement Riley (AmRevTuberc 62 231 1950) 52 Bellevue cases, showing predilection for young Negro adults, mortality about 20% Howles (SouthMJ 43 633, 1950), 43 cases, review Hartweg (DMedWchr 76 1144 1951) 79 cases, lung appears to be portal of entry Simkins (J 146 794, 1951) myocardial involvement Hanes (JKaMS 53 338, 1952), effectiveness of cortisone without which disease is not so benign as alleged Longcope and Freiman (Med 31 1 1952) monographic, 160 cases, cause unknown, multiplicity of symptoms, mechanically damaging Duperrat and Vautier (abs J 151 333 1953) pleuric involvement Rogers and Netherton (J 155 974, 1954) in identical twin Letter from Sweden (J 154 1113, 1954), work of Jörgen Schaumann, who died of coronary thrombosis Aug. 9 1953 Schaumann (AnndeD 80 467 1953) cases with pruritus, prurigo, excoriations, pigmentation and depigmented scars Schlapper (BeitrKlinTuberk 112 83 1954) various manifestations and relationship to eponymic syndromes, case helped by streptomycin Löfgren (abs J 156 1319, 1954) erythema nodosum in sarcoid Löfgren et al. (ActaPaediat 43 Supp 100, 1954) BCG given in 20 pulmonary cases, showing depression of tuberculous sensitivity no positive [illegible] rapid absorption of radioactive BCG in seven cases suggested decreased immunity

LEPROSY

Leprosy is a disease believed to be due to infection with *Mycobacterium leprae* Hansen's bacillus. While Koch's postulates have never been fulfilled (Edit InternatMDig 37 254 1940) this acid fast organism, similar in many respects to *Myco tuberculosis* apparently provokes chronic inflammatory disease of tuberculoid histologic structure with acute exacerbations, or lepra reactions, by altering reactivity and by invading and destroying cutaneous and peripheral nervous structures. Noteworthy similarities exist between leprosy and tuberculosis with respect to chronicity causative organisms, granulomatous and tuberculoid histopathology wide range of clinical manifestations, and dependence of the morbid phenomena on variations of immunity of the host and virulence of the parasite (Johansen AmRevTuberc 35 609 1937) BCG vaccination appears to have a prophylactic influence against the development of leprosy (Schujman InternatJLepr 21 313 1953)

GRANULOMA INGUINALE

Granuloma inguinale is a chronic disease due to infection with an encapsulated bacterium, *Donovania granulomatis* affecting primarily the skin and mucous membranes. There is at first a small papule which enlarges, coalesces with adjacent lesions ulcerates and produces a vivid hued, shining verrucose vegetating plaque of granulating tissue with a hemorrhagic surface surrounded by thin, easily excoriated epidermis (V D Committee Rpt J 116 2405 1941) The disease spreads by peripheral extension and autoinoculation so as sometimes to produce extremely extensive lesions, often resembling vegetative carcinoma, from which the distinction is accurately made only by biopsy (Beerman and Sonck: AmJSyph 36 501 1952) MacKay and Bunch (AmJSyph 36 511 1952) observed carcinoma following vulvar granuloma inguinale so that care in diagnosis is essential.

It is exceptional for healing to occur spontaneously if it ever does. The ulcers are superficial with somewhat raised, nodular irregular borders. They give rise to comparatively little pain. There is seldom associated lymphadenitis. Rarely there is seen a lymphangiitic abscess with bubonulus (Sobel and Pensky ADS 48 494 1943) but abscess formation is exceptional. Nodular ulcerovegetative hypertrophic, and cicatricial types are recognized (Haity s classification Pariser and Beerman: AmJMSc 208 547 1944)

Extragenital cases are recognized (Greenblatt et al. ADS 38 358 1938) The lip neck, mouth and elsewhere generally in association with pudendal lesions, are sites which have been involved The incidence of extragenital involvement approximates 6% (Palik and Schenken AmJCP 15 419 1945)

Neonatal infections were reviewed by Scott et al. (AmJDisChild 38, 242, 1953) whose patient had lesions in the postauricular region followed by ulceration of the umbilicus and penis, and the mother s vulvar sore contained Donovan bodies.

The cervix uteri is occasionally the location (Pund and Greenblatt J 108 1401 1937) The upper lip was affected in the case of Hall (ADS 38 245 1938), the eyelid in the case of Weiner et al. (AmJOphth 26 13 1943) the clavicle and ribs in that of Paggi and Hull (AnnIntM 20: 686 1944) Pelvic involvement, including fatal cases, was described by Pund and McInnes (Clin 3 221 1944) malaise weakness, fever anemia and leukocytosis are features. Polyarticular arthritis and osteomyelitis were noted by Lyford et al. (AmJS

Fig. 440.—Granuloma inguinale, with destruction of penis

Fig. 442.—Granuloma inguinal of the cervix uteri. (Adams and Packe South MJ 48 27 1955.)

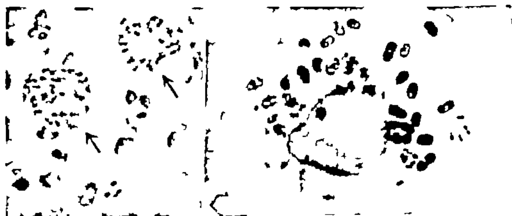

Fig. 443A.—Donovan bodies in large monocytes. (Pund et al. Arch Path 23 224 1937.)

Fig. 443B.—Donovan bodies, Wright stain. (Fox J 87 1785, 1926.)

28 588, 1944) The Negress of Packer et al (J 136 327 1948) had bone metastases and profound systemic manifestations from a cervix primary yet was cured with intravenous antimony

Etiology—Experimentally reproduced infections in human beings were described by Greenblatt et al. (J 113: 1109 1939) The Donovan body was apparently successfully cultivated in the yolk sac as an encapsulated bacterium, *Donovania granulomatis* by Anderson et al. (AmJSyph 29 165 1945 JExpM 81 25 1945) See Cornwall and Peck (ADS 12 613 1925) Success in cultivating the organism on an artificial medium of beef heart infusion broth with some normal egg yolk was obtained by Durham and Rake (AmJSyph 32: 145 1948) A yolk sac culture produced a successful human inoculation, claimed Dienst et al (AmJSyph 31 614 1947); but failure of inoculation with cultured organisms was later reported (AmJSyph 33 152, 1949)

The bacterial behavior of *D granulomatis* was reviewed by Goldberg et al. (AmJSyph 37 60 1953) It appears as nonmotile pleomorphic, gram negative rods, about 0 6 by 2.0 μ in size usually containing granules which are frequently bipolar On Dulaney s medium the organisms were embedded in a matrix of mucoid. No strain could be grown on a medium which did not contain egg yolk or a derivative thereof

Perhaps infection is transmitted by pubic lice (Butts and Olansky: ADS 54 524, 1946)

Diagnosis requires laboratory proof of the presence of the Donovan bodies. The tissue smear method described by Chen et al. (ADS 58 703 1948) is accomplished by selecting a typical red friable bit of granuloma which is cleaned well with a cotton applicator and nipped off with the corners of two slides, obtaining a quantity of perhaps 2 cu mm This is pressed firmly and ground between the slides to obtain a thin smear then the slides are pulled apart and dried. They are stained for 90 seconds with a mixture of 0.5% Wright s stain, 3% glycerol and acetone-free methanol then to this is added an equal amount of distilled water for 3 minutes. After washing and drying Donovan bodies are to be sought in the cytoplasm of the monocytes with the oil immersion lens. The search might be simplified they said, by preliminary use of penicillin or sulfonamide drugs to eliminate other microorganisms. See Cannefax (JVDI 29 201 1948)

A staining method using basic fuchsin 0.5% decolorizing with 0.5% citric acid, washing and counterstaining with 1% aqueous methylene blue was described by Mortara and Dienst (AmJSyph 27: 296, 1943) One may obtain a clean bit of granulation tissue by means of a biopsy punch and smear it as a film; flood the slide with pinacyanole dye 1% in methanol for 90 to 120 seconds, dilute with an equal quantity of neutral water for another 90 to 120 seconds, wash with distilled water and examine (Greenblatt et al. AmJSyph 35 291 1951) The smear must contain intact macrophages sufficient for diagnosis and Wright stain is serviceable (Packer and Dulaney: AmJSyph 33: 63, 1949) Pund and Greenblatt (AP th 23: 224, 1937) demonstrated the presence of true Donovan bodies in their cases with regularity and dependability both in smears and in sections.

Intradermal injection of triturated infected material may yield positive tuberculoid reactions (Kornblith: ADS 60 275 1944) The culture used as antigen gave positive tuberculoid skin reactions, and positive complement fixation tests were reported by Jenson et al. (ADS 55: 324 1947) The complement fixation test is a useful diagnostic tool, according to Goldberg et al. (AmJSyph 37 71, 1953) Skin reactivity to the yolk sac vaccine begins about two weeks after the onset of the infection (Chen et al. AmJSyph 33: 60 1949)

Carcinoma may develop during the course of the disease, or it may simulate granuloma inguinale, in either case introducing a diagnostic problem the solution of which depends on prompt biopsy (Alexander and Shields ADS 67: 395, 1953)

Treatment.—Prior to the availability of effective antibiotics, cures were obtained by the intravenous injection of 5 cc. of 1% aqueous solution of potassium antimony tartrate on alternate days. The drug is likely to provoke vomiting unless given conservatively A dose of 5 cc. of the 1% solution may

be increased 1 cc. at a time to perhaps 10 cc. intravenously Antimony treatment must be persisted with until the lesions are healed. Fuadin a complex trivalent antimony compound, is highly effectual and relatively nontoxic.

Of the many chemotherapeutic agents tried streptomycin in the extremely low concentration of 6 2 gamma per ml. was most effective in protecting the chick embryo (Rake and Dunham Am JSyph 31 610 1947) Streptomycin was found curative in human beings by Barton et al (ADS 56 1 1947) and others. A dose of 0.5 Gm per 6 hours for 2 weeks may be recommended for a total of less than 4 Gm. is likely to be followed by relapse Donovan bodies cannot be found after the fourteenth day and are often gone by the sixth The hazards of eighth nerve damage kidney injury and depression of the bone marrow must be borne in mind when streptomycin is used. Streptomycin, 4 Gm. per day for 5 days is usually adequate wrote Greenblatt et al. (JVDI 28 3 1947) Hirsh and Taggart (AmJSyph 32 159 1948) cured all 21 cases treated with 0 17 Gm. 6 times a day for 6 to 47 days. On 4 Gm. per day for 5 days, 50 of 51 cases were reported cured by Kupperman et al. (J 136 84 1948) Rapid cures with streptomycin were reported by Samitz et al. (JID 12 85 1949) A dose of 4 Gm. per day was recommended by Dienst et al. (UCutRev 51 537 1949) who found that less than 2 Gm. per day is inadequate while Aureomycin proved surprisingly effectual although slightly

Fig 444—Granuloma inguinale *A* before treatment with Chloromycetin *B* aft first course of 20 Gm of Chloromycetin given in 10 days, *C*, after a second, similar course of therapy (Greenblatt et al. AmJObGyn 59 1120 1950 from Crossen Diseases of Women, ed 10 Mosby 1953)

slower All the patients they treated with Chloromycetin were cured and the Donovan bodies disappeared faster than with either streptomycin or Aureomycin. Cases resistant to streptomycin were cured by Aureomycin or Chloromycetin, reported Lariser et al. (ADS 62 251 1950)

Terramycin is also curative (Hendricks et al. J 143 4 1950) The total dose must be 40 Gm. or more, at 1 0 Gm. q.i.d. stated Niedelman et al. (AmJSyph 35 482, 1951) On Terramycin, the Donovan bodies disappear in from 4 to 5 days (Greenblatt et al. JVDI 32 116 1951)

Aureomycin was effective in 5 cases resistant to streptomycin (Greenblatt et al. AmJSyph 33 593 1949) and a total dose of 20 Gm. in 10 days appeared to be the minimal satisfactory schedule The drug was adjudged superior to streptomycin by Hill et al. (J 141 1047 1949) A streptomycin-resistant infection was inoculated into a volunteer in whom also it proved to be streptomycin resistant, but both were cured by Aureomycin, reported Dienst et al. (AmJSyph 34 189 1950) The drug must be continued longer in extensive cases (Wammock et al. JID 14 427 1950)

Chloromycetin seemed superior to Aureomycin in the experience of Robinson and Cronk (AmJSyph 35 378 1951) *Chloromycetin in a total dose of 20 Gm. was excellent and prompt* in the experience of Greenblatt et al. (GaMAJ 38 206 1949) This quantity given at the rate of 0.5 Gm. each 6 hours,

cured 23 female cases either in the first course or the second reported Greenblatt et al. (AmJObGyn 59 1120 1950) The same dose was well tolerated and no relapse occurred in 9 cases of Zises and Smith (AmJSyph 35 294 1951)

Reviewing 295 cases variously treated with antibiotics, Greenblatt et al. (AmJSyph 36 186 1952) judged streptomycin, Aureomycin Terramycin and Chloromycetin all effective. Streptomycin should be given 4 Gm per day for 5 days, but some cases were unresponsive Such cases were responsive to the other drugs, and there was no failure with Terramycin Patients undergoing antibiotic treatment should be hospitalized they believed. Erythromycin, 100 mg q.i.d., cured 8 of 9 cases when given in enteric-coated capsules by Robinson and Cohen (JID 20: 407 1953) Magnamycin appeared curative when tried by Whitaker et al. (AmJSyph 37 466 1953) In doses of 200 to 300 mg q.i.d. it cured all 9 cases of Robinson and Cohen (JID 22 263 1954) Carbomycin gave the best results in the cases involving the cervix reported by Adams and Packer (SouthMJ 48 27 1955)

Penicillin is without effect (Nelson AmJSyph 28 611 1944)

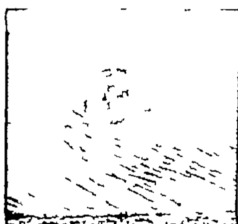
RAT BITE FEVERS
SODOKU AND HAVERHILL FEVER

Two different infections difficult clinically to distinguish from one another may be inoculated by rat bite Sodoku, the usual rat bite fever due to *Spirillum minus* and Haverhill fever due to *Streptobacillus moniliformis* In the spirillar type, the wound becomes inflamed, the regional nodes enlarge and a dark reddish rash may first appear about the bite and then become generalized. In the streptobacillary type, the incubation period is shorter the fever is less regular in its relapses joint pains and arthritis are common and few local inflammatory signs are seen (Brown and Nunemaker BullJHH 70 201 1942)

Sodoku.—*S minus* is a naturally occurring parasite of rats, a short, thick, actively motile organism with tapering ends. Identical with the Japanese *Spirocheta morsus-muris* it has a rigid body moves rapidly with bipolar flagella and is 2 to 5 μ in length, with 3 or 4 waves. After an incubation period of 10 to 40 days, the original wound having healed a nonpurulent inflammation recurs at the scar and lymphangitis and symptoms of general infection develop with intermittent fever of ? to 7-day periodicity Erythematous, indurated plaques develop at the inoculation site and undergo exacerbation with each rise of temperature A satellite bubo is usual, and spirilla may be found here as well as in the chancre on dark field examination. Of 65 cases of rat bite treated at the Johns Hopkins Hospital 10% got the disease 60% were under 1 year of age and none died (Richter J 128 324, 1945) Serologic tests for syphilis become positive in this as in other spirochetoses. The disease followed a cat bite in the patient of Swyer (BMJ 2 386 1945) and was due to the bite of a field mouse in that of Reitzel et al. (J 106 1090 1936) A painless nodule of walnut size with watery discharge and no lymphangitis appeared in the case of Beaumont and Gill (BMJ 1 582, 1935) and the rash,



accompanying a fever of 104° F was circinate appearing first on the forehead, then on the face arms and trunk. Diffuse erythema on the outer aspects of the arms and macular blotches over the abdomen were seen by Beeson (J 123 332 1943) Chills and muscle and joint pains underwent paroxysms at intervals of 5 days in the cases of Leadingham (AmJCP 8 333 1938) See Crohn (AIntM 15 1014 1915) 52 cases Blake (JExpM 23 39 1916), 28 more cases Knowles and Das Gupta (IndMGaz 63 493 1928) 28 cases from Calcutta

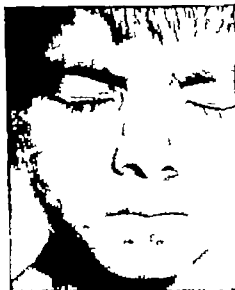
Sodoku has been used to induce fever in the treatment of syphilis (Rothström: Fi sk. Läkaresk. Handl. 77: 51, 1930)

Diagnosis is established by identifying the organism, which can be done by dark field examination of the chancre and by inoculation of the patient s blood i to mice the peripheral blood of which is examined at daily intervals (Watkins JPed 28: 429 1946)

Penicillin is usually curative (Frank and Perlman ADS 57: 251 1948 Oehme DMedWchn 75 1258 1950) Streptomycin cured an unusual case unresponsive to penicillin reported by Jellison et al. (PHRpts 64: 1661, 1949)

Neoarsphenamine effective in the cases of Chopra et al. (IndMGaz 4 449 1937) and of Gilkey and Dennie (SouthMJ 32 1109 1939) fails in Haverhill fever

Figs 445 and 446.—Sod ku hancre t site f bite showing necrosis nd surrounded by inflammation (Gradwohl et al Clinical Tropical Medici e, Mosby 1951.)



Haverhill Fever (Erythema Arthriticum Epidemicum) an illness recognized in Massachusetts in 1926 (Place and Sutton AIntM 54: 659 1934) is characteri ed by abrupt onset with chills fe er vomiting headache, pains in the back and rthralgia. A macular papular or petechial rash appears early especially on the extensor spects of the extremities. The organism cultivated from the blood was called *Ha erhillia mult formis*, late identified as *Streptobacillus moniliformis*. See Place et al. (BostonM&SJ 194: 285, 1926); Pa ke and Hudson (AmJPath : 33 , 19 6), blood cultures; Hazard and Goodkind (J 90 534, 1932) Rat b te inoculated this disease i the case of Farrell et al. (AIntM 64 1 1939) Of 3 cases of rat bite fev r of Kirkwood and Stoll (IllMJ 80: 141, 1941) were spirilla and 1 streptobacillary In the latter type of infection, the incubation period is brief only 3 to 5 days, the feve falls afte only a few days, and the rash is morb lliform. A secondary feve ppears soon after the first deferv escence is quickly followed by polyarthritis, which may pers st fo weeks or months. Some cases unresponsive to rsenical and antimonyl drugs ha e been known to end re for years, with polyarthritis, severe disability and even fatality (Webe a d Favour BullJHH 77 132, 1945) A fatal case with chro c arthritis and f ver was observed by Morse (SoWM 31: 264, 1950)

Accidental inoculations of laboratory wo k rs have been reported by Levin and Civin (AI tM 80 53 1947) and Lom naki et al. (BMJ 1: 510 1949) Both were promptly cured by penicillin.

Pe icillin is usually gratifyingly effective (Wheele AmJDisChild 69: 215 1945; Alteme er J 127 270 1945; Labensky ConnSMJ 10 557 1946) Streptomycin was thought more effectual than penicillin by Sprecher and Copeland (J 134: 1014, 1947) fo tests in vitro show greater susceptibility as Brookeater (JPe : 442, 1943) observed

PINTA

Pinta is a common disorder of Mexico and Central America characterized by startling depigmentary changes. A disease of interesting and exotic history it was long and erroneously thought mycotic in origin.

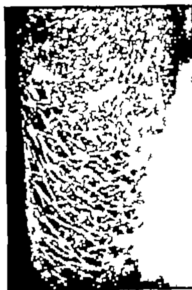


Fig. 447.—Pinta. Blue pigmentation of nose and lips in untreated boy dark-field positive. (Dr Robert Andrade.)

Fig. 448.—Ichthyosiform pintid of leg in untreated boy dark-field positive. (Dr Robert Andrade.)

Fig. 455.—Pinta. Middle finger close-up is shown in Fig. 451. (Dr O. G Costa.)

On Aug 6, 1938, a treponema was discovered in the serum of scrapings from active lesions by Armenteros and Triana in Saenz s patient in Havana, the organism being demonstrated in lymph nodes and tissues of this patient days late by Leon y Blanco (RevMMex 18: 617 1938) See valuable review of Holcomb (USNMBull 40: 517 1943) and Edit. (J 126: 1030 1944)

Fig. 486.—Volar keratoses of corneous pintid. (Dr O. G. Costa.)

Fig 487.—Pinta. Superficial inflammation simulates that of mild lichenoid dermatitis. (Dr H. A. Gall.)

Fig. 488.—Pinta, showing translocation of pigment into dermal chromatophores. (Dr Howard Fox.)

T carateum is a straight spiral 7 to 15 μ in length with 6 to 1. coils, rigid and regular It occurs in the blue lesions. Leon y Blanco inoculated himself successfully and, with Latapi (Medicina 20 315, 1940, also ADS 46 149, 194.) described early lesions. They accredited Herrejon with having earlie established the spirochetal nature of the disease (VDI 21: 270 1940)

In the experimental disease, a small lenticular papule develops on the seventh day at the site of inoculation. This reaches maximum development within 3 weeks, becoming a scaly flattened, oval plaque 2 to 3 cm. in diameter which remains solitary for 3 to 9

months. The dissemination of a secondary generalized eruption sets in. The lesions are hamlike or slate-colored, superficial and scaly, identical with those of naturally acquired pinta, and are accompanied by the development of positive serologic reactions for syphilis. See Oteiza (abs YBD 1940, p. 561)

When *T carateum* was inoculated into each of 9 patients with yaws and free from syphilis, pinta developed in only (Goncalves abs BJD 50 23 1947 Blanco abs YBD 1947, p. 548) Inoculated into 6 syphilitics, there were 5 failures to take (Oteiza abs BJD 58 107 1946)

The naturally acquired chancre develops in 2 stages (Blanco and Lacoa AmJSyph 31 600 1047) at first resembling an infiltrated papule later becoming an erythematosquamous patch of a size varying with its period of evolution The lentil-sized early papule is visible within 10 days or less, becomes an oval brownish red plaque within a month, either elevated 2 or 3 mm or level with a halo of scales. This becomes a flattened sharply demarcated oval patch somewhat infiltrated pinkish, and furfuraceously scaly If the scales are scraped off the surface is lichenoid. Slow progression ensues with centrifugal expansion and confluence of peripheral lesions. The late primary lesion may be psoriasiform dermatomycotic in appearance or lichenoid The initial lesion occurs on the lower extremities in 80% *of the cases on the upper* extremities in 10% and on the face in 5% Dissemination does not occur earlier than 2 months and may be delayed even several years.

Pintids are erythematosquamous plaques like the primary They appear in crops and do not disappear spontaneously They remain localized or if generalized are not as a rule distributed with symmetry The lesions result in depigmentation On a dark skin, bluish scaly lesions and sharply defined vitiliginous lesions may coexist. Remarkable variation of color is seen, and dyschromic patches are often checkered. Pruritus excoriation and secondary infection may modify the picture

Lymphatic involvement is discrete nontender and syphiloid Melanotic pigment and curious hyaline corpuscles are found in the nodes (Deerman AmJMSci 205 611 1943) Serologic tests become positive in all late cases and are likely to be irreversible. Spinal fluid changes like those of syphilis were found in half of the 41 cases studied by Pardo-Castello and Ferrer (ADS 45 843 1942) and cardiovascular changes in two-thirds of them Neurologic and cardiovascular involvement is fully as significant in pinta as in syphilis. Lieberthal (J 123 619 1942) described cases in the United States with late manifestations

Treatment of pinta is like that of syphilis. Mapharsen and penicillin are effective although dyschromia remains as a rule (Varela and Avila AmJ TropM 27 663 1947)

Following the administration of penicillin *T carateum* disappears from the lesions within 6 hours while other antibiotics produced this change only after a much longer interval of time (Rein et al abs J 148 1452 1952) Serologic response to treatment was slow during the 2 years that 350 cases were under study probably because of the long duration of infection prior to treatment The pintids, too required several months to disappear A single injection of microcrystalline procaine penicillin G in oil with aluminum monostearate is highly effectual (Rein et al JID 18 137 1952)

See M LeRun (EdinM&SJ, 1828) Fox (ADS 18 673 1928 in Columbia 31 337 1933 in Mexico 36 614 1937 39 709 1939, spirochetal etiology reported by Saenz et al) Lroeña et al (Primer Censo del Mal del Pinto en la Republica Mexicana 1939-1931 Dept Salubr Mexico, 1934) 11% of 2,500,000 people have it Fernando (JTropM 37 376, 1934) in Ceylon Saenz et al (ADS 41 463 1940) spirochetes in scrapings, cardiovascular changes in 27%, spinal fluid changes 16%, histologic studies Blanco and Oteiza (Sci 101 309, 1945) transmission to rabbit Perez (abs YBD 194 p. 381), CSF changes in 10 cases like those in syphilis Blanco and de Lacoa (abs YBD 1948 p 360) oral lesions Leon (J 148 932, 1951) in Ecuador yaws only in forest regions, pinta in both rainy and arid areas; yaws in lower levels pinta found higher above sea level, vector of yaws ? Hippelates moseorum. of pinta, the simulium fly main difference is in cutaneous lesions, insidious and benign in pinta, acute and destructive in yaws.

Tropical Blue Disease —A chronic dermatoses occurring in the Chillos Plateau of Colombia affecting especially the uncovered parts of the body and productive of exfoliation and ulcerous mucosal lesions, alopecia, general lymphadenopathy and positive STS was reported by Lecoba (abs J 11 .. 1941) as being due to a spirochete different from *S. pallida* and *S. carate* Whether the distinction from pinta is consequential is dubious.

YAWS

Yaws (Frambesia, Pian) results from infection with *Treponema pertenue* which closely resembles the organism of syphilis. Yaws is endemic in certain tropical countries. The course of the disease may be roughly divided

Figs 459 and 460.—Yaws, the crusted eruption. (Dr J A Johnston, Bureau of Science, Manila.)

Fig. 461—Yaws (Dr Isador Dyer)

Fig 462—Yaws, showing resemblance to syphilitic gummas (Dr J A. Johnston, Bureau of Science, Manila)

into 3 stages a primary stage, including the stage of incubation, which varies in duration from 2 to several weeks or longer followed by the appearance of the mother yaw the analogue of the syphilitic chancre a secondary period marked by the appearance 1 to 3 months after the development of the mother

yaw of a generalized papular eruption which persists for several weeks or months and ultimately a third stage in which gummatous nodules and ulcers occur Reference to primary secondary and tertiary stages in framboesia is inaccurate stated Hasselmann (ADS 66 107 1932) because the primary yaw may last throughout the entire course of the disease and should therefore be called the initial yaw while later lesions might be called generalized metastatic papules, keratodermas or ulcers.

Striking features of yaws (Fox J 123 459 1943) are the normally extragenital manner of inoculation, the keratotic lesions of the soles the absence of mucosal lesions in the early stages, the infrequency with which a secondary eruption is seen, and the clinical identity of late manifestations with those of syphilis.

Some 70% of the cases occur in children under 10 years of age. *T pertenue* infects almost exclusively Negroes in equatorial Africa, in the Pacific islands including the Philippines, Malay States, Burma and Thailand, and also in Haiti, Santo Domingo, Jamaica, and parts of South America. The initial lesion often occurs on the leg, perhaps

Fig. 463.—Yaws corymbose, papulosquamous eruption. (Dr O. G Costa.)
Fig 464—Yaw leukoderma (Dr O. G Costa.)
Fig 465.—Yaw psoriasiform lesions in a pot bellied child (Dr O G. Costa.)

inoculated by flies. The mother yaw when it is seen, clinically resembles the common frambesiform eruption excepting its larger size. The typical secondary eruption, when seen, more resembles impetigo than any manifestation of syphilis. Volar hyperkeratotic lesions of yaws seen often in the West Indies may result in a crablike gait Lesions resembling lichen scrofulosus are sometimes observed. Pigmentary changes like those in pinta are found. While spinal fluid changes were demonstrated in half the cases examined, no symptoms of neurologic involvement were reported by Pardo-Castello (ADS 40 762, 1939) in a valuable study of 500 cases in Cuba. Iritis does not occur Juxta-articular nodes may reach the size of an orange in a decade or more of persistence and slow growth (Chambers ADS 50 105 1944) Osseous involvement is common, with more rapid and painful manifestations than occur in syphilis (Helfet JB&JSurg 26: 672, 1944) Marked x ray changes develop in only a few weeks perhaps simulating osteomyelitis following trauma and accompanied by fever swelling and muscle spasm. Sites of predilection are the tibial, distal femoral, medial clavicular and distal humerus regions. Osseous as well as other manifestations are dramatically responsive to antisyphilitic chemotherapy

Lesions of the aorta and other viscera in yaws can not be distinguished from those of syphilis on histopathologic grounds (Weller AmJSyph 20 467 1936; 21 357 1937)

Gangosa (Rhinopharyngitis mutilans) is the name applicable to ulcerative granulomatous destruction of the palatine, pharyngeal and nasal tissues occurring in yaws as a progressive mutilating manifestation (Stitt USNMB 24 1 8 1926) It was recognized as being due to yaws, not syphilis, by Leys

Fig. 466—Yaws mucosal lesions. (Dr O G Costa.)

Fig. 467—Yaws lesions resembling lichen planus. (Dr O G. Costa.)

Fig. 468—Yaws lesions of mother's breast and infant's face. (Dr G. Henggeler MonatshPraktD 11 336, 1905.)

Fig. 469—Yaws. (Dr A. J Geiger.)

in 1904 and was found responsive to antisyphilitic treatment by Odell in 1910 Cases had become rare by 1916 but old, cured patients could be obtained for exhibition, stated Johnson and Depping (USNMB 10 667 1916) Earliest lesions were superficial ulcers of the pharynx or tonsil and the rate

Fig 470.—Osseous nd periosteal lesions of fingers in late yaws. (Drs. C. L. Pickett nd L. M. Pickett.)

Fig. 476 —Gangosa, advanced stage. (Dr A. J Geiger)

of destruction might be rapid or slow with little pain and sometimes with periods of quiescence followed by further progress (Mink and McLean J 47 1166 1906 JCutDis 25 503 1907) See Fordyce and Arnold (JCutDis 24 1 1906) Crichlow (JTropM 24 74 1921) Solomon Islands cases; Lahiri (IndianJPed 15 73 1948)

T pertenue the causative organism of yaws, was discovered by Castellani (BMJ 2 1280 1330 1438 1905) It induces the same serologic phenomena as *T pallidum* for STS become positive in yaws as in syphilis. *T pallidum* and *T pertenue* cause different diseases in animals (Turner AmJHyg 25 477 1937; Ferris and Turner APath 26 491 1938) When the attempt was made to inoculate yaws into syphilitics there were no takes (Turner AmJHyg 23 431 1936)

Treatment.—Penicillin is effective (Whitehill and Austrian BullJHH 75: 232 1944) de Cunha et al. (J 126 1163 1944) Hill et al. Lancet 2 522, 1946 Dwindelle et al AmJTropM 26 311 1946 27 633 1947) Relapses occur as in syphilis. Yaws is as hard to cure as syphilis, and it is treated in the same way Yet a single dose of repository penicillin, which may be all that circumstances permit yielded worth while results in epidemiologic work (Arje USNMB 47 966 1947) When penicillin treatment was more ade quate seronegativity was attained in 59% of the cases in one year (Rein et al. ADS 57 942 1948 JID 14 239 1950)

Fig. 477—Circinate lesions of the face i yaws.

Fig. 478—Same patient as in Fig 477 one week after treatment with 600 000 units of penicillin. (Gradwohl et al Clinical Tropical Medicine, Mosby 1951)

Aureomycin by mouth constitutes effective treatment (Ampofo and Findlay TransRoySocTropM&H 44 311 1950) and so does Chloromycetin (Id. ib p 315) Terramycin, too will eliminate spirochetes in 24 to 48 hours and produce striking healing of ulcerated lesions, and seemed better than penicillin to Loughlin and Joseph (abs YBD 1951 p 93)

See Pearce and Brown (JExperM 41 673, 1925) orchitis in rabbit, Fox (ADS 20 820 1929) differences from syphilis; Butler (ADS 32; 440, 1935) epidemiology Kitamura (DZtschr 71; 61 1935) morphologic identity of T pallid m nd T pertenue Butler (Syphilis et Morbus Humanus, Science Printing Co, 1936) identity of yaw and syphilis Hoffmann (ProcfrancD 43 1200 1936) differences de Wytt (JRoyArmyMC 81 256, 1943) in West Africa troops; Friedheim (AmJTropM 29 185, 1949) treatment with STB orally deri ati of acetarsone; Jelliffe (JTropM 53 228, 1950) "ghoul hand"; Hackett (Bone Lesions of Yaws in Uganda, Oxford, 1952) 242 cases, osseous lesions Hill (Atlas of Framboesia, World Health Organization, see BJD 64 34, 1952); Guimaraes (abs AmJSyph 37 593 1953) Brazilian data Hackett (BMJ 1 74 1953) World Health Organization principles and practice of control First International Symposium on Yaw Control (W H O monograph, Geneva, 1953, bs AmJSyph 38 77 1954)

BEJEL

Syphilis mo g th Bedouins i called bejel. Hudson (ADS 33: 994, 1936; AmJSyph 21: 45 1937; BJVD 27 174, 1931) described this interesting community i fection, which among the isolated peoples f th Middle Euphrates Valley is contracted nonvenereally in ch ldhood n the majority of instances. The epidemiology of bejel is comparable with that f yaws. The esponse to bismuth therapy is favorable. This mild type of spirochetosis is thought to be due to a mild strain of the organism. The public health and economic spects of it were studied by Hudso and Crealey (JTropM Sept. 2, 1936, p. 246) According to Hasselmann (ADS 38 837 1938) the exclusive transmission of syphilis

among Arabs by nonsexual means is a myth. Hasselmann considered *bejel* simply one of many colloquial names for syphilis, all these names being indiscriminately used for all cutaneous ulcers. Syphilitic abortion is commonplace. The disease is not yaws. It is misleading and confusing to call [syphilis] by different local, colloquial names for it runs the same course [among the Arabs] as elsewhere. Syphilis, yaws, pinta, and bejel were interpreted as various modifications, mainly on climatologic grounds, of one disease by Hudson (*Treponematosis*, Oxford Univ Press, 1946). Cases affecting the central nervous system have been observed (Akrawi BJVD 25 115, 1949) and 3 cases of uncomplicated aortitis were described by Akrawi and Rahim (*BJVD* 27 95 1951).

See Rost (ADS 40 305, 1939), bejel *is not* syphilis. Hasselmann (ADS 40 304, 1939), bejel is syphilis. Wilcox (Lancet 1 556, 1951) Southern Rhodesia "njovera," an endemic disease usually contracted in childhood, indistinguishable from syphilis, probably same as bejel. Rink (AmJSyph 35 291 307 1951) rabbit infections do not distinguish syphilis, yaws and bejel. Marshall (BMJ 1 1331 1951) racial variation in syphilis, hypopigmentation in black skin, witkop in South African natives. Csonka (BritJVD 29 95, 1953) 3,607 cases in Iraq, WHO campaign, penicillin cures. McFadzean and McCourt (BMJ 2 1270, 1954) treponematoses in Gambia resembling bejel, drinking cup transmission in small children.

SYPHILIS

Syphilis is an infectious disease due to *Spirochaeta pallida* (*Treponema pallidum*) of great chronicity, systemic from the outset, capable of involving practically every structure in the body in its course and of simulating a large proportion of the entities comprising the field of medicine and the specialties, distinguished by florid manifestations on the one hand and years of asymptomatic latency on the other, transmissible to offspring in man, transmissible to certain laboratory animals, and specifically treatable to the point of presumptive—but not thus far demonstrable—cure by the use of penicillin, derivatives of arsenic, mercury and bismuth and fever therapy (Stokes et al. Modern Clinical Syphilology, Saunders, 1944). Since the time when Stokes et al. expressed doubt about curability with penicillin, this doubt has been dispelled.

Syphilis is widespread among the populations of every country. In the United States of America it was generously estimated that 500 000 new infections were contracted during 1935 and that the cost to the nation annually approximated half a billion dollars. The incidence in 2 million draftees approximated 4% in the white and 20% in the Negro (Vonderlehr and Usilton J 120 1369 1942). It is likely to cost taxpayers a great deal more (Stokes et al. AmJMSc 109 586 1940) although there is no doubt of the profound diminution in the number of cases seen by most practitioners since 1950.

Acquired Syphilis

Course and Pathologic Background of Untreated Syphilis (after Stokes et al. 1944).—A primary incubation period follows inoculation. Although there are no clinical signs of infection during this time, reproduction of spirochetes progresses rapidly in perivascular tissues with general hematogenous dissemination in a very short time. The primary stage is marked by the appear-

ance of the chancre with wide variability in the local reaction. There is satellite lymphadenitis, and systemic symptoms may be manifest such as headache, bone pains, lassitude and malaise. The chancre is produced by lymphocytic and plasma cell infiltration to form a papule at the site of inoculation. Reproduction of *organisms here is at its height* *Other foci of similar inflammatory* structure are developing throughout the body their number location, and activity dependent on the virulence of the organism and the peculiarities of the host Spirochetal septicemia is present. Serologic alterations begin which result in specifically positive reactivity to tests.

The chancre begins to heal in the early secondary stage and disseminated manifestations develop with lymphadenitis, skin lesions, enlargement of the spleen, and osseous, cerebrospinal, hepatic and nephritic lesions. Serologic reaction is now positive. Local immune reactions begin to destroy spirochetes in the chancre and elsewhere and healing sets in. Enormous numbers of new foci are established in the skin, bones, lymphatics and viscera. Lymphocytes *disappear from the healing foci and fibrosis occurs. The organisms are partially destroyed or suppressed.* Activity declines throughout most of the body but innumerable foci remain in the perivascular lymphatics and lymph nodes.

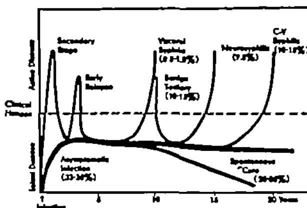

Fig. 473.—The possible courses of syphilitic infection, diagrammatic. (Morgan: J 112 311 1939)

Late in the secondary stage the eruption tends to disappear spontaneously and systemic manifestations subside *coincidentally with widespread destruction of spirochetes.* A few remain and provide the basis for relapse The blood stream contains few of them

With defects of local resistance and revival of foci, occasional showers of spirochetes and crops of lesions may reappear especially on mucous surfaces. The primary lesion and secondary eruption may recur if they had been temporarily aborted by inadequate treatment.

Latency may be established after a time in the prolonged absence of symptoms, or relative quiescence may be punctuated by occasional relapses. Spirochetes are few in number and are held in suppression by systemic and local defense mechanisms. Local lesions, especially of the mucosae bones and skin, may flare. *Chronic inflammatory defense is active but inconspicuous.* It results in degenerative changes and fibrosis. The fetus of a syphilitic woman is likely to be infected.

Latency may persist for many years, but a late phase is likely to appear Its characteristic lesion is the gumma. Gummas are tumorlike masses of granulomatous structure which appear in various organs, skin, liver bones and brain. Endarteritis produces ischemia and necrosis, sloughing destruction and scarring These lesions are comparatively noninfectious, and are apparently due to massive tissue reaction (allergic?) to a small number of organisms.

Degenerative lesions of the cardiovascular and nervous systems and fibrosis of parenchymatous organs, such as liver spleen and pancreas, occur in late stages. Spirochetes are present and may be numerous but are usually demonstrable only on special search in microscopic foci in the aorta heart muscle meninges and viscera. Serologic reaction may have become negative.

Infection may be acquired by direct or indirect inoculation, or through the placenta *Infection usually occurs as a result of direct inoculation generally during coitus.* Extragenital infection is common (Rowntree and Hendon J 115 117, 1940) Occasionally one infected person may unknowingly or carelessly infect several innocent individuals (Zimmermann AmJS 23 104 1939) *Moist lesions of all kinds in syphilis are especially dangerous*, a fact which must be made known to every syphilitic and his contacts. The organisms are most numerous in the primary and secondary stages of the disease.

Lesions of the secondary eruption are fairly readily demonstrated to be dark field positive (Agee NOrlMSJ 95 329 1943) An incidence of about 35% of infection of marital partners was noted by O'Leary (PSMMC 15 1 1940) in a study of the spouses of patients whose treatment had been thought adequate as well as of those whose treatment was inadequate The fresher the syphilis of the partner the greater the liability to infection of the spouse, but even 5 years was not enough to render this liability a small one although 10 years sufficed. The blood and lymph are infectious, but the physiologic secretions are not according to Pariser (JID 3 375 1940) Menstrual blood is infectious, and the vagina is therefore periodically hazardous (Pariser AmJSyph 25 339, 1941) Sores in the mouth make saliva infectious (Barnett and Kulchar JID 2 327 1939) The spinal fluids from 46 patients with secondary syphilis were inoculated into rabbits and in 9 instances infected the experimental animals (Frazier and Pian AmJM 6 443 1949) See Kemp (AmJSyph 22 401 1938) on spirochetes in body fluids.

Spirochete counts in fluid obtained from moist lesions of early syphilis showed 3 700 to 246 000 spirochetes per cmm. while dry lesions yielded roughly one-tenth of this number (Vryonis and Morgan VDI 20 343 1939) Inoculations of from 1 to 6 organisms into rabbits by means of the Chambers micromanipulator failed to transmit the disease (Thomas and Morgan JExperM 59 297 1934)

Infectiousness of untreated syphilis gradually diminishes or immunity increases, until after 4 or 5 years there is considerably less danger of direct transmission inoculation from gummas has been noted, however

A filter passing dark field negative inoculum successfully infected rabbits with the Nichols strain of *S pallida* in the experiments of Wile (AmJSyph 31 109 493 1947)

The Chancre, the primary lesion of acquired syphilis, develops at the point of inoculation usually within 2 to 6 weeks. It generally is a small firm, inflammatory infiltration which becomes eroded and from which oozes a stringy nonpurulent exudate. Spirochetes can be found on dark field examination of the exudate Extragenital chancres are more ulcerative than the usual ones at the coronal sulcus (Wile and Holman AmJSyph 25 58 1941) Most chancres are single but they may be multiple. A chancre may be mixed with chancroidal infection. The lesion may occur anywhere Sites of predilection are glans corona, and shaft of penis, and external uterine os in the female. Primary infection of the distal portion of the penis is unusual in the circumcised male (Hand and Nelson ADS 63 504 1951)

The intraurethral location is not exceptional, induration being palpable as a rule if it is sought, the diagnosis confirmed by dark field examination of material aspirated from the satellite inguinal nodes (Loveman and Morrow AmJSyph 28 79 1944) Frequent extragenital sites are lips, mouth, and hands, especially of physicians and nurses (Downing ADS 39 150 1939) I have seen a woman with chancres on both nipples. Extragenital chancres are often unrecognized, yet Any indolent, indurated lesion anywhere *on the*

body especially if accompanied by unilateral adenopathy should arouse suspicion of syphilis (Tucker et al AmJSyph 32 345 1948) and can generally be identified by dark field examination.

The tonsillar primary sore is accompanied by cervical adenitis capable of being mistaken for Hodgkin s disease (Clodfelter ADS 33 535 1936)

Fig. 485 —Chancre of finger (Tucker et al AmJSyph. 32 345, 1948.)

Fig 489 —Chancre of foot in first interspace. (Tucker et al AmJSyph 32 345, 1948.)

When gonorrhea and syphilis are concurrently acquired the former may mask the latter particularly when penicillin is used, so that syphilis is partially aborted only to appear later the gonorrheal patient treated with penicillin must be followed for several months (Leifer and Martin J 130 202, 1946)

Acquired syphilis is not limited in its incidence to adolescents and adults chancre of the umbilicus of the newborn has been observed and children have been infected innocently (Creswell et al. AmJDisChild 66 611 1943) See acquired syphilis in infants (p 458)

Diagnosis of the Chancre.—Clinical characters are not pathognomonic, and only positive dark field examination is reliable The relatively indolent nature of the syphilitic lesion the long period of incubation, the induration and the lack of response to local medication are typical features. One should select for dark field study lesions which are as young as possible as nearly untreated as possible and as clean and free from detritus and secondary infection as possible (Cares JLCM 29 82, 1944) The chancre rarely may persist for a long time in spite of treatment. Distinction from other genital lesions requires consideration of herpes, granuloma inguinale lymphopathia venerea, chancroid carcinoma etc. (Wilson SouthMJ 41 412 1948)

See Culpepper and Howles (NOrMASJ 8 618, 1935) clinical features unreliable diagnose with dark field, Shackford (USNMB 35 469 1937) physician chancre Zimmermann (AmJSyph 22 757 1938 23 104, 1939), review bibliography extragenital chancres, Hutton (RockyMtMJ 3 191, 1940) extragenital and innocent infections Saduck and Anderson (AmJMSci 203 397 1942) gingiva Ripa and Bartlett (ADS 56 784, 1947) tragus Schipper (IllMJ 75 457 1939) cervix uteri, Lever (NEngJM 231 227 1944) multiple, giant, extragenital lesions Wilcox (BMJ 1 850 1946) accidental, nonsexual transmission.

Inoculation by Transfusion is readily possible and accounts for an occasional case of syphilis acquired without a primary sore (Eichenlaub and Stolar PaMJ 42 1437 1939) This accident to be avoided with meticulous care happens especially when the donor suffers from a seronegative primary infection (Ronchese NEngJM 220 506 1939) Syphilitic osteomyelitis was present despite negative STS in cases of Mandelbaum and Saperstein (J 106 1061, 1936) and Pian and Frazier (ChinMJ 57 301 1940) Prevention requires, of course adequate serologic testing of the donor (Rein et al J 110 13 1938) and physical examination. See Burke (BMJ 2 247 1939) bibliography Arzt (WienKlinWehn 61 105 1949) reject latent syphilitic donors. It is likely that a large dose of repository penicillin given at the time of transfusion would prevent infection.

Mixed Chancres are lesions infected with both *Spirochaeta pallida* and *H ducreyi*. They are characterized by a markedly inflammatory aspect, a tendency to ulcerate extensively and early chancroidal involvement of associated lymph nodes. Chancroidal symptoms so overshadow syphilitic that diagnosis may be seriously confused even until the appearance of a secondary eruption or a positive serologic reaction.

Mucocutaneous Relapse occurred in 6% of some 6 000 patients of a Cooperative Group survey mainly in early cases and shortly after treatment ended The commonest lesion of infectious relapse is the mucous patch papular lesions, moist or dry are also common (Pariser J 113 1206 1939)

Chancre Redux (Chancre Monorecidive) is a form of relapse characterized by the occurrence of a lesion reduplicating the primary sore

Pseudochancre redux is a late, gummatous, syphilitic inflammation appearing at the site of the chancre but the satellite adenitis and positive dark field of a primary sore are lacking

Reinfection after cure can and often does occur (Cannon AmJSyph 17 459 1933 Schoch and Alexander ib 27 15 1943) Reinfections comprise a high but difficultly determined proportion of what must be reported as relapses in evaluation studies of treatment methods. The criteria for diagnosing reinfection were given by Stokes et al (VDI 12 55 1931) see Kopp and Solomon (AmJSyph 23 54, 1939) Clarke and Glicksberg (OhioSMJ 36 517 1940) Shaffer (VDI 24 113 1943) Herman (J 120 283 1942 cases with 3 primary infections in 10 years) Distinction between treatment failures and reinfection was made by Schamberg and Steiger (JVDI 29 92, 1948)

Second Incubation Period.—Following the appearance of the chancre there is usually a second comparatively quiescent period of several weeks.

Vague joint pains, headache slight fever malaise and loss of weight are usual accompaniments. Such symptoms may be mild or severe and they accompany as well as precede the secondary eruption.

Lymph Node Involvement—The satellite bubo which drains the chancre site and appears early is firm painless, freely movable fusiform, olive-sized and typical. It does not suppurate unless the infection is a mixed one. It may be unilateral or bilateral and it is not necessarily on the same side of the body as the primary sore contralateral adenitis usually means syphilis (Fowler BJD 60 279 1948) It is of especial diagnostic importance in extragenital chancres. Herpes simplex also is associated with a satellite gland, but this is large painful evanescent, and in many cases precedes the herpetic lesion.

Immediately after infection takes place spirochetes begin to multiply and invade surrounding tissues, gaining access to lymphatics and blood stream. They are widely distributed over the body even before the initial lesion can be detected. Regional lymph nodes become palpable early in the course of the disease between the fifth day and the tenth They are smooth, firm, oval pea to nut-sized, elastic subcutaneous masses, which are painless and freely movable never fluctuant or matted together Enlargement of epitrochlear occipital and posterior cervical nodes is of greatest import (Beeson ADS 32 746 1935) Too much diagnostic value should not be placed on the presence of palpable lymph nodes, however (Martin Lancet 1 363 1947) They are palpably enlarged in some 70% of early cases. Lymphadenitis in late syphilis is common though frequently unrecognized and is responsive to appropriate treatment.

Fluid obtained from lymph nodes in early syphilis often contains spirochetes demonstrable by dark field examination (Loveman and Morrow Am JSyph 28 44 1944)

Rare cases of syphilitic lymphadenopathy have been known to resemble giant follicular lymphadenopathy (Evans APath 37 175 1944) Enlarged hilar nodes produced a picture simulating sarcoid or Hodgkin s disease in a woman reported by Hornberger (abs J 145 267 1951)

Syphilids are the cutaneous manifestations of syphilitic infection. The eruptions of acquired syphilis were classified by Fox (JCut Dis 31 224 1913)

Early	Late
Macular	Nodular
Maculopapular	Squamous
Papular	Gummatous
Papulopustular	
Pustular	

Cutaneous manifestations of syphilis show great variability in character and in appearance. Lesions may be sparse or diffuse They are generally multiform discrete and comparatively painless, and are never vesicular Because of their multiformity and range of distribution, the lesions may simulate those of many other dermatoses. Syphilids possess certain peculiarities which when considered collectively usually suffice to render clinical recognition possible. They generally develop slowly and in successive crops, which, owing to the tardy disappearance of the preceding lesions, tend to overlap During the exanthematous stage the distribution of the lesions is more or less symmetric, but later especially in relapsing cases, the eruption is often scanty and may involve only certain small areas, favored sites being the nasolabial folds the palms and the upper margin of the forehead. In late stages, the lesions tend to appear in groups and serpiginous and arcuate forms are common. They are usually reddish brownish red or coppery in color Accompanying symptoms often include lymph node involvement cephalalgia, laryngitis and pharyngitis, and eroded papules or mucous plaques in the mouth and other orifices. In the scalp early syphilis may give rise to patchy moth eaten alopecia. Gummatous lesions of the scalp cause cicatrization and permanent alopecia. The nails may be affected at any stage of the disease The

Fig. 496.—Macular early syphilid (Dr J Lamar Callow y)

Fig. 497.—Secondary syphilis

Fig. 498.—Miliary follicular syphilid. (Dr L. W. Ketron.)

forefinger is a likely extragenital site for the chancre. Late syphilids may occur in the nail bed with deformity of the plate Inflammatory or ulcerative paronychia may result

Macular Syphilid.—This is the earliest of the so-called secondary manifestations. It corresponds to symptomatic roseolas of other infections. The eruption is general and symmetric, and usually appears within 3 to 6 weeks after the chancre. The lesions are fairly uniform discrete, erythematous, oval macules. They range from 0.5 to 2 cm. in diameter The sites of predilection are the abdomen sides of the trunk, arms and palms and soles, although no region is exempt. The roseola may be more readily seen at a distance than when close to the examiner It gives rise to no symptoms. It may disappear spontaneously Occasionally it is followed by slight, temporary pigmenta

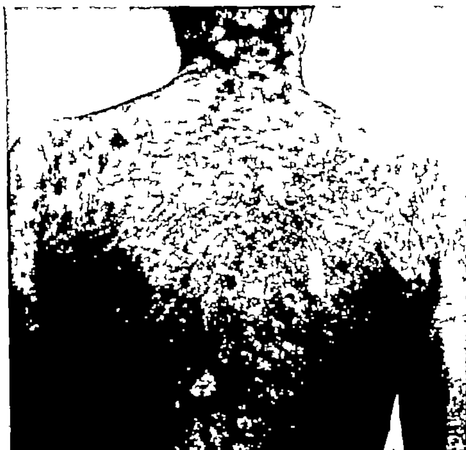

Fig. 193.—Psoriasiform syphilid. (Dr O. G. Costa.)

tion. Recurrences are rarely noted, the lesions being scanty in number segmented or circinate in outline and located usually on the forearms, thighs, and buttocks. If the disease has not been recognized treated, and so caused to recede or if it does not recede because of the autochthonous development of immunity the macules instead of disappearing may undergo further proliferative changes so that macules, maculopapules, papules, and pustules coexist.

Neurosyphilid of Unna.—Persisting roseola-like lesions, sparse nonspreading and capable of progressing 1 to papular lesions or regressing to leave pigmentation, constitute the neurosyphilid of Unna (abs JCutVenDis 8 31 1890; Hall and Schaerrer: ADS 30: 861, 1934)

Vitiligoid and Pigmentary Syphilids.—Melanotic hyperpigmentation of the skin occurs in and near syphilitic lesions, especially when they heal. Vitili-

Fig. 300.—Secondary syphilis, simulating dermatomycosis. (Dr Roy I S Montgomery)

Fig. 301.—Circinate squamous syphilid of arm. (Dr Samuel Sweltzer)

Fig. 302.—"Neurosyphilid" of Ulna. (Dr H H Hazen)

gold depigmentation occurs usually on the back and sides of the neck, consisting of oval ill-defined asymptomatic pigment free patches with hyper pigmented areolae These spots are not pathognomonic. Most of the cases occur in young women. The course is rarely influenced by antisyphilitic treatment (Chargin ADS 2 108 1920)

Papular Syphilid.—For purposes of description, papular syphilids may be subdivided conveniently

Fig. 443 —Papulopustular syphilid. (Dr O L Castle.)
Fig 104 —Pustul syphilid. (Drs. J B. Kessler and J C. Kessler)

Miliary Papular Syphilids are follicular The lesions which are pin point to pinhead size firm acuminate or rounded reddish papules, develop in crops. They tend to be grouped and are generally most abundant on the upper part of the trunk and arms. The eruption is commonly mixed a few lesions presenting summit pustulation and large flat-topped papules commingling with those of the small or large acuminate type In the moist genital and anal regions, the papules tend to be of larger lenticular type and the buccal mucosa is commonly the site of few or many mucous patches.

Lenticular Papular Syphilids may develop closely following the macular eruption, and both types of lesions may be intermixed. The papules are pinhead to bean size or larger brownish or reddish in color with a smooth shining surface which later may become covered with a thin, grayish scale The larger ones are generally flattened and nummular The lesions may be generalized but the sites of predilection are the forehead, face especially the buccal commissures and nasolabial folds, and genitals. They may be discrete or grouped but do not coalesce Pustulation with the formation of papulopustules may supervene

Fig. 505.—Mucous patches. (Dr Sweitzer.)

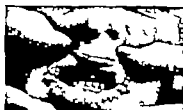

Fig. 506.—Syphilitic split papules. (Dr H. E. Michelson.)

Fig. 507.—Condylomata lata vegetative moist syphilid involving female perineum. (Drs Fordyce and MacKee.)

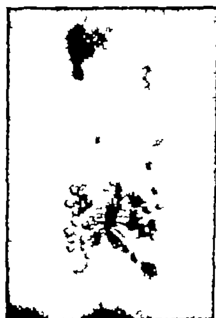

Fig. 508.—Moist papules about the anus.
Fig. 509.—Condyloma latum in left inguinal region, resembling blastomycosis. (Dr Robert N. Andrade.)

PAPULOSQUAMOUS SYPHILID (SQUAMOUS OR PSORIASIFORM SYPHILID).—The lesions are flattish discoid and scaling and may form psoriasiform patches. The papules are dark red and infiltrated with dry grayish adherent scales. The eruption is usually a late or relapsing one of limited distribution. Serpiginous and especially annular configuration is often seen. Concentric and arcuate lesions may develop. The face, scalp, neck, palms and soles in the later stages of the secondary period are the sites of predilection.

MOIST PAPULAR SYPHILID.—As a result of heat and moisture, friction, and maceration, flat papular syphilids in some regions undergo alterations in size and shape. The usual sites for the development of moist papules are the genital, anal and umbilical regions, axillae, buccal commissures, interdigital webs,

FIGS. 310 and 311.—Moist condylomatous and papular vulvar and perianal syphilids, in both cases dark-field positive. (Original of Dr Charles B. Stevenson, from Crossen: Diseases of Women, Mosby ed. 10 1953.)

apposing surfaces of the toes and submammary folds in women. The lesions begin as ordinary flat papules but as a result of their environment become flattened, macerated and covered with a thick mucoid exudate. Ultimately the lesions may become papillomatous. Vegetations occur in the anal and vulvar regions, especially in dirty persons. Purulent matter collects in the interstices of the cauliflowerlike masses, and they stink. Condylomas are moist, flat papules in the anal region which may be mistaken for hemorrhoids, but the general condition of the patient and the presence of syphilitic manifestations elsewhere should serve to prevent error.

PSEUDOSYPHILIS PAPULOSA, described by Lipschütz in 1921, is manifested by an eruption of grouped papules, small in size and asymptomatic, occurring in nonsyphilitic women about the anus and labia, curable by simple cleanliness (Höcker: DWchr 99: 1469, 1934).

Fig. 512.—Annular syphilid. (Dr Lloyd W Ketron.)

Fig 513.—Annular syphilid. (Dr Henry H Hazen.)

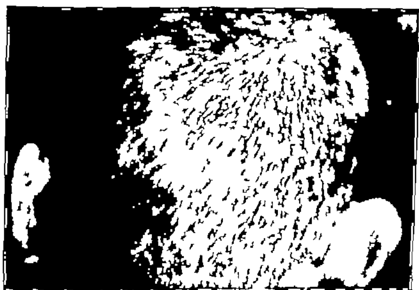

Fig 514—Syphilitic alopecia, showing "moth-eaten" appearance (Drs John A. Fordyce and George M MacKee)

Mucous Patches are flattened, wet abraded syphilitic lesions. They may appear on any mucous surface and are of common occurrence on the oral labial, anal, and vulvar mucosae. The lesions are rounded, flat, grayish superficially ulcerated and teeming with spirochetes. One has a clear grasp of syphilis of the mouth if one bears in mind the fact that lesions there are those which occur on the skin modified only by the influences peculiar to their location.

Fig. 515.—Vitiligoid syphilid.
Fig. 516.—Atrophy and marginal pigmentation of syphilitic scarring.

Fig. 517.—Depigmentation due t maculopapular secondary syphilid in Negro.

Syphilids of the Palms and Soles are usually dry in both the secondary and tertiary stages of the disease Owing to the density of the corneum the appearance of the lesions is considerably modified Macular eruptions of the palms and soles occur as part of the general roseola but papular and nodular forms may be more or less limited to volar regions, especially in relapsing cases. Symptoms are usually absent aside from inflexibility but painful fissures may develop Macerated with sweat, interdigital lesions may simulate dermatophytosis (Dexter ADS 63 581 1951) Wartlike lesions of the volar skin are occasionally seen, constituting the syphilide cornée (Saunders and Youngstrom AmJSyph 34 361 1950) Similarity of the volar lesions of syphilis to those of keratoderma punctatum was interesting in the case of Kerdel-Vegas et al. (BJD 66 449 1954) Compare Pinta, Fig 456 p 375

Atrophy may follow the lesions of secondary syphilis, just as it characterizes the scarring of late lesions. It manifests itself in soft, atrophic macules which may be elevated or depressed, in the distribution of the eruption on which their existence depends (see macular atrophy) Destruction of elastic tissue by the pathologic process is the cause of the lesion. Syphilis is not the only possible cause of macular consecutive atrophy (q v Scull and Nomland ADS 36 809 1937)

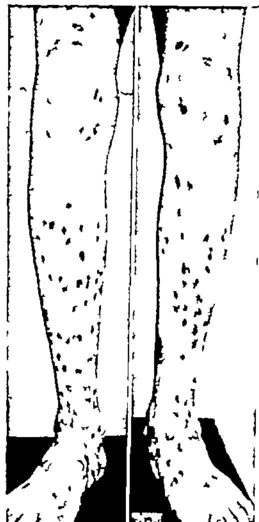

Fig 518.—Secondary syphilis.

Fig. 519 —Secondary syphilis.

Pustular Syphilids may be separated into groups

SMALL ACUMINATE PUSTULAR SYPHILID —The lesions are generally follicular and tiny, and they are likely to be seen along with ordinary acuminate papular syphilids. The pustules are discrete conic, numerous, and symmetrically distributed over the trunk and extremities. They commonly occur during relapses, especially in cases insufficiently treated. On disappearing they generally leave temporary stains and occasionally small scars.

LARGE ACUMINATE PUSTULAR SYPHILID —The lesions, sometimes termed the acneiform syphilid, are pea size or larger discrete, acuminate pustules which are located at the follicular orifices and generally involve the face trunk and limbs. Occasionally the eruption strikingly resembles smallpox and is called a varioliform syphilid The lesions usually develop slowly and in crops. They may be grouped but as a rule they are scantily distributed over the whole body being most profuse on the face

FLAT PUSTULAR SYPHILID.—Lesions of this variety impetiginoid and ecthymiform syphilids, are flat, pea to dime size yellowish or brownish, superficial pustules. On the scalp trunk and extremities, the eruption is usually scattered, but predilection is noted for the face and the genital and anal regions. Large acuminate papules and large flat pustules may be present along with macular elements. The crusts are oval or irregular in outline and of various

Fig 525 —Corymbose papulosquamous syphilid of 6 weeks' duration. (Dr J. R. Shelmire.)

thicknesses. Underlying ulcers are superficial and only slightly inflamed or less commonly deep and crateriform with purplish congested areolae Con fluence of lesions may give rise to the formation of extensive crusts. Crusting and ulceration may be conspicuous in early malignant syphilis, constitut ing the rupial syphilid (Thetford and Callaway UCutRev 44 306 1940)

PUSTULO-ULCERATIVE SYPHILID.—The destructive factor is pronounced and the lesions are brownish or purplish in color with infiltrated bases and thick crusts overlying seropurulent exudate, the rupial syphilid.

Diagnostic Features of Secondary Syphilitic Eruptions are

Multiplicity of lesions.
Widespread distribution even if the lesions are few
Discreteness.
Polymorphism: contemporaneous macules papules pustules, ulcers and scales.
Tendency to form circular annular oval, or reniform lesions.
Tendency to group in crescentic, serpiginous or corymbiform arrangements.
Absence of itching, except in follicular eruptions, which itch.
Absence of pain except in digital and infected ulcers.
Involvement of the mucosae, and sore throat.
Generalized lymphadenopathy in which the nodes are painless, small and discrete.
Constitutional manifestations: malaise anorexia, fever headache aching weight loss.
Positive serologic reaction.
Positive dark field.

Fig. 114.—Papulosquamous, lat syphilid of palm.

Seronegativity in secondary syphilis probably does not occur negative reports being representative of diagnostic or laboratory error (Kuhl and Sauer JID 18: 191, 1949)

In primary and secondary cases, spinal fluids showed abnormality in about 5% of the cases (Bauer et al. AmJSyph 36 309 1952) Patients with negative CSF responded to treatment with reversal of STS better than those with abnormal CSF yet, of the latter group, 86% become negative with respect to the CSF on penicillin. When the spinal fluid failed to respond to treatment about half the cases proved stationary while the other half progressed and showed serologic or infectious relapse.

Tuberculoid or Nodular Syphilid occurs late in the course of the disease seldom before the end of the first year and usually in the third or fourth. From both clinical and histologic standpoints, it is gumma of the skin. Lesions range from pinhead to large pea size They are limited in number and are seldom of general distribution. Sites of predilection are the face especially the forehead, scapular and interscapular regions and extremities. Syphilids of this variety exhibit a strong tendency to form groups and to coalesce with the formation of arcuate reniform and serpiginous patches.

Syphilitic tubercles are smooth rounded, circumscribed elevations, reddish or brownish in color and firm in consistency developing slowly and persisting for weeks or months. Tubercles may disappear with or without ulceration, but there is always scarring The cicatrices in the absence of

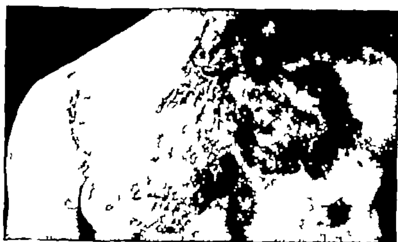

Fig. 527—Serpiginous nodular ulcerative syphilid. (Drs. Kessler and Kessler.)

Fig. 528—Nodular circinate, squamous syphilid. (Dr Grover W Wende.)

ulceration are rounded, atrophic and of mottled hyperpigmentation and depigmentation. In ulcerative cases they are thin glazed and *parchmentlike* occasionally with some scaling New lesions spring up at the borders of the plaques and may undergo regression only to be replaced marginally by fresh ones. So areas of large extent may be affected in the course of years.

Gummatous Syphilid.—In malignant syphilis gummatous lesions may develop early in the disease but as a rule they do not occur before the second year. Gummas are single or multiple, firm rounded, infiltrated granulomas which involve epidermis only secondarily. They are seen as reddish bluish

or brownish pea to walnut size or larger, circumscribed, oval tumors, which may undergo absorption but *generally ulcerate with the formation of soft, sharply defined, punched-out, notably painless sores.* The ulcers are reddish or purplish in color with flabby, necrotic edges and red sometimes greenish, granular floors bathed with mucinous pus. They may involve only the dermis and epidermis, but *subcutaneous tissues are generally attacked.*

The peak incidence of gummatous lesions lies in the first three years following infection, after which there is a sharp drop (Fournier quoted by Wiggall and Hahn AmJSyph 33 270 1949) Yet isolated examples may appear many years, *even as long as 60 years after infection generally being* then associated with neurosyphilis.

Gummas are commonly single but may be multiple The usual sites are the thighs, buttocks, calves, forehead and scalp No region is exempt. *Trauma often determines their location* (Hlgoumenakis abs AmJSyph 24 662 1940) Following an injury to a syphilitic individual, the granuloma may develop instead of physiologic inflammation and healing Diseases as well as injuries serve to localize syphilitic inflammation, and seborrheic dermatitis *may promote the localization of superficial syphilids.*

Fig 534 —Gumma of nose.

Fig 535 —Gumma of buttock.

Ulcerative destruction and *disfigurement are great, especially if the face* is involved An amazingly destructive facial lesion resulting in death was described by Wilhelm and Scholtz (ADS 34 242, 1936) Plastic surgery in the treatment of nasal deformity was discussed by Cinelli (*Laryngoscope* 50 520 1940)

While gummas are here described as they appear in the skin they may affect any organ of the body such as the brain where their presence causes *symptoms of tumor* The location determines the symptoms. In the breast the lesion simulates carcinoma (Braunstein and Woolsey AmJSyph 24 43, 1940) See Osseous syphilis and Visceral syphilis.

See Schmidt et al (AmJSyph 34 182, 1950) penile ulceration, Raich and Nechtow (J 135 347 1947) spinal lesion simulating cancer, Kierland and Underwood (AmJSyph 32 491 1948) gummatous myositis *Laird* (URVD 21 182, 1945) thyroid gland Palmer (AmJSyph 33 481 1949) gumma of stomach.

PRECOCIOUS GUMMA —In malignant precocious syphilis, gummas may develop within a few weeks instead of months or years after infection.

JUXTA-ARTICULAR NODES, or fibroid gummas, are rounded or polylobed firm painless lesions occurring within or beneath the skin in the region of the joints (Greenbaum and Cohane AmJSyph 18 269 1934) They occur in late syphilis in both sexes at any age evolve slowly resemble xanthomas, are associ

Deformed Types of Syphilis are those in which inadequate treatment has altered to some extent the expected course of the disease. One must treat seronegative primary cases adequately for with abortive treatment these cases

Figs. 550 and 551.—Facial destruction due to late syphilis in a woman 42 years old. (Dr John W. Perkins.)

Figs. 552 and 553.—Witkop. (Dr Alexander Mitchell, of Pretoria, South Africa.)

relapsed within 90 to 190 days. Early tertiary syphilis after inadequate treatment is likely to result in serious destructive lesions. When gonorrhea and syphilis are both acquired at one time and a small amount of penicillin cures the former then syphilis may appear later with deformed manifestations

(Hailey ADS 50 269 1944) Syphilis so masked may be detected by following the patient with monthly serologic tests for 3 months (Iefer and Martin J 130 202 1946) The lesions of scabies may obscure the diagnosis, its lesions influencing the distribution and appearance of the secondary eruption (Rattner J 131 1241 1946) See Gougerot (J 104 935 1935)

While penicillin given for another diagnosis often confuses the diagnosis of syphilis (Sternberg and LeVan AmPract 3 720 1949) many of the other antibiotics are capable of doing this too

Latent Syphilis.—Patients who have clinically unrecognizable syphilitic infection, with blood serologically positive and spinal fluid normal fall into this class. If no previous treatment has been given or if treatment has been inadequate then adequate treatment should be given Cooperative Clinical Group studies have shown that without treatment the outcome over a period

Fig. 554.—Syphilitic juxta-articular nodes (Kalz and Newton ADS 48 626, 1943.)

Fig. 555.—Bilateral syphilitic bursitus of Verneuil, showing gelatinoid content of ulcerated bursa. A very rare condition. (Dr John D. Lane.)

of years is favorable in 35% but with proper treatment 85% follow a satisfactory course and only 2 to 5% as contrasted with 20 to 30% of the untreated group actually encounter progression.

Progression of the disease in latent syphilis was estimated in a long term study of 926 cases by Diseker et al. (AmJSyph 28 1 1944) Progression was not more frequent among seroresistant patients than among those whose tests reversed in the first year of treatment Benign late syphilids occurred in 2.2% cardiovascular syphilis in 2.2%, and neurosyphilids in 1.5% of the treated cases. The outcome was satisfactory in 94% of the patients. The highest proportion of the progressions occurred among patients who received less than 15 doses of arsenicals. The system of treatment had little effect on the outcome There were 43 deaths in the group and none of these was thought due to syphilis. The optimum treatment reducing the likelihood of

progression to the minimum was about 20 doses of an arsenical and 20 doses of bismuth More than that amount of treatment did not pay off in improvement of the results from the patient's standpoint.

See Stokes et al. (AmJMSc 206 571, 1943) Chargin and Rosenthal (J 107 1274, 1936) fluctuation of serologic tests, O'Leary (NEngJM 221: 764, 1939) criteria of latency; Jordan and Dolce (ADS 34 1 1936) 10-year observations of 189 cases, Harnett et al. (ADS 69 91 1954) progressions despite treatment more frequent among Wassermann-fast cases than among those showing serologic response Chester et al. (AmJSyph 38: 7 1954) patterns of reduction of seropositivity after penicillin treatment.

Osseous Syphilis.—In the secondary stage syphilis commonly gives rise to aching of joints and muscles. Arthritis with limitation of motion but not much swelling or accumulation of fluid, may affect a particular large joint in early syphilis. Periosteal changes usually too slight to show on x ray examination, may appear locally as tender lesions in early syphilis. Verifiable osteitis in early syphilis is similar to that occurring commonly in late benign syphilis (Newman and Saunders NYSJM 38 788 1938 Squires and Weiner ADS 39 830 1939 Reynolds and Wasserman AIntM 69 263 1942) The skull is the usual site especially the frontal, parietal, and nasopalatine bones the sternoclavicular site is next in frequency and the long bones last. Pain and local tumor respond well to specific treatment penicillin being notably effective (Naffziger et al. J 131 1183 1946) Lesions of the skull in secondary syphilis are not rare if they are sought roentgenologically in all cases 7 of 80 secondary cases manifesting them in the experience of Thompson and Preston (AmJSyph 36 332 1952) Head injury apparently determined the site of osteomyelitis of the skull in 2 cases which proved promptly responsive to penicillin (Thompson and Hailey AmJSyph 33: 34 1949) See also Congenital syphilis, osseous (p 460)

Gangrene of a digit without signs of peripheral vascular syphilis was diagnosed by demonstrating spirochetes in the affected vessel tissues by Moynahan (BJVD 24 104, 1948)

Cardiovascular Syphilis designates the practical concept of syphilis of the aorta with the cardiac changes secondary thereto (Kampmeier Essentials of Syphilology Lippincott, 1943)

Diffuse myocarditis occurs and is clinically manifested by impaired myocardial function, with palpitation, precordial discomfort, dyspnea on exertion possibly failure. Diagnosis is by exclusion of other possible causes in an inadequately treated syphilitic patient (Mattman and Moore AmJSyph 27: 711, 1943) Gumma may occur in the myocardium, giving evidences of its existence that depend on its location and size.

Aortitis is the common cardiovascular lesion. While invasion of aortic tissues occurs early probably clinical manifestations develop only after some years. The pathologic lesion is the usual perivascular one the vasa vasorum being affected and the wall of the great vessel thereby weakened, scarred and allowed to dilate (Howe AmJSyph 27: 50, 1943) The intima shows longitudinal creases or striation, thickened patches of bluish-gray overlying active disease subsequently to be replaced by depressed scars. The aorta becomes dilated and lengthened, and, since the root of this vessel is the usual site of the process, dilation of the aortic ring occurs with separation of the valve leaflets, and aortic insufficiency as a result. The valves themselves may be involved so that their edges become rolled and thickened. The orifices of the coronary arteries may suffer Thus, by degrees and extent of involvement and by location of the pathologic process, the results of syphilis of the aorta are classed as uncomplicated aortitis, aortic insufficiency and aneurysm.

Necropsy studies of aortas from 45 syphilitics who had and who had not received adequate antisyphilitic treatment showed that few of the former but all of the latter had histologic lesions of active syphilitic aortitis (Webster and Reader AmJSyph 33 19 1949) The aortic lesions in the gross are uneven thin and serpiginous or annuliform, closely resembling the analogous lesions of the skin.

The clinical diagnosis of uncomplicated syphilitic aortitis was discussed by Moore (AmJSyph 33: 43, 1949) Most patients with old syphilis may be assumed to have subclinical aortic disease but opinions conflict regarding what proportion of these develop sufficient clinical evidence to justify the diagnosis. This is based on fluoroscopic demonstration of dilation; increased density and loss of elasticity of the first portion of the aorta lowered cardiac reserve in the absence of hypertension or valvular disease, paroxysmal dyspnea or dyspnea on exertion; localized substernal pain which is typically dull aching relatively inconstant, not influenced by exertion and not referred down the arm; and changes in the second aortic sound, accentuation and alteration described as tympanitic, bell-like or of tambour quality The diagnosis rests on the combined evaluation of relatively insignificant symptoms and signs, and on expert radiologic study Cardiac involvement in congenital syphilis is almost completely nonexistant.

Uncomplicated aortitis was diagnosed in 141 of 547 patients with cardiovascular syphilis by Rich and Webster (AmHJ 43: 321, 1953) The average age was 51 years. Males predominated both in the white and the Negro patients. Of the 141 cases, 15% developed insufficiency or aneurysm within 2.5 years, but their prognosis was no worse than that of the group as a whole and was not affected by the age of the patient at the time the diagnosis of uncomplicated aortitis was made

In aortic insufficiency due to syphilis, the clinical course was divided into 4 phases by Montgomery et al. (AnnIntM 37: 659 195-): (1) the period of aortitis dating from invasion of the aorta until the development of an aortic murmur; (2) the period from the first appearance of aortic diastolic murmur until the appearance of the earliest symptoms of decompensation a period apparently both short and asymptomatic and probably to be estimated as 6 months, more or less; (3) the period from the earliest symptoms of congestive failure until severe congestive failure was present, which in about ¼ of the patients required only some 6 weeks to progress from exertional dyspnea to marked peripheral edema and (4) the period from marked congestive failure to death, which averaged bout 1.5 years. Thus the average length of life after the first appearance of a murmur and the initial manifestations of failure was about 3 years.

Aortitis in more than 1,000 patients followed for 20 years was studied by Webster et al. (AmJSyph 37: 301 1953) Patients free from symptoms at the time diagnosis was made survived considerably longer than patients diagnosed after symptoms had appeared, but of this latter group 29% survived for 10 years or more. Absence of angina and bsence of decompensation were favorable with respect to survival. Some 75% of those who died succumbed to cardiovascular disease The effectiveness of treatment could not be assessed from the data.

The EKG in uncomplicated aortitis or aneurysm shows nothing while aortic regurgitation induces the changes of left ventricular hypertrophy and syphilitic stenosis of the coronary ostia ind ces those of myocardial fibrosis, the ch nges being not of a fixed pattern (Cole and Bohning: AmJMSci 207: 317 1944)

Neurosyphilis was concomitant in some 17% of 123 cases of cardiovascular syphilis studied by Dressle (ConnSMJ 9: 844 1945)

Serologic tests in cardiovascular syphilis were studied by Beckh (AmHJ 25: 207 1943) who found wide discrepancies on this subject in the literature In 100 cases diagnosed at autopsy, STS had been positive in 88% of those with aortic insufficiency and in 86% of those with uncomplicated aortitis. In his cases diagnosed clinically, 96% had positive STS, or had rece ved antisyphilitic therapy or had a clear history of syphilitic infection.

In the treatment of cardiovascular syphilis, it was at one time thought necessary to induce slow rather than abrupt, involution, avoiding Herxheimer reaction and therapeutic paradox. Long preparation with bismuth, mercury and iodides was the practice. Tucker and Farmer (AIntM 80 322, 1947) gave full doses of penicillin at once and did not see severe reactions, the dangers of which they judged had been overrated.

The absence of ill effects of i itial full dosage with penicillin has been ttested by many uthors, luding Flaum and Thomas (AmHJ 38 361, 1949); Bunsek (NYSJM 49: 2176 1949); Edeiken et al. (AmJMSc 217 475, 1949; Circ 1: 1355, 1950, 2: 767 1953); Coale et al. (JK asMS 51: 102 1950); Bruetsch (AmJSyph 35: 253 1951); Wheeler and Curtis (AmJSyph 35: 319 1951); Stokes et al. (J 147 944, 1951); Kampmeier and Morgan (Circ 5 771, 1952)

Penicillin therapy was adjudged harmless by Beerman (AmJMedSci 224: 446 1952) whose review was exhaustive, and its safety was attested also by Edeiken et al. (AmJSyph 37 237, 1953) No harm was observed by Eisenberg and Brandfo brener (AmJSyph 37: 439 442, 1953) in whose 43 cases of uncomplicated aortitis no progression of disease took place afte treatment and in whose 167 cases of insufficiency and 11 cases of saccular aneurysm, 63% noted subjective improvement after penicillin therapy

Untoward effects have been reported (Dolkart and Schwemlein: J 129: 515, 1945) Sudden dilation of an aneurysm followed penicillin and was fatal to the aged Negro patient f Diefenbach (NEngJM 241: 95 1949) A young woman with aortic insufficiency died from the Herxheimer reaction within 24 hours of her first dose of penicillin (Whorton

and Denham: AmJSyph 35: 253 1951) Coronary occlusion was fatal after penicillin was given because of an upper respiratory infection in the case of Butterly and Fishman (J 143 3 0 195_)

Patients who have had previous antisyphilitic therapy may receive penicillin without hazard while the hazard in unprepared patients i so slight it may be stated, a to be disregarded. The dose should be high a total of at least 0 000 000 u. being recommended. Penicillin will take out the spirochetes and the active inflammation but it cannot heal a scar Evaluation of its utility was attempted by Padget et al. (AmJSyph 34: 319 1950) but the data then available we e not decisive. Therapy was judged probably to have improved the prognosis to some extent in any stage of aortic syphilis, definitely more effective if given before the onset of symptoms, then progressively less beneficial by Barnett and Small (AmJSyph 34 301 1950) Histologic studies of patients who received penicillin prior to death showed signs of healing of syphilitic inflammation of the aorta if the antibiotic had been given 10 weeks or longer prior to death (Sinclaire and Webster AmJSyph 38: 54, 1954) Evaluatio of the benefits of therapy is difficult as Johnson et al. (ADS 70 799 1954) pointed out; their patients were only doubtfully better off 5 years after receiving 4,000 000 units of penicillin than if they had been treated with heavy metals and arsenic. They thought 10 000,000 units might have been more advantageous.

The Cooperative Group (Cole et al.: J 108 1961, 1937) reported as follows. *Of the approximately 500,000 syphilitics in the United States who seek treatment for the first time late in the course of their disease about 50 000 have detectable cardio ascular syphilis. Of this type of involvement 7% occurs within 5 years of the initial infection; it is late in onset Best treatment is prophylaxis. The disease must be treated gently to avoid therapeutic paradox. Uncomplicated syphilitic aortitis is present in 49% of patients with latent or late syphilis.* It i 3 times as common in the Negro as in white persons. The Wassermann test is positive in 7?% and the spinal fluid is abnormal in 49% of the cases. Of 933 patients with early syphilis followed 3 to 10 years, 1 6% developed cardiovascular invol ement of 103 followed 10 to ?0 years, 6 7% developed it. In the 3- to 10-year group not one developed cardiovascular disease if he had been adequately and regularly treated in the early stages of the infection. If aortitis is clinically evi ent, treatment improves the outlook, more than doubling the expectancy Start with a course of metal and use small doses. Aortic regurgitation is seen most often afte ?0 to 30 years nd is associated in 6 % with spinal fluid abnormality In it, 69% had had no previous antisyphilitic therapy and in the remainder treatment had been gi en irregularly and late The average length of life if the heart was in failure before treatment began, was 30 months if not a fa l re 47 months. In 74 cases of aneurysm, 80% of those of the saccular t pe occurred in pat ents 15 to 3 years after infection. Wassermann tests we e posit ve in 90% pinal fluid was abnormal in 64% and clinical neuros phili wa associated 31% No treatment had been rece ved by % Symptomatic relief wa obtained through treatment i 44% those inadequately treated l ved on an average 3? month after diagnosis, whi e those adequately treated lived 75 months.

Details of the internal medical aspects of cardiovascular syphil s will be fou d in such texts as Moore s and Stokes's. Cardiovascular syphilis is largely pre entable by adeq ate treatment of ea ly syph lis (Thompson et al. AmHJ 17 _56, 1939) Rupture of the aorta is a l kely and dramatic catastrophe in a syphilitic with aneurysm.

See Dressler and Silverman (AnnIntM 19 224 1943) early recognition Schamberg (AmJSyph 30 88 1946) in young dults Hu et al. Visceral Syphilis.—Practically every organ is subject to syphilitic damage in either the early or late stages of the infection.

The Lung.—H d log m n festat are those merely of bronic pulmon ry i fection resembling t ber ulosi (W lson AnnIntM 25 134 1946) Exten i e lu g in ol em t wa present a man w th me ingovascula neurosyphilis at died b Librach (BJVD 26 1?0 1950) M l r t berculoid syph li wa found n tw patie t wh nder went ecropsy (Gadek Kl nWehs 28 41 1950) Pleurisy with effu i n occurred in a case of ea ly syph li a most unusual manifest tion reported by Calsan (Tubercle 30 ?60 1949) The lung m y be affected i late benign syphilis, roe tgenograms showing localized shadows or a more w desp ead process. Resemblances to cancer resulted in lobectomy in the patient of Bradley (ADS 55: 444, 1945)

Syphilis of the lung recognizable as such is rare, and it responds quite satisfactorily to penicillin (Kulchar and Windholz: AmJSyph 31: 166, 194).

THE STOMACH.—Gummatous involvement is rare and is difficult to distinguish from peptic ulcer but it is responsive to specific treatment although deformity may require surgical intervention. Infiltrative, ulcerous and tumor types are described, and gross deformity may result (Palmer: AmJSyph 33: 451 1949) Diagnosis is suggested by gastrointestinal compl ints in a patient below the cancer age with hypoacidity and positive STS. The characteristic x ray deformity is f nnel-shaped or hourglasslike the pylorus remaining open because of stiffened wall which interfere with or prevent peristalsis (Bell AmJSyph 33: 234 1931) See Udaondo (Les Gastropathies des Syphilitiq es, Masson, 1936, p. 16)

THE LIVER is commonly affected with late benign lesions of the tertiary sort. Hepatic gummas destroy blood vessels and induce fibrosis. Resolution is followed by deep and extensive scarring The dense scars are generally stellate and deforming, and the organ may be subdivided into lobes hepar lobatum Patients may be asymptomatic, or may have an uppe abdominal tumor usually firm, with low fever attributable to necrosis within the gummata or there m y be slight icterus epigastric pain and tenderness, and ascites simulating portal cirrhosis. The live may be smooth because the nodules are within it or it may be nodular with palpable firm tumors. See Hahn (AmJSyph 27: 529 1943)

Reviewing 9 cases of syphilis of the liver proved by autopsy, Shapiro and Weiner (AmJMSci 222: 494, 1951) noted that the gumma i the characteristic late lesion. The liver may be increased in size but is often decreased. In 62% of the cases the liver was of normal size, while 9 livers exceeded 2,800 grams in weight. The location of the lesion depends on chance, but it determines the progres and sequelae. Nea the surface and distant from the hilum, the lesion does little harm, but a sca close to the hilum is l kely to result in portal hypert nsion, ascites and fatal esophageal varices. The age ra ge was from 22 to 90 years, but the peak incidence was in the sixth decade males and females being equally affected. Of the 79 cases 27 died of syphilis and the cause of death in 70 of them was bleeding from esophageal varices. Hepatic syphilis caused death in 13 cases. Syphilitic involvement of other organs was demonstrable in 39% Only 1 patient was febrile The combination of hepar lobatum and nutritional cirrhosis practically assured the development of portal hypertension. Vascular spiders were present in only 4 patients, 3 of whom were alcoholics. J undice was present in 13 cases, in 10 of which the icterus index was below 20

Jaundice duri g antisyphilitic therapy is confusing for arsenical into ication m y induce it, and infectious hepatitis may occur especially if the virus thereof is inoculated in a treatment clinic by a break of aseptic technic (Mitchell CanadMAJ 48 94 1943; Anderson: BJVD 19 58 1943) It pparently i safe to continue bismuth therapy d ring such jaundice (Forbes: BMJ : 83 , 1944) The low incidence of jau dice in unt eated syphilis of the liver points to its arsenical etiology in t eated cases (Wile and Sams AmJMSci 187 297, 1934) The case of acute yellow atrophy i early philis reported by Zellermayo (VDI 1: 205 1940) was appa ntly due to Mapharsen. See Irgang (ADS 36: 635, 1937); Dermatitis medicamentosa, arsenical, jaundice.

Syphilitic h patiti in early yphilis responds sat sfactorily t arsenicals, according to Leonard (AmJMSci 208 461 1944) who reported a death from acut yellow atrophy in a jaundiced gi l with the secondary rash who had a Herxheime reaction followi g the first dose of rsenic, the becam more j ndiced. When late syphili of th liver was symptomatic, excellent improvement followed the use of penicillin in the patients reported by Tucker and Dexter (AIntM 58 312, 1946)

THE KIDNEY.—Early syphilis occasionally induces a nephrosis in which the uri e is grossly abnormal but function tests are not much altered. The abrupt onset of symptoms, progressive weakness, with anemia, severe edema, massive albumin ria, but little malaise, and dramatic response t therapy were noted n cases by Ola kv a d McCormick (JVDI 28 45 1947) Syphilitic nephrosis may occur n congenital syphilis (Scully and Yamashi: AmJDisChild 77: 652, 1949) Early syphil tic nephropathies heal promptly under intensive specific therapy and leave no sequelae (Thomas and Scharr AIntM 75 679 1946; Scott and Cla k AmJS 30 463, 1946)

Prost tic involvement was reviewed by Bini (AitalD 22: 339 1949)

Ocular Syphilis.—The conjunctiva may be the site of the primary sore. Iritis occurs in perhaps 4% of cases of early syphilis chorioretinitis is un common but occurs in the late secondary stage uveitis with secondary keratitis in late acquired syphilis carries a serious prognosis (Woods AmJSyph 27 133 1943)

Changes in the iris were described in detail by Lowry (SoWM 2 14 1941) Syphilis as a cause of blindness showed no decrease in incidence be tween 1939 and 1948 (Freeble and Donohue J 146 1500 1951)

Chemotherapy combined with fever is effective in acute iritis, interstitial keratitis and syphilitic choroiditis, especially the early cases noted Knight and Schachat (AOphth 35 271 1946) See Neurosyphilis, optic atrophy Treatment penicillin Congenital syphilis, interstitial keratitis.

Neurosyphilis.—*The central nervous system is invaded early in the course of the infection.* Abnormal spinal fluids were disclosed by Cooperative Clinical Group investigations (VDI 18 45 1937) in 25% of seronegative primary 30% of seropositive primary and 33% of early secondary cases. Abnormality may not be noted with standard methods of testing for inoculations into rabbits of apparently normal spinal fluid from patients with early syphilis gave positive results in 14% of the fluids tested by Chesney and Kemp (J 83 1725 1924) Despite the high frequency of spinal fluid evidence of neurosyphilis in early cases, clinical neurosyphilitic manifestations develop in a considerably smaller proportion of untreated patients estimated at from 5 to 10% There is no doubt that self healing occurs in many instances. Treatment adequate by prepenicillin standards in early syphilis reduced the probability of clinical neurosyphilis to 1 or 2% (Moore) but inadequate or irregular treatment was followed by higher rates of incidence If the spinal fluid remains normal for 4 years after infection, the development of neurosyphilis is extremely unlikely

The Central Nervous System is derived from mesodermal and ectodermal tissues. When syphilis primarily inflames the mesodermal meninges and blood vessels, it is called meningovascular When it primarily degenerates the parenchymatous ectodermal tissues, it is manifested as paresis if the brain is particularly affected, as tabes dorsalis if the spinal cord especially suffers, or as taboparesis if both are involved. Admixtures of these types of involvement are usual although acute meningovascular syphilis may produce only the central nervous system manifestations of irritation and toxic psychosis, both of which disappear entirely when treatment is successful. Tabes dorsalis may be present though inactive when the spinal fluid is entirely normal. Among untreated syphilitics, about 5% may be expected to develop paresis and 15% meningovascular syphilis (Moore) Persistently positive blood tests were associated in 74% of the instances with spinal fluid abnormality in the Cooperative Clinical Group material. But serofastness was not necessarily an attribute of asymptomatic neurosyphilis for in about one-third of the cases of early asymptomatic neurosyphilis under treatment the blood became negative yet there was a great tendency for these cases to relapse About 20% of late asymptomatic neurosyphilis showed negative blood tests so that the fact which deserves emphasis is that negative blood tests in treated syphilitic patients do not rule out the possible existence of neurosyphilis (Kampmeier)

Diagnosis of Neurosyphilis.—A high proportion of persons suffering with neurosyphilis are unaware that they ever had syphilis and are unaware that there is anything at all the matter with them Of those patients of Scherlis and Caravati (AmJSyph 30 330 1946) who manifested any detectable clinical abnormality and who were therefore classed as cases of symptomatic neurosyphilis, 86% had ocular abnormalities and 95% of these had abnormal pupils. The incidence of ocular abnormalities increased as the duration of syphilitic *infection increased. Competent ocular examination is a necessity in evaluating* a case of neurosyphilis, and includes the estimation of the visual fields, which may be reduced as the first indication of syphilitic damage of cranial nerves (see optic atrophy)

The diagnosis of neurosyphilis rests primarily on spinal fluid examination. The one spinal fluid test, of the several which standardly should be employed which is diagnostic of syphilis is the complement fixation test, precipitation reactions being little used and less reliable

The Complement Fixation Test must be done in several dilutions, standardly 1.0 0.5, 0.25 and 0.1 cc It is an error to omit the 1.0 cc dilution for many cases are found to be positive with 1.0 cc. yet negative in 0.5. It is desirable to titer the test to a negative reaction so that a base line may be attained for comparison with later findings. If positivity is found at 0.1 cc one desires to know the result with 0.05 which is not rarely positive and with 0.025. A change between consecutive spinal fluid examinations of only 1 dilution may not be significant but if positivity is found at 0.1 cc. at one time and later at 0.5 with 0.25 negative improvement may be estimated to have occurred. The reagin in the spinal fluid is generally of lower titer than in the blood (Wiener and Derby: Arch Neurol 39: 909 1939)

Misleadingly positive Wasserman reactions are indeed exceptional, although they have been reported in some cases of tuberculous meningococcic and lymphocytic meningitis (Scott et al.: AmJSyph 28 431 1944)

OTHER SPINAL FLUID TESTS are the cell count with differentiation of the varieties of cell a qualitative test for globulin the total protein in mg./100 cc., and the colloidal gold or mastic test. Interpretation of the significance of spinal fluid findings has been clarified by Dattner and Thomas (AmJS 26: 21 194) and by Dattner (Neurosyphilis, Grune and Stratton 1944)

ACTIVITY OF DISEASE is indicated especially by increased cell count, particularly when a high proportion of the cells are polymorphonuclear leukocytes, and by increased protein. In general the colloidal curve, a set of digits ranging from 0 to 5 and indicative of the intensity with which the colloid is influenced by serial dilutions of the spinal fluid, parallels the globulin content. Results are reported as 0000000000 negative or 5555554 100 (for example) first zone or paretic type implying the presence of much globulin, or 0002332000 (for example), "syphilitic" or "mid zone" suggestive of less intense reaction. Gold curves help in evaluating the fluid, but are the least significant part of the complete report. When under treatment a series of such curves are obtained and the 5's drop out improvement may be interpreted but many conditions other than syphilis such as meningitis, myxedema, and bloody fluid, also give rise to abnormal gold curves (Merritt and Fremont-Smith: Cerebrospinal Fluid, Saunders 1938) The presence of globulin found by the Pandy or Nonne-Apelt test is abnormal, but not diagnostic of syphilis. Total protein ought to be 40 mg. % or less and is often about 20 in normal fluid but is elevated by any kind of meningeal irritation. The cells of the spinal fluid are especially significant, and 0 or 1 or 2 lymphocytes per cubic millimeter are clearly normal, while 10 WBC is certainly not normal. The exact number of cells to be interpreted as normal or abnormal cannot be given but 5 is a commonly quoted dividing figure I have often seen neurosyphilis develop when the spinal fluid shortly after an "adequate" course of Mapharsen and bismuth showed 4 or 5 WBC, and neurosyphilis would probably have been identified by a Wassermann test using 1.0 cc., a procedure always to be requested of the laboratory When the cell count is high and contains numerous polymorphonuclear leukocytes activity is great. Counts of 100, 200 or more WBC are found in untreated meningovascular syphilis. The count drops rapidly under effective treatment. Low counts are usual in parenchymatous syphilis of the nervous system. The last abnormality to disappear when treatment of neurosyphilis is effective is usually the complement fixation test. Some fluids retain Wassermann positivity as a manifestation of neurosyphilitic latency when all other abnormality has dissipated.

Spinal fluid studies are almost sufficient of themselves in judging the requirement for further treatment (Dattner) If the formula becomes favorable, with diminution of complement fixation titer return of cell count and total protein estimations to within normal limits and improvement in the colloidal test, and if the formula remains so without relapsing, further treatment is unnecessary The spinal fluid cannot be induced to become entirely normal in all patients, by any means, although this is sought and prized if attainable (Thomas and Stokes AmJSyph 29 667 1945)

SPINAL FLUID IS TO BE EXAMINED IN EVERY PATIENT WITH SYPHILIS at some time during the course of his disease. The examination is not necessary in patients with fresh primary or secondary syphilis until they have undergone a course of adequate treatment for this suffices to clear the spinal fluid in a high proportion of the early cases associated with abnormal fluids. After the administration of adequate treatment in early syphilis, it is wise to wait a month or two to do the tap so that one can evaluate the spinal fluid formula when it is not being depressed toward normal by intensive therapy In late syphilis not diagnosed until, say 2 years or more have elapsed since inoculation, and in cases in which the date of infection is not known, spinal fluid examination correctly precedes the institution of antisyphilitic treatment as a necessary preliminary evaluation measure This enables the physician to know whether he is dealing with neurosyphilis or latent syphilis, the distinction being important.

It is further essential to know with what type of neurosyphilis the patient is suffering In only half the cases of neurosyphilis which occurred in the Army personnel studied by Scherlis and Caravati (AmJSyph 30 330 1946) was a trustworthy history of the approximate date of infection obtainable.

Spinal fluid examinations at intervals of 6 months are the best guide to the effectiveness of antisyphilitic therapy judged Dattner et al. (AmJSyph 36 179 1952) on the basis of long time observation of hospitalized patients. When the cell count is normal and quantitative values of other tests have shown satisfactory trends toward normal, then further antisyphilitic therapy will not produce added clinical improvement. Relapse of general paresis and other types of neurosyphilis rarely if ever occurs more than 2 years after effective therapy The CSF Wassermann usually becomes negative in 10 years, but positivity sometimes persists even longer

SPINAL PUNCTURE may be represented as a safe office procedure, is extremely simple in expert hands, and does not require that the patient be kept horizontal for more than a few minutes after withdrawing the sample. A mild sedative given beforehand is helpful; the apprehensive patient suffers out of proportion to the amount he is hurt, which should not be much. The patient can usually be induced to submit to puncture if it is pointed out to him that there is no other way of ascertaining the state of his nervous system, which, for all he or a physician can know, is headed for disaster unless the facts are disclosed in this way. The cisterna puncture is recommended by some authorities (Spiegel: AmJSyph 28: 96 1944). Cisternal puncture by causing subarachnoid hemorrhage killed 4 of 45,000 patients subjected to the procedure although it was performed by experts (Cecil and Johnwick: JVDI 32: 86 1951). Complications following lumbar puncture are rare, but instances of allegedly resultant osteomyelitis of lumbar vertebrae were collected by Redo (Surg 33: 690 1953).

When the specimen is in the test tubes, its cell count should be determined at once.

If the spinal fluid is found abnormal, repeated examinations for evaluating the effects of subsequent treatment are necessary. Each 3 months for the first year is not too much to ask of the patient whose feelings must be considered but whose ultimate welfare must not be frittered away because of his reluctance to do what may reasonably be asked of him. If the spinal fluid is negative in a patient who has had syphilis for 4 years, further spinal punctures are not necessary.

When seroresistance or relapse is encountered following adequate treatment of early syphilis, the spinal fluid must be examined, even if a previous spinal fluid examination was reported negative.

ILL EFFECTS OF SPINAL FLUID EXAMINATION are trivial in comparison with the value of information so obtainable. About 20% of those who undergo the procedure suffer more or less consequential postpuncture headache. This can be incapacitating for as long as 3 weeks, is relieved solely by lying down, may come on days after the puncture, starts with stiffness of the neck and occipital aching and may be limited to these mild manifestations, is to some extent preventable by using narrow gauge needles (Dattner) and is probably due to meningeal irritation which is less likely to be annoying to persons whose syphilis has already produced meningeal irritation. There is no relation between the amount of fluid withdrawn and the incidence of postpuncture headache (Belarra and Carter: J 148: 841 1952). Thorazin 25 mg q.i.d. may relieve postpuncture headache; codeine generally makes it worse. See Pickering (Brain 71: 274 1948); Noon (ArIslM 6: 19 1949); Glesne (Anesthesiol 11: 702, 1950).

The Varieties of Neurosyphilis *are classified as asymptomatic, wherein* no clinical indication of neurosyphilis can be detected excepting the presence of abnormal spinal fluid, and symptomatic wherein various abnormalities detectable by clinical examination are present in addition to abnormality of the spinal fluid. The following descriptions of these are condensed from O'Leary, Moore, Solomon, Stokes and Thomas (BullUSAMD Sept., Oct., Nov. 1944) *and have been modified to accord with the views developed since that date* mainly as a result of the advent of penicillin.

Classification of spinal fluids according to the degree of abnormality observed on examination by each of the 5 standard tests

GROUP	CELLS PER CC	COLLOIDAL GOLD	SEROLOGIC REACTION	GLOBULIN	PROTEIN MG. PER CENT
Group I (mild)	[illegible]	0000000000 to 0001110000	Negative with 0.6 cc	Negative or positive	25-40
Group II (moderate)	20-100	0001110000 to 0245542000	Doubtful or positive	Positive	40-100
Group III (severe)	10-100	5555544210	Strongly positive	Positive	75-150

Mild includes fluids in which the number of cells and content of globulin and protein may be increased, the complement fixation reaction is negative in 0.6 cc and the colloidal curve may be indeterminate or positive. If positive the curve is usually of the syphilitic zone type.

Moderate includes fluids in which the cell number 20 or more per cc., the complement fixation reaction is positive or strongly positive, and the colloidal curve is of the tabetic or indeterminate type. The estimate of the globulin is positive and the estimate of protein shows increase to an average of 60 mg. per 100 cc. Fluids falling just short of the requirement of the severe group are also included in this group.

Severe includes those fluids that have the paretic formula, that is marked increase of globulin, content of protein averaging about 100 mg. per 100 cc., a strongly positive complement-fixation reaction (0.2 cc or less) and the type of colloidal curves indicating dementia paralytica. The number of cells is decidedly increased. In addition to small lymphocytes, large lymphocytes and polymorphonuclear leukocytes may be present.

Asymptomatic Neurosyphilis is characterized by abnormal spinal fluid *findings, but there are neither physical signs nor subjective symptoms of in-*vasion or involvement of the central nervous system. When a patient mani-

fests clinical symptoms or signs which denote that the infection has involved the central nervous system a diagnosis of asymptomatic neurosyphilis is no longer tenable Asymptomatic neurosyphilis may be encountered in any phase of syphilis. It is noted most frequently in early syphilis, in which the incidence approximated 30% under older methods of treatment The rate is much lower than this among well treated patients. The rate among those untreated or those who have not had good treatment for acute syphilis gradually decreases until it reaches an average of 15% of patients in whom the infection is of more than 4 years duration

Asymptomatic neurosyphilis is the forerunner of clinical neurosyphilis but it responds satisfactorily to penicillin treatment so that the development of clinical neurosyphilis is prevented The results of repeated examinations of the spinal fluid are the only indicators of the response that the patient is making to treatment They also denote the trend of the disease in the central nervous system revealing the tendency for the fluid to change to the mild or to the severe (paretic) type

The significance of each test employed in the examination of the spinal fluid must be understood in order to interpret the results of each test intelligently in terms of therapeutic effect and prognosis. Among patients who have asymptomatic neurosyphilis, the earlier in the course of treatment the spinal fluid is examined, the easier it will be to interpret the subsequent changes in the various tests thus observing the trend and response of the spinal fluid to treatment. Re-examinations of the spinal fluid must be done at intervals of about 6 months if the significance of the changes in the abnormalities of the spinal fluid is to be interpreted accurately

It is possible to recognize from the spinal fluid findings that different types of neurosyphilis are impending It is not possible to make such deductions from one but rather from successive examinations of the spinal fluid. For example in a case of asymptomatic neurosyphilis, the paretic type of formula may be reported in the spinal fluid at the time of the first examination If 6 months after treatment the paretic features of the fluid persist this finding then assumes significant proportions if this paretic formula remains, it is convincing evidence that the patient has a resistant type of infection and that the treatment given him has been inadequate On the other hand, some patients who have asymptomatic neurosyphilis manifest a paretic trend in the original test of the spinal fluid, but 6 months after treatment no longer have the paretic features in the spinal fluid in these negative results may be obtained after the second period of 6 months after treatment If the trend of change in the fluid is from the group III toward the less severe types of involvement the inference is that the program of treatment is probably adequate. If the fluid relapses toward the severe type after a rest from treatment a change of the therapeutic program should be considered Patients who have severe and persistent abnormalities of the spinal fluid deserve neuropsychiatric examinations at least every 3 months.

Results of treatment are best in the cases of asymptomatic neurosyphilis in which spinal fluid abnormalities are least severe and in which syphilis has been present for 2 years or less. When the disease has been present longer therapy is frequently not capable of reversing the spinal fluid findings to normal. In such cases the early use of fever therapy used to be advised When the group III formulas were encountered fever was advised at once, but these cases too are known to be responsive to penicillin. See Hahn et al. (AmJSyph 30 513 1946) on prognosis in asymptomatic neurosyphilis.

Serologic negativity occurs spontaneously in some cases of asymptomatic neurosyphilis. Although the incidence of these cases is not known, they are encountered often enough to emphasize the fact that the forces of immunity of certain patients are mustered early in the course of the disease without the aid of treatment and overcome the invasion of the nervous system completely The development of an immune response plus penicillin treatment prevents clinical neurosyphilis almost invariably

SPINAL PUNCTURE may be represented as a safe office procedure is extremely simple in expert hands, and does not require that the patient be kept horizontal for more than a few minutes after withdrawing the sample. A mild sedative given beforehand is helpful; the apprehensive patient suffers out of proportion to the amount he is hurt, which should not be much. The patient can usually be induced to submit to puncture if it is pointed out to him that there is no other way of ascertaining the state of his nervous system, which, for all he or a physician can know is headed for disaster unless the facts are disclosed in this way The cisterna puncture is recommended by some authorities (Spiegel: AmJSyph 28: 90 1944) Cisternal puncture by causing subarachnoid hemorrhage killed 4 of 45,000 patients subjected to the procedure, although it was performed by experts (Cecil and Johnwick JVDI 32: 8? 1951) Complications following lumbar puncture are rare, but 7 instances of allegedly resultant osteomyelitis of lumbar vertebrae were collected by Redo (Surg 33 690 1953)

When the specimen is in the test tubes, its cell count should be determined at once.

If the spinal fluid is found abnormal repeated examinations for evaluating the effects of subsequent treatment are necessary Each 3 months for the first year is not too much to ask of the patient whose feelings must be considered but whose ultimate welfare must not be frittered away because of his reluctance to do what may reasonably be asked of him If the spinal fluid is negative in a patient who has had syphilis for 4 years, further spinal punctures are not necessary

When seroresistance or relapse is encountered following adequate treatment of early syphilis, the spinal fluid must be examined, even if a previous spinal fluid examination was reported negative.

ILL EFFECTS OF SPINAL FLUID EXAMINATION are trivial in comparison with the value of information so obtainable. About ?0% of those who undergo the procedure suffer more or less consequential postpuncture headache. This can be incapacitating for as long as 2 weeks, is relieved sol ly by lying down, may come on days after the puncture, starts with stiffness of the neck and occipital aching and may be limited to these mild manifestations, is to some extent preventable by using narrow gauge needles (Dattner) and is probably due to meningeal irritation which is less likely to be annoying to persons whose syphilis has already produced meningeal irritation. There is no relation between the amount of fluid withdrawn and the incidence of postpuncture headache (Seiarra and Carter: J 148: 841, 195.) Thorazine 25 mg q i d may relieve postpuncture headache codeine generally makes it worse. See Pickering (Brain 71 4 1948); Noon (ArnM 6: 19 1949) Glesne (Anesthesiol 11: 705, 1950)

The Varieties of Neurosyphilis are classified as asymptomatic, wherein no clinical indication of neurosyphilis can be detected excepting the presence of abnormal spinal fluid and symptomatic wherein various abnormalities detectable by clinical examination are present in addition to abnormality of the spinal fluid. The following descriptions of these are condensed from O Leary Moore Solomon Stokes and Thomas (BullUSAMD Sept., Oct., Nov., 1944) and have been modified to accord with the views developed since that date mainly as a result of the advent of penicillin.

Classification of spinal fluids according to the degree of abnormality observed on examination by each of the 5 standard tests

GROUP	CELLS PER CC	COLLOIDAL GOLD	SEROLOGIC REACTION	GLOBULIN	PROTEIN MG. PER CENT
Group I (mild)	1 to 20	0000000000 to 0001110000	Negati with 0.5 cc	Negative or positi	25-40
Group II (moderate)	20-100	0001110000 to 0115542000	Doubtful or positi	Positi	40-100
Group III (severe)	10-100	5555542110	Strongly posit	Positive	75-15

"Mild" includes fluids i which the number of cells and content of globulin and protein may be increased the complement-fixation reaction is negative in 0.5 cc and the colloidal curv may be indeterminate or positive If positi the curve is usually of the syphilitic zone type

"Moderat includes fluids which the cells numbe 20 or more per cc. the complement-fixation reaction is positi or strongly positi e, nd the colloidal curv is of the tabetic or indeterminate type The estimate of the globulin is positi and the estimate of prot in show an increase t an a erage of 60 mg. per 100 cc Fluids falling just short of the req irement of the severe group are also included in this group.

"Severe includes those fl ids th t have the "paretic formula, that is, marked excess of globulin content of protei a eraging bout 100 mg per 100 cc a strongly positive complement fixation reaction (cc or less) and the type of colloidal curves indicative dementia paralytica. The number of cell is decidedly increased in addition t small lymphocytes large lymphocytes nd polymorphonuclear leukocytes may be present.

Asymptomatic Neurosyphilis is characterized by abnormal spinal fluid findings, but there are neither physical signs nor subjective symptoms of invasion or involvement of the central nervous system. When a patient mani

fests clinical symptoms or signs which denote that the infection has involved the central nervous system, a diagnosis of asymptomatic neurosyphilis is no longer tenable. Asymptomatic neurosyphilis may be encountered in any phase of syphilis. It is noted most frequently in early syphilis in which the incidence approximated 30% under older methods of treatment. The rate is much lower than this among well-treated patients. The rate among those untreated or those who have not had good treatment for acute syphilis gradually decreases until it reaches an average of 15% of patients in whom the infection is of more than 4 years duration.

Asymptomatic neurosyphilis is the forerunner of clinical neurosyphilis, but it responds satisfactorily to penicillin treatment so that the development of clinical neurosyphilis is prevented. The results of repeated examinations of the spinal fluid are the only indicators of the response that the patient is making to treatment. They also denote the trend of the disease in the central nervous system, revealing the tendency for the fluid to change to the mild or to the severe (paretic) type.

The significance of each test employed in the examination of the spinal fluid must be understood in order to interpret the results of each test intelligently in terms of therapeutic effect and prognosis. Among patients who have asymptomatic neurosyphilis, the earlier in the course of treatment the spinal fluid is examined, the easier it will be to interpret the subsequent changes in the various tests, thus observing the trend and response of the spinal fluid to treatment. Re-examinations of the spinal fluid must be done at intervals of about 6 months if the significance of the changes in the abnormalities of the spinal fluid is to be interpreted accurately.

It is possible to recognize from the spinal fluid findings that different types of neurosyphilis are impending. It is not possible to make such deductions from one but rather from successive examinations of the spinal fluid. For example, in a case of asymptomatic neurosyphilis, the paretic type of formula may be reported in the spinal fluid at the time of the first examination. If 6 months after treatment the paretic features of the fluid persist, this finding then assumes significant proportions. If this paretic formula remains, it is convincing evidence that the patient has a resistant type of infection and that the treatment given him has been inadequate. On the other hand, some patients who have asymptomatic neurosyphilis manifest a paretic trend in the original test of the spinal fluid, but 6 months after treatment no longer have the paretic features in the spinal fluid. In these, negative results may be obtained after the second period of 6 months after treatment. If the trend of change in the fluid is from the group III toward the less severe types of involvement, the inference is that the program of treatment is probably adequate. If the fluid relapses toward the severe type after a rest from treatment, a change of the therapeutic program should be considered. Patients who have severe and persistent abnormalities of the spinal fluid deserve neuropsychiatric examinations at least every 3 months.

Results of treatment are best in the cases of asymptomatic neurosyphilis in which spinal fluid abnormalities are least severe and in which syphilis has been present for 2 years or less. When the disease has been present longer, therapy is frequently not capable of reversing the spinal fluid findings to normal. In such cases the early use of fever therapy used to be advised. When the group III formulas were encountered, fever was advised at once, but these cases too are known to be responsive to penicillin. See Hahn et al. (Am.J.Syph 30 513 1946) on prognosis in asymptomatic neurosyphilis.

Serologic negativity occurs spontaneously in some cases of asymptomatic neurosyphilis. Although the incidence of these cases is not known, they are encountered often enough to emphasize the fact that the forces of immunity of certain patients are mustered early in the course of the disease without the aid of treatment and overcome the invasion of the nervous system completely. The development of an immune response plus penicillin treatment prevents clinical neurosyphilis almost invariably.

mal or range up to the first zone type reaction. The complement fixation reaction and flocculation tests vary from normal to the most strongly positive. Any combination in the formula of these tests may be found.

Diagnosis depends on an evaluation of the combined clinical and serologic evidence. The prognosis unless tissue destruction from pressure or scarring has occurred before treatment is instituted is good.

Meningovascular Neurosyphilis.—There is involvement of the blood vessels as well as the meninges. Probably one type of involvement does not exist without the other but when there is clinical evidence of vascular disease the term meningovascular neurosyphilis is used, implying that the meninges are inflamed. The spirochete invades the blood vessel wall and creates the proper condition for the formation of vascular thrombosis.

Resulting symptoms depend on the location and size of the vessel thrombosed. Loss of consciousness, attacks of dizziness, and mental confusion occur. The symptoms also include monoplegia hemiplegia aphasia hemianopsia, cerebellar syndromes, and all types of psychotic behavior. Thromboses rarely occur in the first 6 to 12 months of the infection. They occur more frequently in the succeeding 5 to 10 years with greatest frequency 8 to 15 years after the infection. Characteristic pupillary signs may or may not be present. The spinal fluid gives a group III formula in about 50% of the cases whereas in the remaining 50% weaker formulas of any variety are found.

Tabes Dorsalis (Locomotor Ataxia) is a type of neurosyphilis in which the posterior roots and posterior columns of the spinal cord suffer degeneration with frequent involvement of the midbrain and probably of the sympathetic nervous system. The major symptoms are ataxia pain, visceral crises, diplopia, disturbance of bladder and sexual function, and loss of visual acuity. These symptoms may occur separately or in combination.

Ataxia which is due to the diminution of the sense of motion and position sensation is usually first noted as difficulty in walking in the dark and trouble in making sudden changes in direction and in walking in a straight line. There is usually a sensation in the soles as of walking on cotton or on a thick rug.

Pain of an excruciating lancinating type often described as if a hot wire were thrust into the flesh or as a pinching of the skin is characteristic. Each jab of pain is likely to be instantaneous and repeated over and over again at short intervals for hours or days at a time. Frequently the pain is localized in a small area as in the toe the heel, the ankle the calf, the thigh. The pain may jump from one of these areas to another but often remains in the same spot. At first the pains are mild with long intervals between attacks. As time goes on they become more severe longer lasting and more frequently repeated. These pains are often precipitated by cold wet weather during intercurrent infections or on fatigue. There are infinite variations of the pattern. Some patients describe merely attacks of what seems like a feather being drawn across the skin mild neuralgic pains, or sensations like an electric current being applied to the skin. Many patients suffer from hypersensitivity of the skin especially about the trunk so that the pressure of clothes becomes uncomfortable or getting into a bathtub of warm water is almost intolerable. Some have a sense of constriction about the waist.

Visceral crises of the commonest type are related to the upper part of the gastrointestinal tract characterized by attacks of nausea and vomiting with or without severe cramplike pains or with pain alone. Rectal crises are characterized by pain in the region of the anus and rectum with tenesmus. Sometimes diarrhea at other times constipation, is associated. Other crises such as laryngeal spasms occur. Characteristically these crises occur in spells separated by days weeks or months. In a typical gastric crisis vomiting may last for days, leading to marked dehydration. There are many variants of the gastric crisis. Occasionally one encounters a patient who has regular morning vomiting. Others speak of periodic attacks of indigestion. Duodenal ulcers are not infrequent in patients with gastric crises.

Diplopia is a common occurrence in the tabetic, often the first evidence of the disease Ptosis of the eyelid is also frequent. Paralysis of accommoda tion with internal ophthalmoplegia may also occur Diplopia is the result of partial or complete paralysis of the third fourth or sixth cranial nerve most frequently the third The symptom often disappears spontaneously in the first attack but without treatment there is likely to be a recurrence following which a permanent palsy often results.

Bladder and sexual disturbances comprise loss of bladder sensation lead ing to distention, loss of tone and overflow incontinence and loss of libido and potency a frequent and sometimes early symptom Patients often boast of their capacity to hold the urine all day After voiding there is usually considerable residual urine Secondary infection and pyelonephritis are not uncommon.

Loss of visual acuity due to optic atrophy is a characteristic sign of tabetic neurosyphilis leading to loss of eyesight and complete blindness. Generally it begins with night blindness and more or less rapidly proceeds to complete loss of vision. At an early stage it may be quite difficult if not impossible to differentiate optic retrobulbar neuritis due to an inflammatory process and true tabetic optic atrophy When optic atrophy occurs, the other symptoms of tabes are usually minimum

The objective signs of tabetic neurosyphilis include pupillary changes extraocular palsies diminution or absence of the knee jerks and ankle jerks diminution or loss of vibration and position sense of the lower extremities, more marked in the distal portion Romberg s sign ataxia zones of disturbed sensation about the trunk hypalgesia to pressure on the gonads and the tendo achillis; hypesthesia across the nose and dorsa of the feet.

Argyll Robertson pupils small irregular pupils which fail to react to light but which react during accommodation, are found more frequently in tabes than in any other form of neurosyphilis. The typical Argyll Robertson pupil is often a relatively late sign and is preceded by irregularity inequality and poor reaction to light Although the tabetic pupil is often small, in some instances wide pupils may be found and sometimes the pupils respond to neither light nor accommodation See Langworthy and Ortega (Med 22 287 1943) neural lesion Benton (AmJSyph 37 232 1953) description.

Optic atrophy is demonstrated by the pallor of the optic disk, usually associated with loss of visual acuity and with restriction of the visual fields. The recognition of early optic atrophy by ophthalmoscopy and perimetry is possible.

Joint destruction the Charcot joint is a complication resulting from repeated trauma to a joint which has lost some of its normal protective sensi tivity to pain. The Charcot joint often occurs in patients who show normal spinal fluids and evidence of complete arrest of the other tabetic symptoms. Charcot s destruction of an ankle and foot occurred with great rapidity in a patient with poorly controlled diabetes reported by Antes (J 156 602 1954)

Tabes dorsalis can be diagnosed perhaps not until syphilis has existed for 5 years but may develop at any time during the next 25 years. The onset may be insidious, ushered in by flickering pains or by a disturbance in gait or a mild visceral crisis. On the other hand it may occur suddenly One occa sionally meets a patient who collapses and when helped to his feet is markedly ataxic The onset of a severe gastric crisis may be the first recognized symptom. In most cases, however pupillary changes and absence of the tendon reflexes of the lower extremities precede symptoms by many months or years. The course of tabes dorsalis is generally progressive with an increase of symptoms and signs. However some cases undergo spontaneous arrest or develop a negative spinal fluid but this is not necessarily paralleled by disappearance of symptoms.

Spinal fluid findings in tabes dorsalis vary In many during the acute stage of advance one finds a strong formula such as is characteristic of general

paresis. Weaker formulas are found even in the early period of progression and in about 50% of the cases there are moderate pleocytosis, a moderate increase in globulin and total protein, a moderately strong colloidal gold and a moderately strong complement fixation reaction. The spinal fluid may become normal spontaneously

Penicillin therapy arrests the progress of the inflammatory process and the spinal fluid may revert to normal Unfortunately however in many of the cases in which symptoms have existed for some months before treatment is instituted, these persist despite the return of the spinal fluid to normal

See Bennett (J 107 348, 1936) benefit in lightning pains with fever therapy, Rottmann (KlinW hn 16 106, 1937) cobra venom for pains, Simons (AmJSyph 23; 782, 1939) gastric crises, diagnosis and treatment Costello (NYSJM 39 781, 1939) pseudo-Argyll Robertson pupil f Adie' syndrome does not eact to light, but in accommodation its contraction is slow and after accommodation it remains small for 30 seconds It is usually unilateral, usually on the left side and th affected pupil is usually larger and oval Cochems and Kemp (AmJSyph 26 314, 1942) thiamine for lightning pains gave partial relief in half the cases; Brown and Yakorzynsky (ANeurPsych 47 313 1942), vibratory sensibility seems to require both touch and deep-pressure senses Costell (UCutRev 51 280, 1947), Protamide, a denatured proteolytic enzyme from hog stomach, helped half the cases of tabetic pains Koteen (AmJSyph 33 364, 1949) brief symptoms respond better to treatment than those of 2 years or longer duration; if one form f antisyphilitic therapy fails, another is likely to fail, and results with penicillin are only as good as with other methods Dowling et al. General Paresis ((General Paralysis of the Insane, Dementia Paralytica, Psychosis With Syphilitic Meningo-Encephalitis) is a psychosis due to spirochetal invasion of the brain The pathologic changes, consisting of nerve cell atrophy perivascular infiltration, gliosis, and chronic meningitis, exist long prior to the development of mental changes which are the sine qua non of the disease entity

The mental symptoms of general paresis mimic almost any psychiatric symptom complex. The onset of general paresis is usually insidious, although mental symptoms may begin with extreme suddenness. It is usual to obtain a history that before symptoms were recognized there was a period of months during which the patient complained of headache, insomnia capricious appetite loss of weight disturbance of sleep easy fatigability and difficulty in concentration. This galaxy of symptoms is all too frequently diagnosed as

psychoneurosis. In retrospect, it is generally evident that there was a gradual change in the personality and behavior of the individual, with irritability mild memory loss, poor judgment, lack of care in personal appearance, defect in moral and ethical conduct and unexplained deviations in character In other patients the psychosis may be ushered in suddenly by a convulsion or a period of confusion. In many patients one obtains a history that, several years before the psychosis was recognized, an epileptiform or apoplectiform seizure has occurred, perhaps accompanied by hemiplegia or aphasia of short duration.

Classification of several varieties of general paralysis follows the presenting symptoms

(1) A simple dementing form, characterized by loss of memory loss of calculating ability defects in judgment in association with increasing speech difficulty and tremors;
(2) The grandiose form, in which ideas of grandeur and a sense of euphoria are paramount;

Fig. 557—Paresis, with hypomania and delusions of grandeur
Fig. 558—Paresis, with dementia and deterioration.

(3) The manic form, simulating the manic phase of manic-depressive psychosis
(4) The depressed form, similar to the depressive phase of manic-depressive psychosis;
(5) The agitated form, simulating agitated depressions of involutional psychoses;
(6) A schizophrenia like syndrome, with paranoid, catatonic, and schizophrenic features;
(7) Epileptiform manifestations frequently repeated, often characterized as syphilitic epilepsy
The epileptiform seizures occurring in syphilis are of two types grand petit mal attacks associated with dementia paralytica, and so-called syphilitic epilepsy occurring in persons who may or may not show clinical or laboratory evidence of neurosyphilis. Convulsions in paretics are more likely to be relieved by fever therapy than those in syphilitic epilepsy Anticonvulsant drugs are as effective, in any case, as they are in idiopathic epilepsy and should be employed (J 131 873, 1946)
(8) Parkinsonian manifestations, rarely seen as a result of neurosyphilis (Neill: BMJ 2: 320 1953)

The neurologic signs encountered in general paresis are variable. Pupillary changes occur frequently but are often absent in the early stages of the disease Irregularity and inequality of the pupils are the most frequent of these signs found early Disturbance in the light reaction may occur with

the Argyll Robertson pupil or complete fixation ultimately developing Dilated pupils are more frequent than miotic ones. Speech defects or disorders of articulation are probably the most characteristic somatic disturbance of general paresis. A break in the voice tremulousness, overactivity of the facial muscles even including the orbicularis oculi with stumbling over consonants should raise the question of general paresis. In the early stages, the speech defect is demonstrated by having the patient repeat difficult test phrases such as Methodist Episcopal or Third Riding Artillery Brigade but it is often recognizable in spontaneous speech Tremor is a frequent and early sign and is seen in the facial muscles, the protruded tongue and the extended fingers. Rapid alternating movements of the hands and fingers are poorly performed. The tendon reflexes are often exaggerated if tabes is coexistent they are diminished or absent. Persistent signs of focal damage when they occur suggest that the case is not one of pure paresis.

The course of untreated paresis is downhill, leading to extreme mental and physical deterioration and death In untreated cases about one-half die within 30 months of the onset of mental symptoms and almost all are dead within 5 years. During the course of this downhill trend, epileptiform and apoplectiform seizures are frequent. An interesting characteristic of the paretic apoplectiform seizure is the tendency for a quick recovery from the apparent focal brain damage Following each convulsive attack increased mental deterioration may ensue From 10 to 20% of patients have spontaneous remissions lasting for several months to a year followed by relapse

The spinal fluid in general paresis is characteristic The cell count varies from normal to 80 or more per c mm. globulin is present in large amounts, the total protein varies from 75 to 150 mg per cent the colloidal gold test is of the first zone or paretic variety The complement fixation and flocculation tests are strongly positive Little variation from this formula is consistent with the diagnosis of general paresis.

The prognosis of general paresis under treatment is in the majority of cases an arrest with some residual defect the extent depending upon the amount of damage which occurred before treatment became effective. Whether every case in which the physical state of the patient permits should have fever therapy as well as chemotherapy which has been the consensus in the past, is debatable in the light of more recent knowledge of the effectiveness of penicillin therapy The pathologic process was arrested by 6 000 000 units, as a rule after which macroscopic brain changes were minimal and residual microscopic changes appeared to be due to neurone destruction antecedent to therapy in the patients of Gianascol et al. (AmJSyph 38 251 1954) While inflammation disappeared following adequate therapy meningeal fibrosis and marginal gliosis might persist and correlation between clinical course laboratory data and neuropathologic abnormalities was not uniform In some cases deterioration continued despite the achievement of an inactive CSF formula and the explanation of this fact is not at present forthcoming (Kral and Dorken AmJPsychiat 109 684 1953) Such patients differ from cases of senile dementia in retaining a better contact with reality and in suffering less fatigability

See Winkelman (AmJSyph 19 [illegible] 1935 24 [illegible] 1936) parenchymatous and interstitial form of spinal cord syphilis [illegible] (AmJSyph 26 [illegible] 1942) spinal cord syphilis Merritt and Solomon (AnnSurg [illegible] 1943), relation of trauma to CNS syphilis Greenblatt and Levi [illegible] (AmJPsych [illegible] 1944) electroencephalography showed abnormalities especially in the [illegible] and paretic [illegible] least in tabes, almost [illegible] convulsive disorder frequently in optic atrophy Merritt et al (Neurosyphilis, Oxford [illegible] Press 1946) [illegible] and pathologic aspects, neuropsychiatric diagnosis [illegible] AmJSyph [illegible] 1948 review of 183 institutional cases showed clinical failure to respond [illegible] treatment failure Thompson and Preston (AmJSyph [illegible] 1950) gumma of [illegible] Lewis (AmJSyph 34 [illegible] 1950) psychometric recognition of early dementing paresis Sternberg and Zimmerman AmJSyph 34 [illegible] 1950) psychologic processes in asymptomatic neurosyphilis defects of reasoning social comprehension, memory and learning

Optic Atrophy Primary optic atrophy is a form of neurosyphilis often seen in conjunction with tabes dorsalis (q v) Untreated it always becomes bilateral and progresses to permanent complete blindness within 7 years

(Moore et al J 111 385 1938) Treatment that was adequate by arsphenamine standards delayed its development and in some instances arrested its progress, while malaria therapy was judged capable of arresting about 85% of the cases. If given while the disease was unilateral about 70% of the sound eyes remained sound, Moore stated. Good treatment of early syphilis nearly completely protects against its appearance but it occurs in approximately 8% of cases of neurosyphilis (Moore et al. AmJSyph 26 407 1942) Of the 262,000 blind persons in the U.S.A. some 10 to 15% lost their vision because of syphilis, and of these about 90% were blind because of optic atrophy (Klauder JVDI 32 183 1951)

The pathogenesis is unknown but is somehow related to the organic degeneration which produces tabes dorsalis (Moore and Woods AmJSyph 24 59 116 1940) Histologic studies were reviewed by Bruetsch (AOphth 39 80 1948)

The diagnosis rests upon expert ophthalmoscopic examination, revealing pallor of the discs, especially of the temporal aspects, and on the correct, skillful taking of visual fields and interpretation of them. These examinations must not be omitted in the evaluation of any patient whose syphilis is not primary or secondary (Klauder and Meyer AOphth 43 537 1950) Defect of the visual fields precedes loss of central vision and pallor of discs, and the earliest field losses are for red and green (Klauder et al. AmJSyph 32 574 1948)

Blindness due to optic atrophy should be preventable, if early stages were recognized early and if successful treatment methods were utilized, especially the large total dosage of penicillin (Bruetsch Syphilitic Optic Atrophy Thomas 1953) Comparing treatment with penicillin alone and penicillin plus malaria, Kenney and Curtis (AmJSyph 37: 449 1953) concluded that malaria appeared to add little to the results. They confirmed Moore's thesis that patients with visual acuity better than 6/20 when treatment began tended to achieve arrest while those with worse vision tended in spite of treatment to lose progressively what little they had Problematic indeed are the cases that progress despite treatment. Such cases should be identified as early as possible and given maximum treatment in minimum time and cortisone should be used to supplement retreatment with penicillin (Klauder and Gross AmJSyph 38 270 1954)

Etiology of Syphilis.—Syphilis is due to *Spirochaeta pallida* (*Treponema pallidum*) of Schaudinn and Hoffmann (Arbeit. aus d. k. Gesundheitsamte 22: 527 1905)

T pallidum is a delicate cylindrical spiral motile organism from 4 to 14 microns in length. The number of spirals is from 6 to 15 The organism is anaerobic and is pathogenic to rabbits, anthropoid apes, monkeys and other animals as well as man. Its presence in the tissue fluid of the active primary or secondary lesion can usually be demonstrated by means of dark field illumination. Some staining methods may be equally useful (Krajian AmJSyph 23 617 1939) Similarity of *T pallidum*, *T pertenue* of yaws and *T carateum* of pinta is notable Studies of the morphology of the organism in the tissues by Steiner (APath 29 189 1940) are interesting The end knob and flagella were demonstrated by electron micrography by Wile and Kearney (J 12[illegible] 167 1947)

The organism at first penetrates and multiplies in the mucous layer of the epidermis and lymph spaces of the dermis but diffusion of the spirochetes throughout the body is largely by means of the blood stream. Hematogenous dissemination takes place [illegible] within a few minutes after inoculation (Raiziss and Severac ADS 35 1101, 19[illegible]). The organism dies within a few minutes when dried, but it may remain virulent for days in refrigerated tissues (Rosahn AmJHyg 22 233, 1935 Turner and Fleming: JExpM 620 1939)

Inoculations of from 1 to 6 spirochetes into rabbits by Thomas and Morgan (JExpM 60: 297 1934), using single-cell technic, failed to transmit the infection. Success in transmitting infection by testicular inoculation of rabbits with organisms of the Nichols strain was obtained by Magnuson et al. (AmJSyph 32 1, 1948) almost half the [illegible] when only 2 organisms were introduced. Takes were obtained in almost 90% when [illegible]

organisms were inoculated, and in 100% of intradermal inoculations using *00 000 or ganisms. See Morgan and Vryonis (AmJSyph 22: 462, 1938) quantitative inoculation technic.

See Metchnikoff and Roux (BullacadMéd 1905, p 448) transmission t pes Hoffmann (Di Ätiologie der Syphili) Berlin, Springer 1906 Rosenberger (AmJMSc 1[?]1 14[?], 1906), the spirochet probably does use syphilis Dagi (JPharmExpTher 64 164, 1938) effect

Virulence and Immunity.—The virulence of *T. pallidum* in culture is not great. Considerable variations in biologic characters and virulence of strains of spirochetes are recognized. Vaccine does not alter the immunobiologic apparatus sufficiently to engender riddance of spirochetes from the body. Beck (JPathBact 44: 399, 1937) confirmed the failure of many investigations to demonstrate protective antibodies against the spirochete. Immunity is of the tissues, not humoral (Urbach and Beerman, AmJSyph 31: 192, 1947). Acquired immunity, which can develop only slowly, is responsible for clinical latency, but this immunity is not dependable if unaided by modern therapy and it is inadequate to protect against reinfection or superinfection (Kolmer, AmJS 22: 426, 1938). Recurrence following inadequate treatment of early infections may be more severe than the original reaction to the spirochetes.

Syphilis seems to be a milder disease in women than in men. Some experimental evidence indicates that estrogen given to animals ameliorates their infection (Kemp et al., AmJSyph 22: 9, 1938).

The antibody (reagin) in the complement fixation reaction is apparently identical with whatever substance yields the positive flocculation reaction. In the human being it is a product of infection with the spirochete of syphilis, and also it may be produced by the existence of leprosy, malaria, and other infections. Quantitative studies show that the titer of reagin is rapidly reduced by effective antiluetic therapy (Belding, AmJSyph 24: 29, 1940). The syphilitic antigen is associated with gamma globulins, the separation and purification of which have been studied with great care and with hope of distinguishing the substances responsible for true and falsely positive serologic reactions by Neurath et al. (AmJSyph 31: 347ff, 1947). See Rein and Kostant (ADS 60: 217, 1949) nature of antigens and antibodies, review.

Agglutination of *T. pallidum* in syphilitic serums has received intensive study and appears to have been performed successfully by McLeod and Magnuson (PHRpts 68: 747, 1953) who examined the effect of adding fresh steer serum to mixtures of *T. pallidum* and syphilitic serum. Because of its content of conglutinin, the steer serum caused disappearance rather than immobilization of the spirochetes under the conditions of the *T. pallidum* immobilization test and greatly accelerated and enhanced the clumping of the organisms in the agglutination test. The agglutination test performed by this method appeared to compare favorably in both specificity and sensitivity with the *T. pallidum* test. See Diagnostic tests.

Luetin Test.—The intracutaneous test with spirochetal vaccine analogous to the tuberculin test may be dismissed as being of no practical value. However, it is interesting that the luetin test performed within the scar tissue of a healed late syphilid is negative while elsewhere the patient's skin gives a positive reaction, according to Benceny (DWchr 103: 591, 1939). See Noguchi (Laboratory Diagnosis of Syphilis, Hoeber, 1924) luetin colo plates.

Luetin Therapy.—Spirochetal vaccine used in therapy caused considerable reaction in some patients but no useful immunobiologic effects (Neuber, DWchr 9?: 229, 1934). Immunity acquired by experimentally infected rabbits cured with bismuth therapy was challenged by quantitative inoculations at various time intervals after the animals had been cured, and partial protection apparently was acquired, for from 3 to 4 weeks after infection, it required progressively larger inocula to infect them (Magnuson and Rosenau, AmJSyph 32: 418, 1948). See Wile (ADS 57: 815, 1948); Turner et al. (AmJHyg 48: 173, 1948).

Pathology.—The microscopic lesion is characterized by perivascular round-cell infiltration (Warthin, AmJSyph 2: 425, 1918). Small vessels are the ones mainly involved. The infiltrate in the early stage is made up almost entirely of lymphocytes with a sprinkling of plasma cells. Granulomatous endothelial and fibroblastic proliferation occurs later and more or less giant cell formation is evidenced. The infiltrative clumps of round cells with capillaries at their centers, may coalesce and form what appears to be a massive cellular infiltrate. They may cause vascular obstruction and produce necrosis. Nodules are composed of gross masses of infiltration, and ulcers result from inflammatory infarction and necrosis of tissue. Gummas have the

same basic pathology as other syphilitic lesions. A scar results whether absorption occurs or the weakened overlying epidermis sloughs away Spirochetes are few in late syphilitic lesions in contrast with their profusion early in the infection The reliability of Warthin s criteria for the histologic diag nosis of syphilis was impugned by Rosahn and Schaffer (AmJSyph 28 27 142 1944) whose autopsy material was correlated with clinical data and

Fig. 442 —Acute, early syphilitic inflammation. Chancre, border of the lesion, showing characteristic perivascular lymphocytic infiltration. (Drs Fordyce and MacKee, from Hazen Syphilis—Its Diagnosis and Treatment, Mosby)

Fig 443 —The lementary pathologic lesion of syphilis lymphocytic and plasma-cell infiltration forming a collaret bout a small blood essel. (Drs. Fordyce and M cKee, from Hazen Syphilis—Its Diagnosis and Treatment, Mosby)

Fig 444 —Syphilitic inflammation, from nodula syphilid without lceration, showing gia t cells in gra ulation tissue (Drs Fordyce and MacKee from Hazen Syphilis—Its Diagnosis and Treatment, Mosby)

serologic tests, and indicated that Warthin's lesions were related more accurately to the age of the patient than to proved existence of the disease and that syphilis was not very often the cause of shortened life span. See Rosahn (VDI 27: 293 1940) autopsies.

Staining of T pallidum.—See Krajian (ADS 32 784, 1935) Steiner (JLCM 22: 293, 316 1937; 25 204, 1939), in smears and frozen sections Haire (JLCM 23 1216, 1938); Bailey (JLCM 23: 960 1938) on slide, dry exudate in air cover with N/20 HCl for 10 sec wash in running water 5 sec., cover with Gram iodine 5 to 10 sec., wash, cover with anilin gentian violet 5 sec., wash, repeat Gram. Spirochete stains dark, but not permanently; Friedman (J 112: 134, 1939) distinguish mixed gonorrheal and syphilitic infection by centrifugation of pus in fine capillary tube 12 cm. long, filled by capillarity place this in heavier glass tube to centrifuge 1000 r.p.m. for 10 min., so clearing column of serum to examine with dark field without causing spirochetes to settle Dienst (JLCM 23 646, 1938) nigrosin-formol Kerr (AmJClinPath 8 supp. 63, 1938), improved Warthin-Starry method for tissues Krajian (AmJSyph 22 617 1938) tissues Perrin (AmJClinPath 13 28, 1943) formaldfuchsin; Rosahn and Freeman (AmJSyph 30: 244, 1946) modified Fontana, Onoda (JVDI 26 35 1951); Levine (PHRpts 67 284, 1952), Limura (ADS 67 319 1953) Parker '51 blue-black ink mixed with serum, smeared out rapidly as in smearing blood, dried and examined under oil immersion.

Technic of Krajian Stain.—Sol No. 1 Uranium nitrate 1.0 gram formic acid, 85% 1 cc.; glycerin, chemically pure, 5 cc. acetone 10 cc. alcohol, 95% 10 cc. This is stable and keeps for long periods.

Sol. No. 2: 3 drops of saturated alcohol solution of gum mastic mixed with 7 cc. 95% alcohol. This should be prepared fresh each time.

Sol. No. 3: Hydroquinone, 0.31 Gm. sodium sulfite, 0.06 Gm.; solution of formaldehyde, 40% neutral, 2.5 cc.; pyridine, 2.5 cc. saturated solution of gum mastic in 95% alcohol, 2.5 cc. distilled water 10.0 cc. It is important to use fresh developing solution. This keeps for two or three weeks; when the gum mastic separates and settles, a fresh supply should be prepared.

Rub lesion roughly until it bleeds with swab moistened in alcohol After bleeding stops, smear clear serous exudate and dry in air Flood smear 5 minutes with warm No. 1 Wash in distilled water Apply No. 2 for 2 minutes. Wash off and blow breath over surface of smear then rinse in distilled water Set slide on metal stand. Flood with 1% aqueous silver nitrate made fresh from 10% stock solution. Heat over burner until bubbles begin to form, not boiling, and keep warm 2 minutes. Repeat the silvering process. Pour off silver without washing. Apply thin coat of No. 3. Leave under electric light for 2 minutes while warming gently Wash with distilled water dry in filter paper examine under oil immersion lens. For permanent mounts, dehydrate with absolute alcohol, blot, clear in xylene, mount in dammar

Diagnosis.—Emphasis must be placed on the necessity for careful consideration of the entire symptom complex in every suspected case Dependence on the laboratory for diagnostic aid has grown beyond reasonable bounds. Positive or negative serologic reports in the absence of corroborative clinical evidence may be void of practical meaning or even false but persistently positive tests over a period of several months justify the administration of treatment, and repeatedly positive tests with rising titer make the diagnosis reasonably secure It is a diagnosis to be made discretely advisedly and soberly for the consequences to the patient are great A careful case history and a thorough physical examination of the patient are invariable requirements. In early stages spirochetes can usually be found in material from the lesions or satellite nodes. The evolution of the disease occurrence of mucosal lesions involvement of the lymph nodes and features of the eruption should attract attention. During the tertiary period, cutaneous lesions are generally readily recognizable

The diagnosis of syphilis requires quick suspicion but deliberation in conviction (Grindon JAMA 36 65 1939) and careful examination and prolonged follow up (Friedman and Mazer AmJSyph 22 340 1938) Unsuspected syphilis in the aged constitutes a significant problem in geriatrics (Thewlis and Gale Geriat 3 335 1948)

Contact with infectious syphilis is likely to result in transmission of the disease Abortive treatment is justified and effectual, and if 900 000 units of penicillin in oil is given during the incubation stage protection is almost 100% successful (Alexander et al. AmJSyph 33 429 1949) This view now generally accepted, supersedes the older judgment that treatment should be withheld until the diagnosis becomes unmistakable.

The obligation persists to trace contacts and find cases even though the reservoir of infectious syphilis has undergone marked diminution in recent years, and biologic cure with penicillin in early syphilis is practicable in almost all patients (Kampmeier SouthMJ 46 226 1953)

The history of previous treatment and response to it in detail are especially significant in planning treatment. The occurrence of repeated miscarriages without apparent cause is suggestive of syphilis in women.

The spinal fluid must be examined in all but the fresh cases (Shaw ADS 42 456 1940) The fundamental data to be obtained are (1) the cell count and its differential constituents (2) a qualitative test for globulin (3) total protein quantitatively (4) the colloidal gold or mastic test, and (5) the titrated complement fixation test Without spinal fluid study the diagnosis of latency cannot be made The one abnormality diagnostic of syphilis in the spinal fluid is the positive complement fixation test other diseases are capable of altering any or all of the other aspects of the spinal fluid as syphilis does, but *falsely positive specific tests are extremely uncommon.* Base line studies of the nervous system include evaluation of the psyche and tests of the function of cranial nerves, including examination of the visual fields and ocular fundi of the response of the pupils in light and accommodation, of speech of muscle stretch reflexes, particularly at the heels and knees, and of vibratory and pressure sensibility especially of the lower extremities.

The blood pressure should be recorded bilaterally and the state of the heart and aorta requires painstaking clinical and roentgenologic investigation, preferably fluoroscopic

---

Serodiagnosis of Syphilis

(Pages 430–437)

By Charles R Rein MD

Serologic Tests for Syphilis depend on the detection of syphilitic antibodies and, desirably the quantitative estimation of them. Reagin is the name applied to the substance that effects specific reactivity in classic complement fixation and flocculation tests for syphilis. It is now known that several antibodies (q v) exist, and that the one demonstrated by the classic tests can be removed from a serum which thereafter still exhibits syphilitic antibody different from reagin and demonstrable by the newer specific tests *employing Treponema pallidum antigens (TPI TPIA TPA and TPCF tests)* see Antibodies in syphilis (p 433)

In serologic diagnosis of syphilis are used flocculation complement fixation, treponema immobilization and agglutination tests of which the first two have long been standard, while the last in 1954 were new and may be expected to be found of especial value in determining which of the serologic reactors are syphilitic and which are biologic false positives. Flocculation tests entail bringing suspected serum and specially prepared antigen together under suitable conditions then flocculation occurs and is visible if the serum is syphilitic

Complement fixation (Wassermann) tests entail two steps (1) suspected serum has its complement inactivated by heating and is mixed with specially prepared antigen then a known quantity of complement is added with the result that complement is used, fixed if the serum is reactive and is not fixed if it is not reactive (2) the fixation or nonfixation of complement is determined by the result of reaction between the serum, as prepared by step (1) and a hemolytic indicator composed of (a) sheep red blood cells and (b) antisheep-cell rabbit serum which has been heated to destroy its complement. If complement was fixed in (1) hemolysis will not occur on the admixture of (2) and the test is read as reactive a result which may mean that syphilis is present or may mean that nonsyphilitic conditions productive of false positive reaction resulted in the fixation or deviation of complement

Tests must be performed skillfully under standard conditions (Parran et al J 100 4[illegible]3 183 see also *Serodiagnosis of Syphilis* (VDI Suppl. 9 1939 Parts I and II), and Manual of Serology of Syphilis (USPHS 1954) A standard test [illegible] continually being sought ([illegible] Am J Clin Path 18 143 1948)

Results of tests must be interpreted skillfully (Harris [illegible] VDI Suppl. 14 1941). Falsely negative and falsely positive reactions sometimes occur (Kahn [illegible] 30: 92, 1939) The [illegible] of [illegible] positive reaction [illegible] proof that syphilitic affection exists or that [illegible] syphilis must be treated. The existence of a negative reaction *is not* proof that syphilis is not present or that treatment is not necessary See Evaluation of serologic test

The problems of interpretation are very real, for most practitioners have seen clinically syphilitic patients whose serologic tests were reported negative and other patients whom they believed nonsyphilitic whose serologic reports were inexplicably positive. Such discrepancies are not amazing however for one knows that there are no *specific* tests for syphilis, with the apparent exception of the treponema immobilization test devised by Nelson et al. (AmJSyph 34: 101 1950) and other tests employing *T. pallidum* antigens.

Exact details of the methods for performing various tests are to be found in laboratory guides and journal articles to which references are given.

Historical Aspects of Serodiagnosis of Syphilis.—Serodiagnosis of syphilis was inaugurated by Wassermann, Neisser and Bruck (DeutschMWchn 32: 745 1906) with their complement fixation test. Soon after Michaelis, using a similar antigen, the saline extract of syphilitic liver outlined a method for producing visible precipitates with syphilitic serum, thus describing the first precipitation reaction. When Wassermann et al. developed the first serologic test for syphilis (1906), they believed their test to be specific because they employed a saline extract of syphilitic liver for the antigen. They thought it adequately sensitive because positive reactions were obtained with the blood of many individuals with active clinical syphilis. It was soon discovered, however that these antigens were nonspecific for alcoholic lipid extracts obtained from normal tissue were more specific and more sensitive than aqueous extract of syphilitic tissues. Antigenic lipids may be obtained from beef, lamb, horse, guinea pig, rabbit, pig, and human tissues, the heart, liver, brain and muscles being particularly rich sources. Even though these lipid extracts are not true antigens in the biologic sense they do react in an extraordinarily specific manner with syphilitic serum. There are numbers of hypotheses regarding the nature of syphilitic reagins and the mechanism whereby nonspecific lipid antigens produce positive serologic reactions for syphilis. As yet, none fits all the facts. When human heart tissue was used as the source of antigen positive complement fixation reactions were found in about 20% of healthy individuals, reported Osler et al. (AmJSyph 28: 534 1934)

Many methods of complement fixation testing have been devised, but it was not until about 1922 that the great possibilities of flocculation technics were demonstrated. Their first chief advantage was their apparent simplicity. Economy in regard to glassware reagents and expenditure of time prompted their use in many laboratories. Various flocculation tests had reached such degrees of sensitivity and specificity that, in 1928, following comparison with various accepted complement fixation tests at the Second Laboratory Conference of the League of Nations (Copenhagen) the better flocculation tests were considered equal to the better Wassermann tests. Similar results were obtained at the Montevideo Conference (1930) where the best of the flocculation tests were demonstrated to be superior in sensitiveness and equal in specificity to the Bordet Wassermann reaction and its modifications. The results of the American Serological Conferences (1935) in which serodiagnostic tests for syphilis used in the United States were evaluated, indicated that efficient complement fixation tests and efficient flocculation tests for blood or spinal fluid specimens are of about equal clinical value.

Additional conferences held in the United States have shown that at least 5 complement fixation and flocculation tests (Eagle Hinton, Kahn Kline and Kolmer) gave satisfactory results when performed by persons other than the originators.

Improvements in Serologic Methods and Materials.—Combined efforts of research minded serologists and clinicians have done much to improve the procedures employed presently in the serodiagnosis of syphilis. Some recent improvements in laboratory technics and materials are described as follows

Serum Preservatives.—In warm climates, clotted blood specimens become hemolyzed and therefore unsatisfactory for testing. Army facilities found it necessary to separate the serums from the clots to eliminate hemolysis. Frequently it was necessary to ship specimens to distant laboratories, and it was difficult or impossible to ensure sterility in the collection and preparation of serum. During the several days required for specimens to reach laboratory they often became bacteriologically contaminated and unsatisfactory for testing. A suitable substance was needed to prevent contamination without interfering with serologic reactions. Merthiolate (sodium ethylmercurithiosalicylate) proved an excellent antibacterial agent for the preservation of both serum and spinal fluid and for several years has been employed by the United States Public Health Service United States Army and other agencies. In the Division of Serology Army Medical School, serum preserved with 0.1 mg of Merthiolate per milliliter have been used routinely with excellent results (Rein and Bossak: AmJSyph 30 ... 1946) Less than 0.1% of over 20,000 merthiolated specimens were unsatisfactory for testing because of bacterial contamination (Rein and Kelcec AmJSyph 38: 508 1954) Sodium azide is also an excellent preservative.

Inactivation of Serum.—It was long believed necessary to heat or inactivate serums prior to using various flocculation tests for syphilis, and it was thought that such inactivation was necessary only to destroy natural complement present in fresh serums when tested with complement fixation procedures. Investigations by Rein and Pillmer not as yet published elsewhere indicated that fresh syphilitic serum contains a thermolabile substance which inhibits or retards the aggregation of lipid antigens in flocculation reactions. Strongly positive serums often give negative reactions when tested in the raw or unheated state. All serums had to be heated before testing with complement-fixation or flocculation procedures (Rein and Hazay: AmJClinPath 10: 225, 1940) Serums

heated for 10 minutes at 56° C., or for 1 minute at 69.5 C., or for 7 seconds at 100 C. in boiling water gave results practically identical with those obtained with serums heated for the routine 30 minutes at 56 C. Unnecessary prolongation of the heating period tended to destroy some of the reagin in the serums. Rapid inactivation of serum is especially valuable in saving time when rapid flocculation tests are used for the detection of syphilis in donors prior to transfusion.

ANTIGENS.—Considerable progress has been made in the improvement of the various lipid antigens. Isolation of cardiolipin from beef heart (Pangborn JBiolChem 143 47 1941; 153: 343, 1944; ProcSocExpB 48: 484 1941) and the development of methods for the purification of lecithin prepared from both heart and egg yolk (Pangborn JBiolChem 137: 545 1941) have been consequential in improving the serodiagnosis of syphilis. The preparation of cardiolipin antigens for use in various complement fixation, macro- and microflocculation tests has been described by Harris and Portnoy (VDI 3: 353 1944) Harris et al. (VDI 27: 169 1946) Kline (AmJClinPath 10: 68 1946) Brown (JBact 47: 581 1944) Maltaner and Maltaner (JImmunol 51: 195 1945) Kahn and McDermott (JLabClinM 33 1220 1938) Kolmer and Lynch (JVDI 29 160 1948) and Mazzini (personal communication) At the Army Medical School, a cardiolipin antigen was successfully adapted for use in a microflocculation slide test for the serodiagnosis of syphilis (Rein and Bossak: AmJSyph 30 40 1946) The sensitivity of this test was higher than with the Kline diagnostic, Mazzini, Kahn, Hinton, Eagle Boerner Jones-Lukens and Kolmer tests. This increased sensitivity was obtained without a y apparent i crease in onspecificity Extraordinary specificity of the cardiolipin antigen in the presence of malarial infection was repeatedly demonstrated (Rein and Kent: J 133 101 1947)

PRESERVATION OF SHEEP BLOOD.—One of the difficulties in the performance of complement fixation tests lies in obtaining satisfactory sheep blood. Laboratories of modest institutions lack facilities for raising sheep and have to obtain their supply from a slaughter house Red blood cell suspensions prepared from such blood often prove unsatisfactory A preservation technic for maintaining prolonged uniformity in the properties of sheep cells would be a great laboratory convenience. Aseptic collection of sheep blood in modified Alsevers solution at ordinary temperatures and subsequent refrigeration do, in fact permit preservation of the blood for several months w thout appreciable hemolysis or change in susceptibility to lysis by guinea pig complement and rabbit amboceptor it was shown by Bukantz et al. (JLabClinM 31: 394, 1946) Preserved sheep cells are commercially available.

SPECTROPHOTOMETRIC STANDARDIZATION.—Accurate standardization of the hemolytic system in complement fixation tests has become of paramount importance in maintaining constant level f sensitivity To this end the spectrophotometer has been adapted by Kent et al. (JImmu l 53: 37 1946) not only f r quantitative titration of complement and amboceptor and for standardization of sheep cell suspension but also for final readings of the tests themselves The use of this instrument ha been adapted also for complement fixation tests fo other diseases such as malaria (Rein et al. AmJHyg 49: 3, 1949) and amebiasis (Kent and Rein Sc 103 598 1946)

AMBOCEPTOR PREPARATION.—The preparat on of antisheep amboceptor with the elimin tion of rabbit shock is dvantageous to laboratories performing complement fixation tests. The chief difficulty in preparing amboceptor has been the heavy loss of rabbits because f hock part cularly following the injection of the second dose f cells Furthermore when whole cells are employed, finished amboceptor may contai relatively large amoun t of agglut nogen o precipitins, rendering it unsat sfactory fo use A method was de eloped for the preparation of antisheep amboceptor utilizing the cell stroma instead of the packed washed cells by Sawyer and Bourke (JLabCl nM 31 714 1946) The strom i p epared by pecifically hemolyzing wa hed beep cells with mboceptor and compleme t Sati fa tory amboceptor has been produced in about 10 d ys, and titers re h gher tha those usually obtai ed by other methods.

COMPLEMENT SUPPLY.—Most small l boratories do not have fa ilities for maintaining a colony f gu ea pigs necessary for the s pply of complement. Dried o lyophilized gu nea pig serum ha been used n various types of complement fixat on test with ex celle t result Dried gui ea p g complement supplied t the Arm Medical School wa required to meet the following specificatio

(1) T t the xact hem l t unit hould be contained i more th n 0.45 ml of l 30 dilution when titrated by the Kolme method.
( ) *Moist re Content* should not exceed 1% by weight.
(3) *Hemoglob n Cont t* should be minimal.
(4) *Sou f Gu ea Pigs* serum should be obtained from ormal healthy guinea pigs never previously used for a y other purpose
(5) *P serv e Flu d* upplied w th the dried product should cont n 0% sodi m eet te nd % bori acid.

Sev ral commerc al concerns do p epare dried gui ea pig compleme t meeti g these requirements and giving satisfact ry results.

SERUM CONTROLS.—A pos t e nd a egat e serum co trol should be ncluded every time serologic xam nat on re made Th h lps t e sure th sensitiv t of th test employed and tend to min mi the occurrence of techn cal rrors. Ma y laboratories unwisely select fo their cont ol a stro gl pos t serum, wh h i unsat f ctory for detecting a decrease or increase in the sen ti ty f a serologic procedure; for f seas

tivity were reduced or increased by as much as 50% a strongly positive serum might still give a four-plus reaction. The use of weakly positive or partially positive serums would more readily detect changes in sensitivity due to technical error or to deterioration of material employed. If strongly positive serums are utilized, they should be subjected to serial dilutions and tests performed on each dilution. A reduction or increase in titer would then indicate a change in sensitivity. Routine utilization of a strongly positive serum (quantitative control) and weakly positive serum (qualitative control) is of utmost importance in controlling the sensitivity levels of serologic procedures.

OTHER IMPROVEMENTS.—There have been many other improvements, such as (1) the use of recalcified plasma instead of serums for serologic testing (Barnard and Helz: JLabClinM 29: 1-87 1944) (2) the use of the 50% hemolytic unit instead of 100% end point of hemolysis in determining the degree of fixation of complement by specific antigen antibody complex (Wadsworth: Standard Method of the Division of Laboratories and Research of the New York State Department of Health Williams & Wilkins, 1939, p. 224); (3) the introduction of wetting agents for the proper washing of serologic glassware, (4) the use of buffered solution in preparing the antigen emulsions, complement and amboceptor dilutions and for diluting strongly positive serum for the various quantitative tests; and (5) the prevention of nonspecific and prezone reactions in the complement fixation test with spinal fluid by the addition of egg albumen or normal serum to the complement.

Antibodies in Syphilis.—On the basis of experiments with pallida Eagle and Hogan (JExperM 71: 215 1940) demonstrated the presence of 2 antibodies in syphilitic serum: an antilipidal antibody and an antitreponemal antibody. When syphilitic serum was adsorbed with an excess of beef heart lipidal antigen all reagin was removed. The reagin free filtrate still gave agglutination and complement fixation reactions with spirochetal suspensions in the same titer as the original serum. When this serum was adsorbed with spirochetal suspensions, its reactivity with lipidal and with spirochetal antigen was removed.

Other studies confirmed the presence of multiple antibodies in syphilitic serum. Working with palligen 3 distinct antibodies in syphilitic serum, (1) antilipidal (2) antitreponemal (thermolabile) and (3) antitreponemal (thermostable) were demonstrated by D'Alessandro (BollIstSieroterMilan 25: 133, 1946). He expressed the beliefs that in early primary syphilis the antitreponemal antibodies manifest themselves before the antilipidal antibodies; in secondary and tertiary syphilis both types run a parallel course and in cases of prenatal syphilis the antilipidal antibody often exists alone. This work was confirmed by Puccinelli and Oddo (Gio ItalD 87: 447 1946) who described the technic of demonstrating the 3 antibodies.

Convincing evidence of the existence of specific antitreponemal antibody in syphilitic serum is seen in the work of Nelson and Mayer (JExperM 89: 369 1949). Employing the virulent Nichols strain of *T pallidum* kept alive on a special basal medium, they showed that these actively motile spirochetes lost their motility when incubated at 35 C. for 16 hours in the presence of syphilitic serum. No such immobilizing effect was observed with normal and with false positive control serums. They demonstrated furthermore that immobilizing antibody is distinct from antilipidal antibody; after adsorption with lipidal antigen of all the reagin of a syphilitic serum, so that the filtrate gave negative flocculation and complement fixation reactions, the immobilizing effect of the serum remained unaltered. The same specific immobilizing antibody is present in the spinal fluids of patients with untreated neurosyphilis. The antitreponemal antibody appears to be truly specific of *T pallidum* infection.

Evaluation of Serologic Tests.—Interpretation of laboratory reports requires considerable knowledge of serology. Reliability of a laboratory depends to some extent on the volume of work done, meticulous adherence to standardized methods, and frequently repeated checking with other good laboratories. It is fundamentally a mystery why a lipid extract of tissues of a normal animal reacts with the serum of a syphilitic human being and it is true that the serums of some nonsyphilitic persons, as well as the serums of some persons suffering with diseases other than syphilis, give syphilitic reactions on testing. The biologic false positive cannot by classic means be distinguished from the truly positive (Rein and Elsberg JID 6 113 1945) although complex procedures investigated by Neurath et al. (AmJSyph 31 347 ff 1947) made it hopeful that the puzzle might be answered. See Treponema immobilization test (p 430) Antibodies in syphilis (p 433)

See Cumming et al (J 110 1943, 1935) evaluation of tests in U.S.A., Committee Rept. (VDI suppl. #1 1938) Parran et l. (J 109 422, 1937), stat laboratories Binkley (OhioSMJ 35 731 1939) interpretation of reports, Kolmer (AmJPubH 34 510, 1944), advises use of more than 1 test and repeated tests; Rein (NYSJM 47 2480, 1947) the higher the total dose of penicillin and the longer the time during which it is given, the shorter the time required to attain seronegativity.

QUANTITATIVE TESTING is becoming routine, early encouraged by Moore and Eagle (AnnIntM 14: 1802, 1941). When a low titer persists after adequate treatment, no further

treatment is indicated unless the titer rises significantly according to Thomas (AmJSyph 30 317 1946) Clinical relapse is regularly heralded by rise of titer Persisting high titer after presumably adequate treatment may justify continuation of therapy In neurosyphilis, the spinal fluid findings, not those of the blood, are the reliable guides. Variation in titer is puzzling especially in low titer patients, where a test may be negative at one time and weakly positive at another this is sometimes due to variations in the sensitivity of the test (Mohr and Smith AmJSyph 4 122, 1940) Extremely sensitive tests give more false positives but miss few actual cases, and less sensitive testing technic yields positives more to be trusted but misses some weakly positive cases (Tuft and Richter: AmJSyph 23 31 1939) Test technic was described in detail for several standard tests in VDI Suppl. 9 1930 Hi richsen (VDI Suppl. 14, 1941) reviewed the subject in detail. The anticomplementary test sometimes means the titer is extremely high (Carter: ADS 46: 842, 104) Discrepancies between results of testing the same serums with different tests were studied in detail by Mahoney (NYBJM 43: 843 1943)

The demand for quantitative serologic testing increased markedly following the development of rap d therapeutic measures for the treatment of syphilis with penicillin. It must be pointed out, however that a quantitative serum test i not necessarily an aid to diagnosis. It determines only the maximum dilution in which that particular serum still gives a pos tiv reaction. A syphilitic patient whose serum is positive in a 1 16 dilution is no less syphilitic than the one whose serum is positive in a dilution of 1-256.

Too much emphasis has been placed, in routine qualitative testing on the pseudo-quantitative method of reporting positive reactions as 1 plus, " plu , 3 plus and 4 plus. The physician is often lulled into a sense of false security on serologic recheck if the laboratory reports a reduction in titer from 3 plus to 1 plu and he and the patient may be unduly concerned if the report changes from a 1 pl s to a 3 plus reaction. Furthermore a 4 plus reaction does not necessarily indicate a strongly positive reaction since one 4 plus serum may be positive only in a dilution of 1: whereas another 4 plus serum may continue to give positive reactions in a dilution of 1 .56 The latter serum was 128 times more positive than the first serum, yet both we e reported as 4 plus or strongly positive by the routine qualitative method.

The value and importance of carefully performed and properly interpreted quanti tat ve tests cannot be overemphasized. Unfortunat ly th re has been a great deal of confusion regarding the p esent tatus of quantitative procedures because of the dis sim lar methods of performance interpretation and reporting of the tests.

The chief value of quantitative tests lies in the fact that the physician can by their use ad antageously evaluate the serologic response of his patient to a particular treatment schedule from the onset of therap throughout the period of clin cal a d serologic follow p. A reduction in serologic titer may be the only clue and a valuable one as to the success of antisyphilitic therapy

Carefully performed and prope l interpreted quantitative tests are of value to the pract ci g physician in the following ways

(1) To est mate response t treatme t. Short xtend e method of therapy es pecial with pen c llin, are completed while the pat ent is still seropos t ve If serologic tests are to contribute in determining the efficacy of therapy quant tati e procedures performed at regular mo thly ntervals are eces ar If quant tati e tests rema n strongly pos t ve long after reversal to seronegativ ty m ght be anticipated, one may judge the case a treatment fail re although there are various factors wh h infl ence th t me requ red to attain se onegativity

( ) To diff rent t between se ologic relapse and rei fection.

(3) To diff rentiate between pren tal syph lis and passive reagi emia.

(4) To determine reagin fastness (seroresistance)

(5) To d fferentiate between true and false posit v serologic reactions for syphilis

Limitations of Serodiagnostic Procedures for Syphilis.—It is true that most of the positive serologic reactions obtained with currently used non-specific lipid antigens are due to syphilis. It is also true that positive results occurring in some normal individuals are unrelated to syphilis and represent a general biologic phenomenon. False positive nonspecific reactions may also occur as the result of a variety of infectious diseases, immunizations and metabolic disturbances. Not infrequently when false positive reactions have occurred in the absence of syphilis, persons have been stigmatized and given treatment solely on the basis of positive reactions disclosed by routine serologic examinations. Compulsory preinduction prenatal and premarital serologic examinations and the increasingly widespread use of routine blood testing in medical practice in industry and on separation from the Armed Forces increased the number of individuals needlessly subjected to antisyphilitic treatment

Serodiagnostic tests are not truly specific for syphilis so that the physician must be aware of conditions other than syphilis which may produce nonspecific, nonsyphilitic reactions.

FALSE POSITIVE REACTIONS may be either technical or biologic

Technical false positives may occur with serums containing no antibodies and may be due to (1) technical errors in the collection and labeling of specimens (2) the use of unsatisfactory contaminated or hemolyzed blood specimens (3) errors in the performance of the serologic tests (4) the use of faulty materials and reagents in the test or (5) errors in recording or reporting the final results. With the improvement of serologic technics and the use of improved materials especially purified antigens of the cardiolipin type there has been achieved a marked reduction in the incidence of technical false positives.

Biologic false positives may be due to (1) the presence of antibody like substances similar to the antibodies produced in syphilitic diseases; (2) an increase or alteration of the seroglobulin fraction or (3) an increase or alteration of some other chemical substance or substances in the blood.

False positive tests may sometimes be avoided by requesting several different procedures on the same serum by different laboratories. One never diagnoses syphilis on the basis of the report of one test

When the test is positive because of the existence of nonsyphilitic disease the positivity is as a rule transient, lasting for only a few weeks or months, and as a rule the titer is not high. Disorders which induce pseudosyphilitic positivity include upper respiratory infections vaccination against smallpox infectious mononucleosis, typhus, filariasis, hyperproteinemia, varicella injections of foreign protein such as tetanus toxoid, infectious hepatitis, malaria leprosy tuberculosis, lymphopathia venerea leishmaniasis and scarlet fever Syphilitic reaction occurs in yaws pinta rat bite spirochetosis, relapsing fever and other spirochetal infections. Before interpreting tests as indicative of syphilis, consideration must be given these possibilities (Mohr et al. AnnIntM 77 332, 1946 Beerman AmJMSc 209 525 210 524, 1945 Albrecht CurMDig July 1947 Stokes et al. J 130 57 1946)

See Hasen et al. (ADS 37 431 1938) in malaria Parran and Emerson (VDI 1: 1 1939), in tuberculosis Baduak (J 112 1462, 1939) in mononucleosis; Lynch et al. (J 117 591, 1941), in vaccinia Mohr et al (AIntM 68: 898, 1941) 1 normal persons; Cardon et al (ADS 46 712 1942), in hyperproteinemia; Kahn (JLabClinM 28: 1175, 1943) verification; Kissell and Puccinelli (BullUSAMD Sept. 1944, p. 3) in jaundice, Faust and Ross (VDI 25 173, 1944) in leprosy, more often in lepromatous than tuberculoid; Eager and Moffat (VDI 25 271, 1944), familial; Helmoff (MilSurg 95, 419 1944) after tetanus toxoid Kane and Henneman (NEngJM 233 407 1945), in varicella, Lofgren (ActaD-V 26 241, 1946) in erythema nodosum Page and Helmoff (AnIM 73 181, 1946), 100 instances; Rein and Kent (J 133 1001 1947), 1 malaria, Singer and Boerner (AmJMSci 214 89 1947), familial, Karafonetis and Kent (JLabClinM 43 243, 1954), in infectious mononucleosis Ahlson and Dick (*Lancet* 2 364, 1954) in virus pneumonia *Portnoy and Edmundson (InternatJLepr 22* 181, 1954) syphilitic serum from patient with or without leprosy shows increased reactivity if choline chlorid is added to antigen suspension, but choline diminishes reactivity of false positive serum from leper

Acute and chronic types of biologically false positive reactions may be distinguished (Moore and Mohr: J 150: 467 1952) The former are associated with various infections and are transitory The latter may signify the presence of serious underlying disease sometimes of the collagen type, and every effort should be made to follow the patient and determine the cause. False positive serologic reactions may precede other symptoms identifying systemic lupus erythematosus, and in fact may foreshadow this dread disease (Haserick and Long: AnnIntM 37 559 1952) A false positive reaction for this reason alone necessitates painstaking investigation.

Many normal animals give positive tests (Kemp et al.: AmJSyph 4 537 1940) Biologic false positivity life-long when it occurs in normal human beings, has been difficult to identify by serologic methods (Scott et al. AmJSyph 29: 505 1945)

The treponema immobilization test generally gives negative results in biologically false positive reactors and constitutes a significant procedure for distinguishing syphilitic from nonsyphilitic individuals (Mohr et al.: AmJSyph 34: 405, 1950)

Persistent positivity perhaps justifies the giving of adequate treatment now that penicillin makes such a recommendation less hazardous to the patient than this advice would have been a few years ago. In pregnancy the evaluation of positive reactions is less conservative for the fetus must be protected possibly at the cost of giving unnecessary treatment to some women (Stokes and James: AmJSyph 33: 14 1949) Persistent positivity alone and not corroborated by clinical or other evidence of the disease or by positive reaction with a specific treponemal test, does not justify the diagnosis of syphilis.

ACUTE FALSE POSITIVE REACTIONS.—*Since the large majority of false positive reactions are of the transient type,* reverting to seronegativity within a short time and due to any of many possible nonsyphilitic conditions in susceptible serologic reactors, all individuals with *positive serologic reactions* for syphilis whose apparent infection is unconfirmed by history or clinical evidence should be followed serologically without treatment for 3 months, serologic tests being performed at intervals of from 2 to 4 weeks. Then the patient should be completely reappraised in an effort to ascertain whether syphilis is present. Continuing diminution of serologic titer in a relatively short time without antisyphilitic treatment, is strong evidence favoring interpretation of serologic reactions as nonspecific. Irreparable harm can be done by ill-considered hasty diagnosis. If treatment is started prematurely the evidence which could finally lead to an accurate diagnosis will be obscured. *Serologic tests become negative after a few injections,* so that one never knows whether the reversion to seronegativity represented response to therapy or merely reflected the fact that the patient was not syphilitic.

CHRONIC FALSE POSITIVE REACTORS AND THE PROBLEM OF DIAGNOSING LATENT SYPHILIS.—Physicians are occasionally confronted with individuals in whom routine serologic examinations reveal positive serologic tests for syphilis uncorroborated by any other evidence of the disease. The patient is not likely to be subjected to all the procedures required to establish or exclude the diagnosis of syphilitic infection but is likely to receive penicillin therapy in preference to a necessarily time-consuming and relatively expensive investigation. The importance of serologic and clinical follow up after such therapy is generally not stressed for one may fail to realize that once treatment has been instituted the individual *must be considered* as probably syphilitic and *therefore entitled to the same follow up as if he had been proved to be syphilitic* (Rein and Elsberg AmJClinPath 14 461, 1944).

The existence of specific antitreponemal antibodies in the serums of latent syphilitics by means of the immobilization phenomenon has been proved by Nelson and Mayer (JExperM 89 369 1949). Whenever possible a diagnosis of latent syphilis should not be made until these specific antibodies have been demonstrated. The TPI test approaches absolute specificity in nonsyphilitic patients, having proved negative in 99.7% of almost 1 400 of them tested by Zellman (AmJSyph 38 506 1954). The degree of positivity of this test increases with the duration of infection.

SEROPOSITIVE *REACTORS* SHOULD BE *CAREFULLY INVESTIGATED in an attempt* to establish or exclude a diagnosis of latent syphilis prior to therapy

(1) Whenever possible demonstrate the presence of specific antitreponemal antibodies *by means of the immobilization phenomenon. A biologic false positive reactor* may be correctly identified even after and in *spite of* antisyphilitic treatment.

(2) Withhold therapy *for* from 3 to 6 months in *order* to afford the transiently false positive patient an opportunity to revert spontaneously to seronegativity

(3) If adequate work up is not feasible due to lack of facilities or poor cooperation of the patient penicillin therapy should be administered to prevent the possibility of the development of late syphilitic sequelae

(4) Once therapy is administered the patient should be considered as a latent syphilitic and should have the benefit *of the same follow up as is due a patient known to have* latent syphilis

FALSE NEGATIVE REACTIONS.—A serious limitation of serodiagnostic procedure *is the occurrence of false negative reactions.* When the serum of a patient with clinical syphilis gives a negative reaction that patient is said to have seronegative syphilis, and the reaction is interpreted as falsely negative. Actually the serum contains so little reagin that the test failed to detect its presence. If the same serum were rechecked by a more sensitive test there might result a positive reaction. Such discrepancies are frequent in patients with primary syphilis. After the development of a primary lesion, the serum may give *negative reactions with insensitive tests for a week* or longer, yet with more sensitive tests positive reactions may be obtained within a few days

after the appearance of the chancre In an unpublished study of experimental syphilis in rabbits, Rein found it possible to detect the evidence of syphilis by means of a sensitive serologic test as early as 5 days before the clinical appearance of the chancre. This suggests that although antibodies begin to appear in the blood soon after inoculation with *Treponema pallidum*, routine tests are not sufficiently sensitive to detect their presence. The incidence of seronegative primary syphilis depends then not only on the time elapsed since inoculation but also on the sensitivity of the tests employed.

Similarly in seronegative late syphilis, as exemplified not uncommonly in patients with syphilis of the aorta (there are reports that the incidence of seronegative cardiovascular syphilis and neurosyphilis is as high as 40%) seronegativity results from the relative insensitivity of the tests used. When the more sensitive tests are used the incidence of negative reactions markedly decreases. Thus the number of cases of seronegative late syphilis does not depend wholly on the biologic course of syphilis but rather on the sensitivity of particular tests. Yet even with the most sensitive tests available one may obtain a negative reaction in a patient who has syphilis.

Seronegativity in the presence of syphilis may be due to several factors (1) the amount of antibody is minimal and cannot be detected by tests of ordinary sensitivity (2) so much antibody may be present that false negative zone reactions occur (3) if fresh serum is used, containing considerable amounts of thermolabile-inhibiting substances, the test may be negative and (4) the presence of a thermostable-inhibiting substance in the albumin fraction of the serum may result in negative reaction.

Serologic Response in Penicillin-Treated Syphilis.—Some physicians are disappointed when serologic tests remain positive fo several months or more following penicillin therapy Several factors, however influence the time required to attain sero egativity (Rein: NYSJM 47 450 1950):

(1) State of Disease.—The olde the disease and the longer the spirochetes have been present the longe it takes for the host tissues to stop formi g antibodies. As a rule patients with secondary syphilis require more time to become sero egative than patients with seropositive primary disease.

(2) Immunologic Responses of Individual Patients Related to Serologic Titer.—Some patients with syphilis develop more ant bodies than others. As a rule, patients with high serologic titers at the onset of therapy require more time to attain seronegativity than those with relatively low titers.

(3) Sensitivity of the Serologic Procedure.—The more sensitive the serologic test, th longe it takes to attain seronegativity a measured by it. Whe one employs battery of serologic tests with various sensitivities, negative reactions may be obtained with the less sensiti e tests long before more sen itive test become negative

(4) Type of Test.—Certain types of tests m y remain positive long after other tests have become negative even though they may be of comparable sensitivity

It must be pointed out that th re are many variations in these factors, and no fixed rules can be made regarding the time required to attain seronegativity It is generally agreed that the persiste ce of positive serologic reactions does not necessarily indicate the persistence of act e syphil tic infection, and that it is not necessary to retreat patients merely because they may not have reverted to seronegativity soon afer completion of therapy

The pattern of return to seronegat vity as determined by applying a battery of 7 tests to 100 patients with primary syphilis and 100 with secondary treated with penicillin, wa studied by Cutler et al. (AmJSyph 37 514 1953) Reversal was faster follow ng treatment f primary syphilis than of secondary and sensitive tests were slower to revert than relatively insensiti e o es. Individual patterns of response were seen which were quite variant from the usual patterns.

Prognosis.—The earlier treatment is instituted and the more thoroughly it is carried out the better the outlook in general. Clinical cure of the infection, but not of its scars and their mechanical and physiologic sequelae, can nowadays be expected with confidence The consequences of undetected and untreated disease are as disastrous as they ever were and it could at one time have been said that the consequences of the disease were disastrous be-

cause of the treatment in the days of mercurial and arsenical therapy In tolerance of penicillin, too has taken its relatively small toll and must be given due consideration.

Failures of adequate treatment to eliminate the causative organism are *nowadays extremely unusual, and many of the "failures" are in fact rein* fections. The individual who acquires syphilis, unless it is an innocent infec tion, is usually the type of person who is likely to expose himself again. It does no good and perhaps provokes psychologic trauma to tell the patient this, yet it is difficult to erase the moral stigma associated with syphilis (JMoSMA *34 467 1937 35 65 1938)*

Alcoholism tobacco and mental physical and sexual excesses are detri mental to the welfare of the patient The location of the initial lesion exer cises no influence upon the aftercourse of the disease. In patients whose syph ilis is adequately treated the probability of late complications is greatly di *minished.*

The disease may materially lessen life expectancy in men with acquired syphilis this was shortened from that of the general population in the age group 30 to 60 years by 17% in the white and by 30% in the Negro Usilton and Miner (VDI 18 231 1937) reported from their study of Cooperative Clin ical *Group material Between 1939 and 1948 the total syphilis mortality rate* was reduced approximately 47% (Usilton et al AmJSyph 37 403 1953) Mortality was relatively greater among males and among nonwhites. Of the total syphilis deaths, cardiovascular syphilis in 1948 represented a much greater proportion than in 1939

Review of actuarial studies by Schamberg (AmJSyph 30: 540 1946) showed that the best figures indicated that even the well-treated group had an appreciably higher mor tality a fact probably due to factors of selection. Schamberg concluded, "There is no evidence that syphilis adversely influences life expectancy except through the known lethal effects of its serious late manifestations in particular those of the central nervous and cardiovascular systems. There is no evidence that syphilitic infection per se or anti *syphilitic treatment predisposes to tuberculosis, pneumonia, nephritis,* or other nonsyphilitic diseases. Increased mortality in syphilitics is caused in part by death due directly to syphilis, in part to the higher death rate in segments of the population which have a high syphilis prevalence Adequate antisyphilitic treatment will in the majority of cases pre vent the late manifestations of syphilis. . . . Employers may safely hire syphilitics. The incidence of cardiovascular syphilis is inversely proportional to the amount of treat ment received in the early stages of the disease ranging from 18% in untreated cases to 0.4% in those adequately treated (*Kemp and Cochems AmJSyph 1 625 1937)* Moore and Schamberg (*J 134 1532 1947*) stated that the applicant with untreated syphilis in any stage should be granted life insurance if the applicant can demonstrate good health otherwise in all patients the spinal fluid should have been shown by adequate and reliable tests to be normal after adequate treatment and not earlier than 2 years after infection. See JVDI 27 34-52 1946.

The outlook intimately *depends on treatment. Stokes et al. (AmJMSc 188: 660,* 1934) in the Cooperative Group studies, stated that relapse diminished as the number of arsphenamine injections increased. Continuous treatment was to be preferred to inter mittent, irregular or tensive attack. Arsphenamine did not predispose to central nervous system involvement but irregular treatment certainly did. Adequate treatment (20 to 30 arsenical injections and bismuth in courses) *for* years yielded symptomatic cure of 96% of early cases, while inadequate treatment cured only 73% Any treatment is better than none yet neurosyphilis was 3 times as common in the poorly treated cases as in the untreated series.

Comparable statistics regarding the outcome in patients treated with penicillin can not be compiled for a number of years, for the drug was first used in 1943 but its striking effectiveness has been most encouraging (Moore et al. J 190 07 1944; Stokes et al. J 1?6 73 1944)

See Medico-Actuarial Mortality Investigation (Assn Life Ins. Medical Directors and Actuarial Soc of Amer N Y 1912 1914 Medical Impairment Study 1929 (Actuarial Soc Amer and Assn Life Ins Med Directors, N Y 1931) Impairment Study 1938 (id 1939) Stein et al (JSocHyg 23 258 1937) life insurance and syphilis Morgan (J 113 341 1939) Murrell and Manson (SouthMJ 32 322 1939) Statistical Bulletin, Metropolitan Life Ins Co 23 8 1942 Tait (JVDI 31 95 1950) mortality dropped from 14 in 1938 to 8 in 1948 per 100,000 Rosahn (ADS 66 547 1952) controlled experiments with populations of mice syphilis decreased longevity McElligott et al (BritJVD 29 64, 1953) deaths in England and Wales, 1931 1950

About one fourth of all patients who contract syphilis can expect spon taneous cure without treatment and another fourth achieve complete latency About one-sixth of all syphilitics who develop positive serologic tests will re main seropositive *with or without* treatment

UNTREATED SYPHILIS.—Bruusgaard (AfDuS 157 309 1929) surveyed the 2,181 patients who were given no specific treatment by Boeck who from 1891 to 1910 at Oslo preferred no treatment at all in early syphilis to the mercurial treatment then in vogue. This carefully studied untreated series served as the control in the Cooperative Group review of the effects of treatment in early syphilis. Comparison of treated with untreated syphilis (Sowder Am JS 24 684 1940) showed that (1) central nervous system relapse is 2 to 4 times as frequent in untreated cases (2) cutaneous and osseous relapses are 17 to 26 times as frequent in untreated cases; (3) treatment results in freedom from symptoms in 77% if adequate and 63% if less than adequate, while no treatment is followed by freedom from symptoms in 24 to 36%; (4) in cases of seronegative primary infection, despite treatment there occurs 1.2 to 1.5% incidence of spinal fluid abnormality within 3 to 20 years (5) adequate treatment results in freedom from symptoms in 96% while no treatment is followed by freedom from symptoms in 61% of cases in the 3- to 10-year period while in the 10- to 20-year period treatment has the advantage of 74 as compared with 50% freedom from symptoms (6) syphilis is relatively benign but it is worth treating; (7) irregularity of treatment seemed the chief cause of complications. Low dosage of arsenicals with intermittence of treatment resulted in a high incidence of neurosyphilis. Continuous treatment for 2 years cured 86% of seronegative primary cases, 64% of seropositive primary cases, and 81.5% of secondary cases. A florid secondary eruption seemed an advantage

TREATED AND UNTREATED SYPHILIS. COOPERATIVE CLINICAL INVESTIGATION AND BRUUSGAARD'S SERIES

	GROUPING BY YEARS AFTER INFECTION	INCIDENCE IN GROUPS	
		TREATED	UNTREATED
1 Relapse in the form of clinical involvement of central nervous system	*(years)*	*(per cent)*	*(per cent)*
	(3-10)	1.4	5.1
	(10-20)	9.3	16.7
2. Relapse in the form of cutaneous mucosal, and osseous lesions	(3-10)	2.0	34.2
	(10-20)	1.—	31.7
3. Symptom free cases with positive Wassermann	(3-10)	17.6	36.7
	(10-20)	*16.3*	*13.6*
[The similarity of proportions in treated (16.3%) and untreated (13.6%) cases of the 10-20 yr group suggests that about 15 per cent of fixedly positive Wassermann cases is perhaps an irreducible minimum.]			
4 Symptom-free cases with negative Wassermann	(3-10)	70	4.0
	(10-20)	63.3	36.4
5. Cardiovascular symptoms	(3-10)	0.7 1.3(?)	0 (unrecognized ?)
	(10-20)	5.8 10.4(?)	1.5
	(20-30)	?	10.0
	(30-40)	?	12.5
6. Symptom-free cases, serum positive or negative		(Adequate treatment)	(No treatment)
	(3-10)	96.0	60.7
	(10-20)	74.0	50.0

Bruusgaard's patients were restudied by Danbolt et al. (ActaD-V 34 34 1954) who were able to pick up about 20% of them. Cardiovascular syphilis was found in about 10% of them and neurosyphilis in about 6%. Some 67% of the untreated syphilitics had at no time suffered late manifestations of the disease.

Autopsies of 380 untreated syphilitics revealed anatomic lesions of syphilis in 39% and no such lesions in 61% while 23% of the series died as a result of syphilis, a death rate approximating that of Bruusgaard's series, as reported by Rosahn (JVDI 27 293 1946). Some 17% of these persons had achieved spontaneous cure without treatment.

Untreated Negro males, 231 cases followed for 16 years were reported on by Pesare et al. (AmJSyph 34 201 1950). There was a higher mortality rate

in each 10-year age group than in the controls. There was a higher incidence of potentially disabling conditions of heart, aorta and other parts of the body until age 55 was attained.

Toxic reactions to medication probably do not affect the status of the disease favorably or unfavorably except in so far as they may signify that it is impossible to use a particular drug.

Prophylaxis.—Avoidance of exposure to *S. pallida* can be depended on to prevent infection. Yet the admonition to avoid exposure is futile, for the human herd is promiscuous. It is generally possible to prevent infection despite a syphilitic contact if advantage is taken of the antiseptic effects of the prompt and generous use of soap and water followed by diligent application of Metchnikoff's paste composed of 35 to 50% calomel in hydrous wool fat and petrolatum. The Army prophylactic kit, a single tube containing 30% calomel and 15% micronized sulfathiazole achieved a failure rate of 0.13% (BullUSAMD 76: 25 1944). Mechanical separation of presumably infected tissues from those to be kept pure is probably best (Cautley et al.: AmJMSc 195 153, 1938). Moist sores teeming with spirochetes are not regionally limited to genital distribution.

The maintenance of an adequate level of bismuth by injecting a suspension of it into prostitutes every 2 weeks may keep them noninfectious (Hanzlik et al.: AmJSyph 24 465 1940).

If the possibility of infection has been incurred, and the time for prophylaxis has passed, one does not know whether inoculation has actually taken place. In such cases, abortive treatment comprising 900,000 units of repository penicillin 0.05 Gm. Mapharsen and an intramuscular injection of bismuth, all in one visit, prevented the development of syphilis, according to Alexander and Schoch (ADS 59: 1, 1949). They argued that waiting for a definitive diagnosis is outmoded, yet it seems highly desirable to know whether the patient was infected or not. See Treatment penicillin (p. 44)

See Stokes (BJD 48 57 1936 VDI 23 193, 1942) Hazen et l. (J 115 1185, 1940) condom, soap and calomel ointment Eagle et al. (AmJSyph 31 25 , 1947) arsenoxid ointments Edit. (J 139 925, 1949) oral penicillin frowned upon, although it works (Eagle et al. PHRpts 63 1411 1948)

Control.—As a public health problem, syphilis has been attacked with vigor in the United States. Heller (AmJSyph 31 569 194) estimated the death rate at 16 per 100,000 in 1936 and estimated it as 9.2 per 100 000 in 1946, while infant deaths from syphilis dropped from 69 to 25. He quoted as basic the 9 principles of control advocated by Parran: provision of an adequate and adequately trained public health service staff, case finding and case holding premarital and prenatal serodiagnosis, provision of free diagnostic services, provision of treatment facilities distribution of drugs for therapy routinization of serodiagnostic tests, the dissemination of scientific information, and public education. The efforts of the New York City Health Department were similar and effective as described by Rice (AnnIntM 12 503, 1985)

Case finding and case holding, the tracing of contacts and inducing patients once gotten under treatment to persist in treatment were discussed by Woods (VDI 20 3 1 1939). Practical problems were reviewed by Stokes (AmJSyph 23: 549 1939). Contact tracing can be worth while and successful (Casselman and Cadwallader VDI 20 153, 1939). While professional prostitution is relatively unimportant statistically, it must energetically be suppressed, it is generally agreed (Clark VDI 21 349 1940 Stokes VDI 23 193, 193 194 ; Williams CanadPHJ 31 461, 1940). Amateurs of the civilian public were the greatest hazard to the Armed Forces. Contact tracing sustained by quarantine authority can disclose numerous infectious individuals and bring them under treatment (Freeman OhioSMJ 36 616 1940).

Rapid treatment centers established during the war emergency and most creditably managed in the United States by Wile contributed greatly to the control effort. The risks of intensive treatment as then practiced led Stokes (J 1 0 1093 194) to question the wisdom of dangerously rapid treatment in dealing with the latent cases comprising some 0 to 50% of the total cases uncovered by diligent case finding. See p. 449

An especially remunerative method of case finding is the serologic testing of large groups of individuals (Anderson et al. J 120 8 3 194 . Smith and Gill (SouthMJ 43 183 1950). There has been a marked reduction in the numbers of cases so found. Nevertheless Syphilis is still with us and case finding by routine STS in industrial groups should be persisted with, stated Downing (J 153 465 1953) who pleaded for expertness in evaluating employees found to react positively.

Premarital blood testing is in general favor and succeeds in reaching large numbers of persons (Kolmer: J ILL: 2353 1939) although it has been argued against (Nelson AmJSyph 23 58, 1939 see p. 336). Recognition is universal that serologic tests during pregnancy are essential and that congenital syphilis is a preventable disease (Hogan NYSJM 37 929 193) see Pregnancy and syphilis (p. 44). Prenatal treatment (p. 466

Case holding has become less problematical since penicillin therapy has so markedly reduced the duration and simplified the treatment of syphilis, the mortality of which is steadily diminishing (Wright: J 140: 8, 1951). Yet the disease is not defeated merely

by effective treatment, and the aim of global control is far from achieved although the realization of such a goal can no longer be considered fanciful (Moore AmJSyph 15 101, 1931)

See Smith and Brumfield (J 161: 1955, 1933) contact tracing Vonderlehr (J 107: 782, 1936) epidemiology; Nelson and Crain (Syphilis, Gonorrhea and the Public Health, Macmillan, 1938); Stokes and Ingraham (J 113 1132, 1939) syphilis and the law Packer et al. (VDI 23 289 1942) follow-up of delinquents from treatment; Sweeney (VDI 23 137, 1942) contact tracing, Frost (JVDI 29: 41 1948), case holding in VD clinic (VDF ct Sheet, DI VD Office of Statistics, USPHS, #6, 1949) estimated incidence 1936-1949 case rates, mortality epidemiologic data, costs, results of penicillin therapy; Marcussen and Bendal (AmJSyph 34 144, 1950) epidemiology in Greenland Willcox (BMJ 1: 677 1953) syphilis and marriage.

Marriage should be undertaken by a syphilitic person only after he has undergone a complete course of adequate treatment and after he has remained free from evidence of the disease for a considerable period after the termination of active therapy Perhaps 2 years and preferably more should have elapsed from the time of infection. When the infection was 5 years old at the time of marriage 30% of the partners became infected, but after the tenth year the likelihood of the normal partner s acquiring the disease was almost nonexistent (O Leary: PSMMC 15: 1 1040) See Jones (JMoSMA 36 196, 1939) It is probable that the estimate of the waiting time t be recommended would be considerably shorter than 2 years if modern treatme t were pursued energetically

Conjugal neurosyphilis was studied by *Hutton (JMentalSci 87: 315, 1941)* whose observations supported the theory of a neurotropic strain of *S. pallida*. The marital partner of a known syphilitic must of course, being the most intimate contact, be carefully investigated.

Surgery in the Presence of Syphilis.—In undertaking surgery upon syphilitic individuals there is a real but small risk of acquiring syphilis by accidental inoculation (*QMN: J 133: 625 1045*) *As for the patient, there is an ideal focus for the development* of acute syphiloma in a surgical wound. In preparation for operation 2 or 3 doses of arsphenamine and of bismuth in a period of 2 weeks were known to suffice to protect against untoward results (Wile CalWM 49 7 1938; Wiltrakis et al.: IllMJ 79: 141, 1941) Penicillin should be used.

Tuberculosis does not contraindicate the treatment of concomitant syphilis, unless the *medication schedule is too intensive* (QMN: *J 124: 308, 1944*) *Penicillin is well* tolerated and efficient. There was a higher than normal incidence of tuberculosis among the Negro syphilitics in the clinic of Goldblatt (ADS 40 792, 1939) possibly to be explained on sociologic grounds. The tuberculous patient with syphilis needs and benefits from antisyphilitic treatment. See Warring (AmRevTuberc 40: 175, 1939)

Diabetes accompanied by syphilis was studied by Parkin (A IntM 31 27* 1944) When 19 such patients were treated for syphilis, their diabetes improved. There seemed to exist a relation between syphilis and gangrene occurring in mild diabetics. It is doubtful that syphilitic diabetes occurs, however (McDaniel et al. AIntM 66: 1011, 1940)

Treatment of Syphilis.—See articles on particular drugs in chapters on Treatment and Dermatitis medicamentosa. Syphilis has often indeed been mistreated. Classic but dated reviews of treatment emphasizing need for prolonged and continuous therapy are those of Stokes and Usilton (ADS 35 377 1937) Moore et al. (J 116 2405 1941) Padget (AmJSyph 24 692, 1940) and Cole (J 117 1001 1941) See Moore (Penicillin Treatment of Syphilis, Thomas, 1946)

One expects nowadays to eradicate spirochetes from an infected person who may or may not suffer significant cicatricial damage leading to injurious sequelae. The cured patient with scars aneurysm or demented brain still requires medical care. Some syphilitics suffer deleterious psychologic effects from knowing they have been infected, and the psychiatric aspects of such individuals, possibly organically unharmed by the disease that has otherwise been cured, comprise a real and challenging medical problem.

External Treatment.—Cleanliness and hygiene are important. In mixed infections with both *T pallidum* and *H ducreyi*, local treatment is as for chancroid. Cauterization or excision of a chancre is futile. Nonulcerative syphilids require no local treatment Ulcerative or pustular lesions may be covered with poultices moist with 1 8,000 bichloride of mercury solution or 2% ammoniated mercury ointment The cutaneous manifestations of syphilis are so promptly responsive to penicillin therapy that as a rule they require no local treatment at all. Ulcers in a syphilitic patient may be due to streptococci, carcinoma or other diseases, just as in nonsyphilitic individuals.

PRINCIPLES OF TREATMENT—Best treatment of early syphilis in the prepenicillin era entailed (1) early correct diagnosis (2) the use of drugs of proved worth (3) continuous treatment *without rest periods* (4) *a treatment* period of an arbitrary minimum of 12 to 18 months (5) determination of cure ' only by lifelong posttreatment observation and (6) the avoidance of poisoning the patient (Moore AnnIntM 10 30, 1936) Continuous therapy *the injections being given at regular intervals without rest periods*, The American System, is believed to be best The duration of the period during which chemotherapy is actually administered is considerably diminished with the use of penicillin. Treatment must be purposeful individualized and carefully planned and executed The patient must be brought to trust his physician and to cooperate intelligently and willingly

Treat the patient not his blood (Moore) When a patient has latent syphilis and has received adequate treatment he should be let alone except for periodic titered serologic tests and checkup physical examinations. One must remain continuously aware of the hazards of any therapeutic agents used seeing to it that the treatment is not worse than the disease A large proportion of syphilitic infections are comparatively benign and harmless. Mental and physical breakdowns have been precipitated by persistence in misguided therapeutic measures, overtreatment being responsible for depression, *emotional instability fatigue weakness, loss of weight and nervous irritability* (Cormia CanadMAJ 40 445 1939)

Clinical cure is usually achievable and the patient should be given encouragement and reassurance (Moore AmJSyph 22 648 1938) While almost all physicians treat syphilis, *few are syphilologists. A wise physician is humble admits his doubts to himself and takes advantage of consultation with experts.*

DURATION OF TREATMENT—*It was once thought proved that few cases of* syphilis are cured before the end of 1 year and that the majority require at least 2 years of active medication. American practice sustained by evidence collated by the Cooperative Clinical Group insisted on the continuous method of treatment with no rest periods. *If* no clinical evidence of the disease was to be found after 18 months of treatment a 6-months vacation from medication was taken and then serologic tests were made

Titered serologic estimations are particularly instructive If examination proves negative after 6 months, a further rest of 6 months is taken, provided always that no reinfection is manifested and a second examination is made If still negative a further rest of 6 months, and a third test A year later a final examination is made *If* any of the analyses are positive treatment is reinstituted.

With speedier methods of treatment the old standards have required revision. *Following a treatment period ranging from a few days to a few weeks* in duration, titered serologic tests should be made monthly for a year then at lengthening intervals. If the serologic titer remains zero or low and if the spinal fluid remains normal or of inactive formula and if the cardiovascular examination including *fluoroscopy is normal and if 5 years have elapsed* since the termination of treatment the patient may be judged cured

Spinal fluid is often abnormal when the blood ceases to show evidence of the disease Asymptomatic neurosyphilis is a great danger to the patient, for it is manifested by no abnormality whatever in the clinical examination, yet presages progressive neurosyphilis and the worst results that syphilis produces.

PREGNANCY—*Treatment of 116 women during pregnancy with* Mapharsen and bismuth was followed by 94 7% live births in the 76 patients who received 6 or more doses (Castello et al AmJSyph 23 332, 1939) *Danger of severe reactions among pregnant women treated intensively with arsenicals is greater than is generally realized* (Ingraham J 112 1037 1939) The pregnant woman is not exempt from any of the more severe types of reaction of in

tolerance including fatal hemorrhagic encephalitis, acute circulatory collapse hepatic damage, dermatitis and aplastic anemia Treatment of syphilis during pregnancy does not increase the liability to toxemias of pregnancy (Peckham AmJSyph 25 280 1941; J 117 1863 1941)

It is essential that all seropositive pregnant women receive treatment in order to prevent prenatal syphilis.

The effectiveness of penicillin and its safety in pregnancy render out-of date the studies of the use of less modern drugs. Penicillin can be used successfully late in pregnancy if the child is still viable (Cole et al.: ADS 54 255 1946) It should be used routinely (Goodwin and Moore J 130 688 1946) See Congenital syphilis, prenatal treatment (p 466)

NEUROSYPHILIS AND EARLY TREATMENT — Asymptomatic neurosyphilis was found in 13.5% of 5,300 patients of O'Leary et al. (ADS 35 387 1937) Adequate treatment of early syphilis was followed by an incidence of spinal fluid abnormality of 7.5% and irregular treatment by 22.6% Of those with abnormal spinal fluid 14% had negative blood tests. The less the degree of spinal fluid abnormality the better the response to therapy proved to be If treated syphilis remained latent the spinal fluid remained so in 99% of the cases. Serologic relapse warrants another examination of the spinal fluid Seroresistance of 4 years duration or more was associated with 75% incidence of central nervous system involvement. Penicillin therapy of early syphilis is followed by a notably low incidence of neurosyphilitic relapse

FAVORABLE RESPONSE TO THERAPY is measured by disappearance of spirochetes from sores, healing of visible lesions, diminution of titer of quantitative serologic tests, improvement in the spinal fluid formula manifestations of well-being of the patient such as gain in weight and in ability to perform mental and physical work which syphilis handicapped prior to its treatment and relief of symptoms of the myriad varieties for which syphilis may be responsible Quantitative serologic studies (Belding AmJSyph 24 29 1940) showed that chemotherapy reduced the titer in about a third of the cases of late acquired syphilis and half the cases of congenital syphilis arsenicals reduced the titer twice as much in early syphilis as in late.

One should not be stubborn in attacking the blood test for at least 15% of all syphilitic positives remain so no matter what is done The absence of necessity for reversing serologic tests must be explained to the patient if he falls into this unfortunate group who are frequently subjected to overtreatment its hazards and its costs, and who frequently develop syphilophobia. See Latent syphilis (p 409)

It is likewise inadvisable to push treatment unreasonably in cases of neurosyphilis, in which a positive STS was found to persist in some 84% of those followed for 5 years and in 70% of those followed for 10 years by Thomas (J 153 718 1953) He found furthermore, positive tests for reagin in the spinal fluids of 63% of patients followed for 5 years and 28% of those followed for 10 years after treatment Fluctuations in results of tests proved to be a curious phenomenon, but *relapse of neurosyphilis as determined by* increases in CSF cell count and other quantitative tests never occurred later than 2 years after treatment had rendered the infection inactive Whatever the explanation may be for the bizarre serologic patterns noted in a prolonged follow up of treated syphilitic patients, it is reasonably certain, Thomas concluded, that, in the absence of other evidences of relapse or progression of the disease they do not indicate continued activity of the syphilitic process, and treatment should not be continued solely on the basis of such serologic patterns.

See Serodiagnosis, evaluation of tests (p. 413)

UNFAVORABLE RESPONSES TO THERAPY include dermatitis medicamentosa (q v) the Jarisch Herxheimer reaction therapeutic paradox resistance to treatment and relapse Reinfection when it occurs—and this is not seldom—represents a good therapeutic result in the original infection upon which a new infection is superimposed

THE JARISCH HERXHEIMER REACTION is a temporary inflammatory aggravation of the symptoms, which usually occurs following the first administration of spirocheticidal drugs. It is attributed to enhancement of allergy by the killed spirochetes. This sudden symptomatic flare is to be avoided when the optic nerve, auditory nerve or aorta is involved for the results of vigorous *treatment may be extremely harmful*. See *Dermatitis medicamentosa* p 172. See excellent study of Farmer (J 138 480 1948). The reaction is provoked especially when the active spirocheticides, penicillin and Mapharsen, are used. It was apparently produced by the injection of immune serum into rabbits with experimental syphilis, a phenomenon of hypersensitization (Sheldon et al AmJSyph 35 405 1951). Benadryl did not influence the phenomenon, according to Stewart (ADS 60 427 1949) and ACTH does not prevent it (Heyman et al. BJVD 28 50 1952). It is not related to histamine.

It occurs in about 40% of patients with early syphilis and in from 60 to 80% of neurosyphilitics started on penicillin (Heyman et al). The rate of occurrence was 48% in early congenital syphilitics treated with penicillin by Lardo and Tucker (AmJSyph 33 225 1949).

Histologically the sequence is marked by early congestion of the capillaries and small vessels. These become crowded with polymorphonuclear leukocytes, which line the vessel walls and migrate into the surrounding tissues. The *endothelium swells, the vessel walls become edematous and* the edema then disappears with subsidence of the acute phase. The infiltration resorbs and is replaced by a small number of large mononuclear cells, while eosinophiles are not increased during any stage of the reaction. The changes *are sharply confined to the syphilitic lesions. They make their appearance* within 4 hours after treatment and subside within 18 hours (Sheldon and Heyman AmJSyph 33 213 1949).

THERAPEUTIC PARADOX.—The ill effect of a curative medicine is known as *therapeutic paradox. The question was discussed by Mohr and Hahn* (AmJSyph 36 82 1952) in connection with 4 patients who developed aortic insufficiency following penicillin therapy and in spite of it. Deaths attributable to the phenomenon have been reported: a patient with gumma of the *brain died within 14 hours after the initial injection of penicillin, and an* aneurysm ruptured after 2 days, reported Scott et al. (J 139 217 1949) while a woman with pachymeningitis developed high fever and exaggeration of symptoms and died 10 days later, reported Shaffer and Shenkin (AmJSyph *34 78 1950). The phenomenon anticipated but rarely observed in cardio*vascular syphilis, is little heard of in current syphilology. One does not hesitate to give curative doses of penicillin as soon as the diagnosis of syphilis is made. See Cardiovascular syphilis, treatment.

RESISTANT CASES.—While favorable results generally follow proper treatment this does not always happen. Penicillin resistance has never been demonstrated.

Serologic resistance is a relative term, which Moore and Padget (J 110 96 1939) defined as serologic positivity in syphilis of less than 2 years duration after 6 months of continuous, prepenicillin treatment, and in syphilis of more than 2 years duration after a year of treatment. Regard must be given the sensitivity of the test. In early cases, seroresistance apparently signified that foci of active syphilis existed. In late cases, it meant merely that immunity hangs on. One sees great harm result from dogged treatment of a persistent blood test in an asymptomatic patient—asymptomatic that is until he is poisoned or has been pushed into a psychopathic state.

The percentage incidence of seroresistance is high in early involvement of the central nervous system but in late syphilis it is an integral part of latency; in fact in late syphilis seroresistance may actually be of favorable prognostic import rather than bad. The aims of treatment are to eradicate spirochetes, to heal the lesions, to relieve the symptoms, to maintain health and to prevent relapse. Serological reversal is the least important aim.

Cooperative Clinical Group figures for percentage incidence of seroresistance according to the type of syphilis were: early 10%; early congenital, 12%; meningeal neurosyphilis, 14%; tabes dorsalis, 19%; latent syphilis, 35%; meningovascular 45%; late cutaneous and cardiovascular each 50%; late visceral, 60%; late osseous, 65%; late con-

genital, 70%; and dementia paralytica 80% Early cases proved seroresistant in 10% under continuous treatment 35% with intermittent treatment, and almost 70% with irregular treatment.

Serologic resistance may be summarily dismissed a inconsequential after adequate penicillin therapy, for a proportion in the vicinity of 15% of all patients who become seropositive remain so despite curative treatment. Resistance of the spirochete to penicillin is extremely rare if it occurs at all (Tyson JID 6: 270 1945) Cases of spirochetal resistance to arsenicals proved curable with penicillin (Noojin et al: NoCarolMJ 6: 34 1945) Treatment failures following penicillin are quite likely to be reinfections see Schamberg (AmJSyph 34: 3 1950)

Resistant cases were classed (Beerman: AmJSyph 20: 296 1936; 27: 400 1943) a those of (1) attenuated arsphenamine respon iveness, (2) recurrence under arsphenamine (3) true arsphenamine resistance in which spirochetes remain actively present in the lesions despite treatment, and (4) arsphenamine activations. Similar types of resistance to bismuth occur In combating these Beerman suggested that one might (1) change from bismuth to arsenic or vice versa; ( ) intensify treatment; (3) combine bismuth, arsenic, and iodine (4) stop treatment for a time; (5) use minor drugs; or (6) try fever lutein, or nonspecific protein while endeavoring to improve the general condition.

RELAPSE —Within 2 years after cessation of treatment most relapses which are to take place have done so. Relapses under continuous treatment occurred in 13% under intermittent treatment in 21% under irregular treatment in 45% and after intensive treatment in 41% (Cole J 107: 2123 1936) A high proportion of alleged relapses are really reinfections. Abnormal CSF does not predispose to relapse according to Sackett and Boggs (JVDI 30 219 1949) *who examined 437 patients with early syphilis who relapsed after* 2.4 million units of penicillin. Patients who received inadequate penicillin therapy and relapsed showed less abnormality of CSF than patients who relapsed after inadequate therapy previously conventional.

Chemotherapy of Syphilis.—In specific treatment, several antibiotics and metallic drugs are known to be spirocheticidal penicillin tetracycline chloramphenicol, arsenicals, bismuth and mercury Adequate treatment is usually harmless in tuberculous patients. Adequate treatment emphatically desirable is usually tolerated in pregnancy

Sulfonamides (Campbell AmJSyph 21: 524, 1937) and streptomycin (Edit.: J 131: 403, 1946) are among the drugs which are not useful in syphilotherapy

THE IDEAL ANTISYPHILITIC DRUG should possess a high chemotherapeutic rati that is, it should be of low toxicity to the human being and of high potency against the spirochete It should be easily administered and inexpensive Pe ic llin possesses all these qualities. O'Leary and Kierland (J 132 430 1946) summarized their evaluation by pointing to the f w untoward reactions penicillin prod ces, the short time needed for its administration its excellent effect on cuta eous, osseous, gastric ea ly hepatic and meningeal syphilis, and its particularly gratifying influence on the pregnant syphilitic woman, for whom it seldom fails to prevent the development of syphilis in the offspring Barksdale (SouthMJ 39 229 1946) stated, on th bas of the effect of penicillin on dark field and serologic tests, healing f lesions, and improvement of spinal fluid abnormalities It is the best drug we have ever had n the treatment of syphilis.

PENICILLIN —Four cases of early seropositive syphilis were treated with the arbitrarily selected dose and time factors of 25 000 units each 4 hours for 8 days for a total of 1,200 000 units by Mahoney et al (VDI 24 355 1943 AmJPubH 33 1387 1943) with reversal of the dark field within 16 hours and of serologic reaction in 30 to 70 days. Herxheimer reactions occurred in all, and the clinical lesions healed with notable rapidity Since their report, syphilotherapy has undergone astonishing change.

Evaluation studies were k pt ord rly by Moore and his collaborators of the Penicillin Panel of the Subcommittee on Venereal Diseases of the Nation Research Council, who controlled the penicillin available for the treatment of syphilis when the supply was limited. With the end f war and the unlimited availab lity of pure penicillin, th most various therapeutic schemes have been and are being tested. One of Mahoney' original cases underwent a gradual serologi relapse, which was rei terpreted as a reinfection, lat r (see JVDI 30 350, 1949); nd he and colleagues (J 126 63, 1944) were able to report results 1 100 additional cases: 2 instances of mild exfoliative dermatitis appeared, the average time fo serolog reversal was 70 days, patients underwent serologic relapse and it ppeared th t, as with rsenicals, certain proportion of patients fail to enjoy a curative response. Th Penicillin Panel a preliminary report (J 126: 67 1944) showed that on dosage schedules with totals ranging from 60,000 to 1,200,000 units the

relapse rate varied inversely with the dose, and that penicillin in combination with 320 mg Mapharsen a subcurative dose of the arsenical, *gave the lowest relapse rate of the* schemes tried. The excellent influence of penicillin was observed on meningovascular neurosyphilis, arsenical and bismuth resistance, and congenital syphilis in infants. Stokes et al. (J 126: 73 1944) reported on the results in late syphilis, 122 cases of 183 being neural. Gummas of skin and bone healed promptly Reagin was reduced in 50 to 60% of all late cases. Patients seroresistant with previously employed treatment methods usually improved on penicillin. Spinal fluid abnormalities improved in 4% to at least some degree the common change being a drop in cell count and total protein, so that fluids of low cell count showed comparatively little improvement Previous treatment *for neurosyphilis by older methods including fever therapy did not appear to prepare* patients for superior results with penicillin. These fundamental findings have been confirmed and elaborated by later studies.

Penicillin G is the most potent of the penicillins (Arnold et al. AmJSyph 31: 469 194) The effect of penicillin on the morphology of spirochetes was studied by Morton and Ford (AmJSyph 37: 529 1953)

The esults of a nationwide study of penicillin in early syphilis showed that the final therapeutic outcome is not related to the blood serum titer of penicillin, and that only 6 consequential reactions of intolerance occurred in 1,600 cases (Elder AmJSyph *33: 19 1949)*

Quantitative serologic tests were followed in cases of early syphilis treated with penicillin by Gustafson and Bowen (ADS 59: 303, 1949) By the end of a year 71 of 117 patients were seronegative and, of these 50% had become negative within 3 months and 91% within 6 months after treatment started. See Serodiagnosis penicillin effects (p 437)

Dubious of proof that penicillin is lastingly effective Reynolds (AmJSyph 32 233, 1948) reported treatment failure in late syphilis (including alleged drug resistance clin i al progression and recurrence of cl nical lesions) and the appearance of new lesions. A patient whose chancre remained dark field positive despite 100 000 units of penicillin q 3 h. was observed by Wexler et al. (ADS 60: 1207 1949) and Mapharsen cured this case

The Council on Pharmacy (J 136 873 1948) approving at that time a schedule of 100 000 nits each 3 hours or 600,000 unit in wax daily for 10 days stated that no proof had as yet been obtained of the existence of a strain of *T pallidum* resistant to penicillin.

Relapse during penicillin therapy apparently occurred (Cole et al. OhioSMJ 4. 595, 1946) and failures minimally of 15% when the 400 000- nit dose was employed were recognized by the Committee on Medical Resea ch and the U.S.P.H.S (*J 131: 265, 1946*) The failure rate is higher in syphilis of longer duration. Reinfection certainly accounts for some failure but no one knows precisely what proportion. The relapse rate in the 06 cases of ea ly syphilis of Leifer (J 129 1.47 1945) was 8.3% Of 72 patients followed a year o more, 70 were seron gati e; of 60 patie ts whose spinal fluids were ex am ed 6 months o longer afte treatment 60 were normal, including 6 whose fluid were not normal prior to treatment. The investigation of 726 patients deemed to require re treatment aft r pen cillin therapy was interpreted by Thomas and Land (AmJSyph 34 176 1950) to ndicate that at least 50% of the treatment fail res rep esented reinfection. In every retreated pat ent whose spinal fl id was examined, the results were normal.

Th persisting problem of the best dosage and time schedule was el cidated by Eagle t al. (BullJHH 70 169, 1940) who showed that in rabbit syph lis the greater the n mbe of i ject ons the less the total amount of penicillin requ red for cure a d that c re s favorably i fluenced by in reas ng the freque cy and number of injections and the total dose. A total peni llin dose f 000 000 un t wa proved to be inadequate by Sm th et al ADS 55 644 1947) Doses of 600,000 to 1,200 000 its were inadequat too (B nkley et al. ADS 51 200 1945) I adequate doses may temporarily suppress th disease obscuring it and mak ng it clinicall ncosp uous (Magnuson nd Eagle AmJSyph 30 597 1945) so that t trongl adv sable to watch for month a patient who rece ved pe le ll fo gon rrhea nd wa ured of that i fection by a dose nade quat to re syphilis. Precoc ous t rt ar m may follow i deq ate dosage (Marshall: BMJ 61., 104)

The minimum dose in human syph l hould be at least ,400,000 un t in 7.5 days w th terval t ot er 3 hours between i ject ons, said Sehoch and Alexa d (J 130 696 1946) The ,400 000 unit sched le with 3 hou ntervals between doses of 40,000 units yielded satisfactory result i 94 3% of seronegati e primary cases, 89.9% of seropositi primary and 82% of secondary whil post treatment spi al fluid exam a tion f 19 early cases howed abnormality i nly 5 (Sternberg d Leifer J 133 1 1947) Result w th 40,000 units ea h 2 bours for 85 i jectio s and a total of 3 400,000 un t we reco led 25 cases by Arn ld t l (JID 8 280 194) n patient had to interrupt treatment because of rea ti n to the a t bi t c and retreatment wa required for onl 1 of whom 14 showed linical idence of early yphil s wh ch might h e been rei fect n, wh l th rema ng 3 were apparently true stances of serologic relapse or f ilu e. On a queou pe ll n, 200,000 ts ea h 2 h rs fo 3 days, totalling 7,200,000 its, Arn ld t al (JVDI 30 1-3, 1949) la med a e molat v retreatment need of only 5% a d th thought the schedule ffect ve on

Progress contin ng in the development f ffective sched le utilizing prepara tions of slow absorpti n so that treatment can be given to patients of out patie t status,

avoiding the requirement for hospitalization and the 3-hourly needle of the early period of penicillin therapy Case holding o a schedule of 600,000 units twice a week was 93% successful in schedules requiring from 7 to 10 week tried by Scott et al. (JLCM 34: 999 1949) With 600,000 units given twice a week a total dose of 3 000,000 units appeared adequate and advantageously brief to Rausch (NYSJM 49: 1068 1949)

While Cohn et al. (AIS 57: 900 1949) were not able to establish a standard treatment schedule they found total doses ranging from 2,000 000 to 5,000 000 units apparently satisfactory and were confident that treatment with penicillin accompanied by absorption retarding agents would become standard. A schedule of 300,000 units daily for 16 doses was highly effective in primary infections b t somewhat less so in secondary ones reported Chargin et al (ADS 59: 695, 1949) Army experie e reported n by Altshuler et al. (AmJSyph 33 1?6 1949) in 31,000 cases of early syphilis treated with 60 doses of 40,000 units of aqueous penicillin for 7.5 days showed, among 5,600 patient whose CSF wa examined, abnormality in only 0 4%, suggesti g that penicillin prevent or cures early neurosyphilis. Thoma et al. (VDI 28 19 1947) found that th re was no advant ge of injections of penicillin in oil daily over 1 that failure statistics were no worse than with a y other type of rapid treatment and that as with other treatment schedules, most rel pses or r infectio s occurred during the first 6 months after treatment. In their series of 802 patient given 600 000 units daily one group in 2 doses of 300 000 units each and the other 600,000 unit in on dose for 8 days o ly 2 pati nts had to discontinue therapy i both instances because of severe urticaria. A schedule of 8 injections of 300,000 units given in 8 da s appeared satisfact ry in 58 of 60 patie ts treated by Romansky and Rein (J 132: 84 1946) Daily injections of 600,000 unit in wax and oil to a total of 4 800,000 u its was followed by a relapse or reinfection rate of 31% in the e perience of Rauschkolb et al. (ADS 60: 0?0 1949)

An injection once a week of 300 000 units, using a preparation of microcrystalline penicillin in peanut oil with 2% aluminum monostearate to delay absorption, gave theoretically effective blood lev ls for 4 days, this dose given weekly for 4 weeks netted cli ical cures of early cases in 94 % while clinical a d serologic cures amou ted to 89.3%, reported Buschemeyer et al. (AmJSyph 3? 67, 1951) The same preparation given in a dose of 600,000 units daily for 3 days was believed to be an effective regime by Wright et al. (JVDI 31: 225, 1950) Procaine penicillin G i oil with % aluminum monostearate i doses of 600 000 units given twice a week constituted as good treatment as had been devised (Thoma AmJPubH 39: 1361 1949) and on such a schedule the total dose should reach in late symptomatic and eurosyphili tic cases, at least 6,000,000 units given in not less than 15 days.

Penicillin in oil, 300,000 units twice a week for 8 weeks, a total of 4,800,000 units, was considered to be a good treatment schedule by Sobel et al. (JID 15: 18, 1950) In 70 cases given 600,000 units twice week for 8 weeks, total of 9,600,000 unit the cumulative failure rate was 11.3% (Shaffer and Courville: ADS 60 253 1949)

A single dose of 1,200,000 units w s as ffective a a single dose of 400,000 units (Thomas et al.: AmJSyph 35: 473 1951) A single dose of 2,400,000 units cured 0% of dark-field positive early cases (Rodriguez AmJSyph 35 46 1951) Various schedules of giving 1,200,000 units pe dose weekly fo a f w doses all yielded good results for Thomas et al. (AmJSyph 33 523, 1949) A single injection of 1,200,000 units of procaine penicillin was not lequate treatment but such dosage given weekly for from ? to 4 weeks seemed to be as good s any treatment (Jo es and Heyman AmJSyph 36: 250 1952) There seemed to be o significant difference between the results obta ned with 2,400,000 units and with 4,800,000 units of crystall ne penicillin G when these doses were given in a period of 7.5 days (Platke et al.: AmJSyph 35 40 1951); and the cumulative fail re rate of either schedule was about 14% at the end f 1 to 15 months. PAM totaling 4.8 million units, gi en 2.4 the first dose f llowed by 1.2 given twice, constitutes good treatment for primary nd secondary cases, according t Cutler et al. (AD 71 239 1955)

Early syph lis may be cu ed by a single dose and it is incorrect nowadays to wait for indubitable diagnosis, believed Schoch (ADS 65 14, 1952) who n ted that the treatment of early syph lis is bette than statist cs indicate because of the effect of reinfection on statistics. Treatment f reinfect on is at least a successful as treatment of the n tial, early syph litic fect o (Schoch and Alexander ADS 60 090 1949) A single injection of 1.2 mill on un t of PAM often suffices in primary syphilis, and 2.4 million in secondary bel e ed Thomas et l. (AmJSyph 37 574 1953)

Decision as to a dosage schedule has got to be made when one has a patient to treat, and one may recommend a program of injecting 600 000 units in oil with 2% aluminum monostearate thrice a week for 3 weeks (total 5 400,000 units) in cases other than neurosyphilis, in which one may give the same weekly dose for twice as many weeks. One may be fairly confident that a patient treated thus has received about all that penicillin therapy holds for him. If a satisfactory result has not been attained, fever therapy may be indicated unless the unsatisfactory result may be presumed to signify reinfection, which for therapeutic purposes, means simply starting over

The ill effects of penicillin are dermatitis medicamentosa (q v) and Herxheimer reactions, but rarely is intolerance actually a serious menace to the

patient (Thomas et al. JID 10 77 1948) When penicillin cannot be used, one may recall that arsenicals particularly Mapharsen, cured high proportions of the cases treated with them before antibiotics were discovered. The use of tetracycline should be considered.

PENICILLIN COMBINED WITH OTHER THERAPEUTIC AGENTS.—The combination of penicillin with other chemicals may or may not be advantageous, and optimum therapy for human beings has not as yet been determined. It might consist of some combination of penicillin Mapharsen and bismuth (Eagle et al. VDI 27 3 1946) Hyperpyrexia along with arsenicals and bismuth was thought to increase the therapeutic efficacy by Eagle et al. (AmJSyph 31 239 1947) Penicillin plus neoarsphenamine and bismuth seemed better than penicillin alone to Jones (OhioSMJ 47 131 1951) Daily injections of 300,000 units in oil combined with 20 doses of arsenical and 5 of bismuth comprised the ambulatory scheme which was effective in the experience of Hazel (VDI 28 103 1947) Early syphilis treated with penicillin, Mapharsen and bismuth did no better than when penicillin was used alone (Chargin et al ADS 63 104 1951) but the rate of relapse or reinfection was less on combined therapy The prolongation of treatment by combining a course of bismuth injections with a course of penicillin seemed advantageous to Pardo-Castello and Pardo (ADS 61 196 1950) Combination chemotherapy was reviewed by Kolmer (UCutRev 53 338 1949) who could not reach a decision regarding superiority of merits of any particular scheme. The trend at present is to rely on penicillin alone

ARSENICALS, BISMUTH MERCURY AND IODIDES.—The historical aspect of the succeeding paragraphs justifies their inclusion, and the discussion of Mapharsen is significant because the drug is an effectual one in cases where because of intolerance penicillin cannot be given Tests of therapeutic effects in vitro of various arsenical and bismuth preparations were interpreted by Eagle (AmJSyph 23 310 1939) as suggesting a spirocheticidal action

ARSENICALS.—Ehrlich's salvarsan, o arsphenamine the 606th preparation of a series of synthesized compounds, is dioxy-diamino-arsenobenzene dihydrochloride. It is a yellow powder containing 31% of arsenic, soluble in water forming a strongly acidic solution. The average practical dose of arsphenamine for an adult was 0 40 Gm. (6 grains) and the drug was given, *after neutralization* intravenously When ingested, it is poisonous. Exposure to the atmosphere results in oxidation deterioration, and the formation of toxic substances.

Various arsenicals are given intramuscularly subcutaneously or intravenously Acetarsone is given by mouth Neoarsphenamine may be given to infants intramuscularly and sulfarsphenamine was so given to adults. The subcutaneous route is likely to cause slough. The usual route is intravenous.

MAPHARSEN the arsenoxide responsible for the activity of the arsphenamines, superseded old arsphenamine and the later variations (Tatum and Cooper JPharmExpTh 50 198 1934) It was used in many thousands of doses as the standard therapeutic agent in the military services of the U S. A. in World War II, with notably few serious reactions. Its chemistry and effect venesection have been reported on by Cole and Palmer (ADS 36 561 193) R in a d Wise (J 113 1946, 1939) Chargin et al. (ADS 40 *03 1939) Stokes and Beerman (AmJMedSci 201 601 1941) Long (ADS 47 226, 1943) Gay (b p. -35) and many others.

Many other arsenicals have been synthesized and studied (Eagle et al. JPhExpT 69 84 70 11 221 1940)

Toxicity—To treat syphilis wisely toxicology must constantly be kept in mind. See Dermatitis medicamentosa (p. 172)

In investigations of toxicity use is made of the terms *maximum tolerated dose* (M.T D) *minimum effective dose minimum curative dose therapeutic index* (M.T.D. divided by M.E D), and *curative index* (M.T D divided by M.C.D) Grohmt (ADS 32: 848, 1935) stated that T I. of Mapharsen is 18, of arsphenamine is 14 of neoarsphenamine is 9 C.I. respectively is D 11.6 and 8.8 Cole (J 107 1-3, 1936) gave the therapeutic index for arsphenamine as *0 1 to 30 1 bismuth intramuscularly 50 1 and mercury 1:1 to 1 –

Technique of Administration of Arsenicals—ARSPHENAMINE.—All apparatus and solutions must be sterile. Freshly distilled, dependably pure water should be employed. Gravity infusion is safer than injection by syringe. The ampule is tested by immersion in alcohol If intact, its content is sprinkled int a known quantity of water which contains a drop of phenolphthalein, and 0.85 cc normal sodium hydroxide per 0.1 Gm. arsphenamine is added Dilution is made up with water to 25 cc. per 0.1 Gm of arsphenamine The solution, filtered, must be clear and alkaline (pink) It is injected slowly into the vein, at the rate of 0.1 Gm arsphenamine per minute, with great care not to infiltrate outside the vessel. This information is of historic interest only

Inunction has been a valuable method of administration (Sollmann et al. ADS 31: 18 331 1 24., 1935) The 33% unguentum hydrargyri mitis was the favorite preparation, 4 to 6 Gm. daily to be rubbed and massaged into nonhairy regions in turn, so that each area was used only once in 6 days, so that irritation was not likely to ensue. Inunctions were given in courses, a series of daily treatments extending over a period of from a fortnight to a month being alternated with similar periods during which some other form of antisyphilitic therapy might be administered. A series of 40 rubs was often prescribed.

Injection supplied a convenient and efficient method of dosage. Soluble or insoluble preparations might be employed. The injections were commonly made in the gluteal region. Colloidal mercury sulfide was recommended by Zakon and Jacobson (JIDLJ 76: 172, 1939).

Soluble salts were well thought of but to maintain an adequate concentration of the ion, they had to be given at frequent intervals. The bichloride in doses of from 1/12 to 1/8 grain, the succinimide in doses of from 1/6 to 1/4 grain, or the biniodide or benzoate from 1/10 to 1/4 grain might be given once daily or on alternate days. Mercuric salicylate, insoluble and suspended in vegetable oil, was extensively used. The initial dose was 0.065 Gm., and injections were given at intervals of 3 or 4 days.

Heat in the Treatment of Syphilis.—The remarkable effectiveness of penicillin in neurosyphilis has rendered fever therapy almost obsolete. Fever therapy was at one time believed to be indicated in all cases of neurosyphilis unless contraindicated by the patient's estimated inability to withstand it. Until penicillin therapy of meningovascular syphilis had been evaluated—and penicillin alone early proved to be adequate in at least some cases (Gammon et al. J 128 653 1945 O'Leary et al J 130 698 1946 Stokes et al J 131 1 1946 Moore and Mohr *AmJSyph 30 405 1946* Heyman *AmJMedSci 213* 661 1947 Leavitt ADS 56 233 1947)—one could say that neurosyphilis had not been treated adequately until fever as well as chemotherapy had been utilized. See Neurosyphilis, treatment fever therapy

Chemotherapy Combined with Fever.—In primary and secondary infections, the use of fever combined with chemotherapy was considered experimental (Kendell et al APhysM 26 76 1945) The combination of fever therapy with chemotherapy has seemed to be advantageous however apparently yielding better results than chemotherapy alone in early stages of syphilis as well as in late (Heckh and Barnett AIntM 63 974 1939) Fever used to be used almost routinely in neurosyphilis (q v) where various combinations with chemotherapy have been evaluated. Adequate treatment with arsenicals and bismuth has been assessed as yielding when used auxiliary to fever at least twice the spinal fluid reversal rate of fever alone (O'Leary et al J 115 677 1940) See Thomas and Wexler (J 126 540 1944) Epstein (ADS 37 254 1938) *fever adjunctive and helpful especially in CNS syphilis.*

Combinations of penicillin with fever therapy seemed especially promising to Curtis et al (AmJSyph 31 618 1947) and to Schwemlein et al. (J 137 1209 1948) Malaria combined with penicillin was commended by Lescher and Richards (BMJ 2 565 1947) and by Reynolds (AnnIntM 26 393 1947) The cure rate in early syphilis was better with penicillin plus fever than with penicillin alone, reported Plotke et al. (AmJSyph 34 161, 1950) Yet the combination of Mapharsen bismuth, penicillin and fever appeared to possess no advantage over repository penicillin alone according to O'Brien et al. (AmJSyph 36 451 1952) and their view is generally held at this time

Obsolete standard practice utilized more than one agent in syphilotherapy wherein treatment plans involving arsenicals and bismuth penicillin and arsenic and bismuth or fever with these were then modern science while the exhibition of mercurials and iodides in conjunction with these might have been classed as art. Multiple attack upon the infection was empirically known to be effective *the agents used being divisible into the spirocheticides and the* resistance builders. Fever therapy could be called the final resort in difficult cases exemplified by neurosyphilis, resistant syphilis, interstitial keratitis and optic atrophy However when it is correct to use fever therapy at all it is usually correct or even urgent, to use it promptly rather than hesitantly and belatedly after irremediable damage has been done. In the most difficult imaginable case of syphilis, with reservations regarding cardiovascular or hepatic damage disastrous to the victim, the patient could have been said to *have received everything when he received adequate penicillin, arsenical, bismuth* and fever therapy

Nowadays it is felt that, when all detectable debilitating adjunctive conditions have received the attention they deserve and when fully adequate

penicillin therapy has been given, there is reached a time when one can do no more nothing is gained by flailing a dead horse

Nonstandard Chemotherapeutic Agents.—Iodides have been dropped from syphilotherapy completely outmoded. Tryparsamide has been discarded, a dangerous drug of perhaps tonic but no antisyphilitic value. Experiments have been performed with a wide assortment of metals, including magnesium, beryllium zirconium ruthenium, yttrium and others, by Jahnel (ZtschrImmun&ExperTher 91 3L., 1937; 93: 86, 1938; 93: 184, 1938) and no useful agent was found. Rhodium salts apparently cured rabbit syphilis (Pavanati: abs AIntM 64: 1084, 1939) and a vanadium salt seemed effective and low in toxicity (Pereira: abs J 114 933, 1940)

ANTIBIOTICS.—Penicillin is recognized as the best, but next best is tetracycline and then Erythromycin, Aureomycin, Terramycin, Chloromycetin and streptomycin, in that order according to Turner and Schaeffer (AmJSyph 38 81 1954)

CHLOROMYCETIN though it shows no treponemicidal effects in vitro, heals the primary and secondary lesions, and organisms disappear (Robinson et al.: AmJSyph 33 509, 1949) Romansky et al. (Sci 110: 639 1949) observed similar phenomena and a rapid decline in serologic titer in most cases within a month, but Herxheimer reactions were mild or absent. Their cases followed for 6 months (AmJSyph 35 .34, 1951) showed the effectiveness of the drug the dose of which probably should be 60 mg./kg./day for at least 15 days. Willcox (BMJ 1: 467 1950) thought the drug useful because it also cures gonorrhea and chancroid if they too are present.

AUREOMYCIN was first tried in 2 cases of human syphilitic infections by O'Leary and Kierland (PSMMC 23 574 1948) and was found to possess antispirochetal activity Hellman showed that its effectiveness in animal experiments exceeded that of penicillin against some spirochetes (O Leary OklaSMAJ 4 : 315 1949) In 9 early cases given from 750 to 1500 mg. per day healing was prompt, and only 1 case relapsed during a brief follow up, reported Willcox (BMJ 1 1076 1949) The benefits were considered slow by Wiggall et al. (AmJSyph 33: 416 1949) The initial decline in serologic titer is satisfactory but adequate dosage upsets the gastrointestinal tract almost always, stated Rodriguez et al. (J 141: 51, 1949) The comparison with penicillin indicated the slower effectiveness of Aureomycin and the high incidence of vomiting and other toxic reactions, according to Olansky et al. (AmJSyph 34 436, 1950)

The drug reaches the CSF when given orally and favorably influences CSF abnormalities (O'Leary et al. PSMMC 4 302 1949) It also passes the placental barrier (Kierland et al.: ADS 61: 185 1950) In neurosyphilis early results with Aureomycin equal those obtained with penicillin, according to Kierland and O'Leary (AmJSyph 34: 443, 1950) and its usefulness may be considerable in patients who do not tolerate penicillin. In cases of neurosyphilis followed fo a year more or less the early clinical improvement continued but was greatest in the early period of treatme t; no case of asymptomatic neurosyphilis became symptomatic while unde treatment, and all but one showed moderate to marked improveme t (Kierland and O'Leary: AmJSyph 35: 544 1951)

A reomycin may be assessed at this time as effective, but of u determined long range effectiveness (Rodriguez et al.: ADS 60 59 1932; 63: 433, 1951; Taggart et al.: AmJSyph 36: 174 1952)

TERRAMYCIN appears to be effective, fo under treatment with 60 mg./kg./day lesions heal promptly (Hendricks et al. J 143 4, 1950) While 4 of 5 cases of early syphilis became seron gative 1 relapsed with CSF abnormality (Robinson and Robinson: AmJSyph 35 4 9, 1951) The value of the drug is *sub judice*. Terramycin resistance was observed in 1 of 10 cases of early syphilis treated with the antibiot c by Irgang and Alex a der (AmJSyph 37 4 1953) who noted cure of all kin lesions. Herxheimer reactions occ rred n 2 of their patients.

ERYTHROMYCIN.—Spirochetes in culture media are highly susceptible (Keller and Morto AmJS ph 37 3 9 1953) It was found effective in early syphilis by Alexander and Schoch (AmJSyph 38 107 1954)

BACITRACIN, 5,000 units per kg cured rabbit syphilis i one dose (Eagle and Fleischma PSExpe M 68 415, 1948)

CORTISONE may have a bad effect in syphilis, for infected rabbits given cortisone devel ped soft spo gy lesions rich in mucoid mat rial and i demonstrable pirochetes, and wh the drug w withdrawn there was a rebound phenomenon in which the lesio reached an sual ize (T rner d Holla de BullJHH 87: 503 1950; AmJSyph 38 3 1 1954 Fa rable effect f cortisone were reported by de Graciansky and Gropper (la J I 9 6 1953)

Treatment of Neurosyphilis.—Meningeal syphilis responds satisfactorily to chemotherapy meningovascular syphilis responds less well and parenchymatous neurosyphilis, tabes and general paresis respond relatively poorly from the clinical standpoint Penicillin kills spirochetes but does not cure scars.

The quiescent CSF formula by Dattner's criteria does not guarantee a favorable clinical outcome whether it has been achieved by use of penicillin

alone or of penicillin combined with malaria noted Horne (AmJSyph 33 454, 1949) in reporting 11 paretic patients who underwent rapid progression and deterioration despite therapy

Histologic studies on 4 cases of dementia paralytica treated with penicillin were reported by Smith and deMorais (JMentSci 94 0 1948) In 2 of these, who had improved, inflammatory changes were less intense than in untreated cases but in _ of the juvenile type which had not improved deterioration had progressed despite penicillin and there wa no mitigation of the inflammatory reaction. Autopsies on 7 cases of neurosyphilis following penicillin therapy by Gammon et al. (AmJSyph 34: 22 1950) showed that in flammatory lesion had been dissipated but degenerative changes had not

Penicillin alone improved every type of neurosyphilis followed for from 90 days to 3 years by Stokes et al. (AmJSyph 32: 28 1948) whose results appeared to indicate th value of high dosage and repetition of courses, although subsequent courses f treatment yielded no great additional effects. Most patients showed most improvement in the first 00 days, and there was little tendency to relapse Blood tests often failed to improve while the spinal fluid did. Symptomatic improvement was a good after 3 years with penicillin alone as with malaria, but malaria appeared to do more for tabes dorsalis. Penicillin alone was best in asymptomatic neurosyphilis. At the end of 4 years, the good effects of penicillin alone were sustained (Stokes et al. AmJSyph 32: 521 1948) There was a recognizable increase in the proportion of normal, near normal and markedly improved spinal fluids, and it could be concluded that penicillin wa entitled to the status f first choice in therapy on the scores of safety convenience and effectiveness By the end of 5 years, improvement had been observed in 53% of the cases of paresis and in 80% of the cases of tabes and asymptomatic neurosyphilis (Stokes et al.: AmJSyph 33 537 1949) It had become apparent that retreatment is desirable in relapses and slowly responding patients. Yet in any phase of neurosyphilis there was hope for arrest by penicillin. One might observe however serologic cures without clinical improvement, and vice versa. Optic atrophy might be arrested by penicillin alone and tabetic pains relieved. Doses higher than 6,000,000 unit appeared not superior, a d once daily injections were as effective as those given around the clock. There were still required evaluation of the individual case repeated CSF examinations, and prolonged observa tion of the patient.

In various forms of neurosyphili in 106 patie t , a total of 3,000,000 u its gave no better results than older methods of therapy i the opinion of Rose t l. (AmJSyph 29: 487 1945) 5 of whose 6 cases of optic atrophy were howeve , apparently arrested. Intra thecal penicillin wa at one time tried (R bin and Leitch: JMoMA 43: 100 1946; Goldman: J 141: 431 1949) but this procedure was condemned u necessary and dangerous by Dattner et al. (J 141: 1960 1949) Intramuscular injection relieved the shooting pains of tabes in 17 of 4 patient of Koteen et al. (AmJSyph 31 1, 1947) but their patie ts with gastric crises were not helped.

In acute syphilitic meningitis, penicillin alone yields excellent immediate results, and no relapse occurred in 10 patients gi en up to 4,000,000 units in from 7 to 11 days by Nelson nd Duncan (BullJHH 75 327 1944) Th dose should be at least 5,000,000 units, and caref l, prolonged follow p is necessary (Pardo and F rmer AmJSyph 32: 587 1948)

Previous treatme t with other methods did not interfere with f vorable response to penicillin reported Barker (JID 10: 169 1948)

The usual CSF responses were observed by Callaway et al. (SouthMJ 43 41_, 1950), in whose 07 cases some 23% showed little or no benefit the cell count and protein fell fast, the gold curve approached normal m re slowly and the Wassermann changed little. No patient with asymptomatic eurosyphilis developed clinical symptoms during or afte treatment. The clinical response was best in pat ents with symptomatic paresis. Dattne et al. (JVDI 32 33, 1951) reported on 438 pat ents with variou types of active neurosyphilis treated with penicillin only: the disease became inactive in 400 of these, and of the 38 therapeutic failures, 31 were retreated. Of the retreated cases, 27 had normal CSF when *last examined. The routine treatme t with preparations of d layed absorption* consisted a 600,000 units given daily for 15 days.

The lack of correlation between serologic responses of the blood and spi al fluid STS was noted by Scully et al. (AmJSyph 32 24 1948) of whose 313 cases of latent asymptomatic e rosyph li less than 10% becam seronegative. From the laboratory standpoint, penicillin induces certainly as good results as any previously used treatment, and of 43 patients who f iled to respond well ft one course of treatment half responded when the course was repeated with a large dose (Datt er AmJSyph 33 571 1949) Treatment failures may represent underdosage.

The spinal flu d response is most rapid during the first yea after penicillin therapy in all kinds of eurosyphilis, found I graham et al. (AmJSyph 34: 568, 1950) and the percentage of normal nd near normal fluids levels off in the third year Response is slowest and least satisfactory in paresis a d taboparesis, while normal CSF was found in highest proportion in tabes dorsalis. CSF relapse occurred after the third fourth year i 5% of the cases, usually in paresis, taboparesis o tabes dorsalis; d increasing the total dose of penicillin did not seem t affect the ultimate result. Th optim l dose approx imates 6,000,000 n ts, and retreatment produces furthe improvement in only from 3 to 5% Of 603 patients, 30 d ed d ring the 7 year observat on period, but syphilis was a contributory ca se of death of only 5 of them.

See Serologic tests, evaluation (p. 437) Treatment favorable response to (p. 433)

PENICILLIN COMBINED WITH OTHER CHEMOTHERAPEUTIC AGENTS AND WITH FEVER THERAPY.—Nothing seemed to be gained by giving Mapharsen and bismuth in addition to penicillin, in asymptomatic neurosyphilis, reported Johnwick (JVDI 31 303 1950)

Dattner (NYSJM 47: 244 1947) compared patients treated with malaria plus chemotherapy and those with penicillin alone: about 85% of both groups obtained satisfactory results. Relapses were highest among those who received less than 5,000,000 units of penicillin. Dattner (AmJSyph 3 : 399, 1948) reported that only 11% of 301 patients treated with penicillin alone required retreatment, and over half of the original failures responded well to retreatment with larger doses of which the maximum was 9 000 000 units.

Penicillin accompanied by malaria was considered to be the best treatment available in dementia paralytica by Reynolds et al. (J 131: 1-55 1946) Concurrent with fever therapy 3,000,000 units of penicillin was judged to be not adequate for late symptomatic neurosyphilis by Rose and Solomon (J 133: 5, 1947) In tabes dorsalis, penicillin alone in doses up to 20 000,000 units yielded symptomatic improvement in "% of the cases, whereas combining malaria with penicillin resulted in 57% achievement of significant symptomatic improvement in the experience of Chesney and Reynolds (ANeurPsych 59 347 1948)

In tabes dorsalis, penicillin alone does about as well as penicillin plus malarial therapy (Packer and Wong AnnIntM 31 96 1949)

Paretics treated with penicillin alone did as well as those treated with both penicillin and malaria, according to Wong and Packer (AmJSyph 32: "12, 1948)

Artificial fever with hot blankets combined with penicillin gave good results for Epstein and Key (ADS 60: 543 1949) although the CSF Wassermann reversed in only 14.5% of the cases within the first year As judged by effects on CSF complement fixation tests the results of penicillin therapy were not inferior to those obtained with malaria and penicillin (Wong and Packer: AmJSyph 33 535, 1949)

In severe parenchymatous disease, the addition of fever was favored, while in milder cases penicillin alone appeared to be adequate to Kierland et al. (AmJSyph 32: 470, 1948) In 294 patients with late symptomatic neurosyphilis, the comparison of results obtained with penicillin alone and with penicillin plus fever therapy showed that the combination of penicillin with malaria gave better results for Kopp et al. (AmJSyph 32 509 1948) Curtis and Horne (MichSMSJ 47 1111 1948) felt that a final conclusion could not be reached as yet. Response may be faster when malaria is combined with penicillin, even if the end results turn out to be equivalent concluded Curtis et al. (AmJSyph 32 546, 1948) but the 3-year results were equal, they reported later (AmJSyph 33: 5.7 1949) Their 5-year results, with evaluation of 430 patients, indicated that penicillin alone is adequate in all types of neurosyphilis except perhaps severe paresis and optic atrophy (AmJSyph 34 554, 1950) Malaria in addition to penicillin appeared to offer no advantage in the experience of Spiller and Stewart (JID 14: L.1, 1950) a view concurred with by Hahn (AmJSyph 35: 433, 1951) Perlo et al. (AmJSyph 35 659 1951) and Epstein and Allen (ADS 63 419 1951) who would reserve fever therapy as an additive measure only in dementia paralytica, primary optic atrophy tabes dorsalis and cases of penicillin failure. Penicillin with malaria was adjudged the best treatment by Brown (ANeurPsych 66 464 1951) in a study of 50 cases of severe dementia paralytica.

Penicillin may continuously accompany fever therapy malarial or artificial, in doses of from 40,000 to 100,000 each 3 hours or 600,000 units daily of a repository preparation. A course of therapy I consider adequate in any variety of neurosyphilis but superseded by doubt as to the real need of treatment other than penicillin requires 3 weeks of hospitalization, with artificial fever therapy holding the rectal temperature at 105 F for 4 hours on alternate days 3 times a week to a total of 9 bouts and penicillin to a total dose of L,000 000 units. A course of 10 to "0 injections of 0.- Gm. bismuth at weekly intervals might follow th I am confident that a patient who completes such a schedule is not undertreated, and I have not experienced trouble with it administration. Three artificial fever treatments a week are tolerated by patients who tolerate fever treatment at all. During such a hospitalization, I concurrently eliminate focal infection.

Fever therapy with malaria the means most prevalently used and, all things considered, productive of the most satisfactory results, has been effective in all forms of neurosyphilis. It is necessary to supplement malaria with spirochetlcidal antibiotic therapy

MALARIAL THERAPY.—See review of Simpson et al. (BJVD 17 1 1941) Wagner von Jauregg (185) noted its beneficial effects and began using inoculation systematically in the treatment of general paresis in 1917 The effects of malarial therapy may be attributed to activation of the reticuloendothelial system, promotion of the development of the immune reaction, and enhancement of tissue immunity (Brnetsch JIndianaSMA 4- .11 1940)

To inoculate malaria, 5 cc of blood of a malarial patient is injected intravenously without cross matching, and 10 chills more or less, are allowed to follow. If the patient tolerates the infection Quinine or quinacrine is then given in order to kill the plasmodia and stop the chills.

Malaria yields best results when given early in the course of neurosyphilis. In asymptomatic neurosyphilis it was assessed the best agent known, for it prevented half the cases from becoming symptomatic, and it succeeded sometimes after chemotherapeutic agents failed (O'Leary J 110 42, 1938). It fails in paresis due to prenatal syphilis. The best outlook is in patients with acute nervous system involvement who have a background of treatment, but improvement or failure does not parallel the spinal fluid complement fixation reaction (Wile and Hand: AmJSyph 20: 630 1936).

Complications of malarial therapy include (1) fatality from cardiac or hepatic failure or from rupture of the spleen, and (2) nonfatal difficulties, such as headache, vomiting, diarrhea, toxic psychosis, edema, jaundice, purpura, herpes etc. (Head et al. AnnIntM 24: 444 1946 Beberius and Cara (1): AmJSyph 30 320, 1946).

It is possible that a quartan strain may be preferable; it more frequently "takes" than tertian and is a milder disease although the incubation period and duration of infection are longer and more hospital time is consumed (Kroll AmJSyph 24 148, 1940). Chills may be regularized by single doses of Thio-bismol (Cole et al. J 115 432, 1940) although this is seldom necessary or desirable after one has become intimate with the supervision of therapeutic malaria, details of which are not given here. Deaths following malarial therapy were carefully investigated by Wile and Mundt (AmJSyph 26: 181 1942).

Benign tertian malaria (Plasmodium vivax) is generally used, but for persons immune to that, quartan malaria will usually take, among Negroes, Orientals, and people who live in malarious districts. Caution is desirable and it is better to terminate malaria unnecessarily in a number of cases than it is to lose one patient unnecessarily. Headache, malaise, and anorexia with nausea and vomiting are common features of induced malaria. Lightning pains of tabes and psychotic symptoms of paresis are frequently exaggerated during the fever but generally can be controlled by analgesics and sedatives. Exhaustion and prostration which result from loss of chlorides through sweating can be avoided by the routine administration of 1 to 8 Gm. sodium chloride daily. Malaria causes a rapidly progressive anemia. Hemoglobin determination should be performed at intervals, but interruption of the fever need not be considered unless the hemoglobin falls below approximately 7.0 Gm. % or the red blood cells below 2.0 million. In approximately one-half of malaria cases, mild jaundice occurs, perhaps from rapid destruction of red blood cells. Rarely, deep jaundice develops, usually in association with a large, tender liver; when it occurs it should be viewed with alarm. The spleen is enlarged in the majority of cases and is frequently painful. Rupture of the spleen followed by death is a remote possibility but occurs in somewhat less than one in thousand cases. A moderate increase in N.P.N. with albuminuria is frequent and of no special importance. However, renal failure needs always to be considered and especially watched for in elderly patients. Retention of urine is common in tabetic and taboparetic patients and may require catheterization. The blood pressure falls in every case. A reliable sign of the state of the vascular system is the pulse rate, which normally rises to 120-140 during the paroxysms but should fall promptly to 70-90 with defervescence. A persistently elevated pulse rate, 140-160 during fever, 110-130 during afebrile periods, is to be considered a serious sign and calls for termination of the malaria. The diet may be as desired, and every effort should be made to keep the fluid intake at a level of from 3 000 to 4 000 cc per day.

Authorities differ on the amount of fever which constitutes an adequate course of malaria. Some carefully calculate the number of hours of fever above 102° F and try to attain a minimum of 130 hours. Others base the calculations on the number of paroxysms of fever reaching 102 F and above and try to attain a total of from 8 to 12 paroxysms. Either method is satisfactory.

Quartan malaria is less satisfactory than tertian because of the long incubation period of about 3 weeks, the length of time required to obtain an adequate course with paroxysms every third or fourth day and the poor quality of fever which generally occurs. The results of treatment by quartan malaria are, however, good, and the time factor should not deter its use when needed. In individuals found immune to tertian malaria, quartan is the treatment of choice.

The contraindications for malaria are age of 60 years or more unless exceedingly well preserved; cardiac disease with history of congestive failure; hypertension with evidence of renal involvement; extensive renal disease, etc., or extensive healed pulmonary tuberculosis; thrombophlebitis; cellulitis and other potentially severe suppurative infections and physical debility and malnutrition. Malaria carries with it more than ordinary risk in patients with heart disease with aortic regurgitation, convulsions, severe or uncontrolled diabetes, cirrhosis and other diseases of the liver, severe psychotic condition requiring sedation and tabetic bladder with urinary retention.

Malaria should be interrupted for persistent tachycardia (120-140) in afebrile periods; intractable nausea and vomiting; rise in N.P.N. to 70 to 80 mg. per 100 cc; severe prostration and debility; severe jaundice; vascular collapse with systolic blood pressure below 70 mm. Hg, cyanosis, weak, thready pulse and clouded consciousness, convulsions not controlled by medication; severe anemia (below 7 Gm % hemoglobin or below 2 million red blood cells) and detection of infection with falciparum parasites.

See Paul O'Leary (PMDIC 9 750, 1934) best agent in asymptomatic neurosyphilis; Dattner (Moderne Therapie der Neurosyphilis) Wien, 1933; Wile and Hand (AmJSyph 20 570 1936), 10 years experience no help in juvenile paresis; Gelsen (DW kn 104 815 848, 876, 611 623, 1938) statistics of 1,255 patients with 16 deaths, malaria and neoarsphenamine best prophylaxis against tabes and paresis. Kahon (ADS 48 82, 1943) priority of discovery of value of fever therapy belongs to Rosenblum, who used relapsing fever therapeutically in paretics in 1876 (see Lilit J 124 1061 1944); Lilit (J 131 404, 1946) complications of malarial therapy.

Hyperpyrexia May Be Produced Artificially by foreign proteins such as intravenous typhoid injection (Dri... and Shaw J 101: 2016 1933; Nelson OklaSMAJ 27 87 1934; Lawrence AmJSyph 23 789 1944; Smith et al. SouthMJ 38 194 1945; Bellach ConnSMJ 12 848, 1048; Nooj... et al. AmJSyph 34: 153, 1950).

Foreign protein therapy may favorably influence the course of syphilis as an accessory measure especially in resistant cases and in interstitial keratitis. The effect is at least in part due to fever. Since resistance to penicillin therapy is practically nonexistent and since cortisone topically has been found marvelously effective in interstitial keratitis, foreign protein therapy of syphilis is now practically a dead letter. A pyrogenic polysaccharide, Piromen, was thought preferable to typhoid vaccine by Klein and Kulwin (ADS 6_ 571 1950).

Typhoid Vaccine Intravenously in graduated doses may be used for the production of therapeutic fever. The most practical and the safest method is the dilution of stock vaccine in small amounts of normal saline so that 1 cc of solution is equivalent to about 100

million bacilli. For the first treatment a dose of 50 to 75 million is used, for the second treatment 100 to 150 million, and with each subsequent treatment an increment of 100 to 200 million organisms. The temperature response is facilitated by the application of hot water bottles and blankets. If a second injection, one-third to one-half the dose of the first, is given as the fever rises following the original chill, the height and duration of the fever are increased. The injections must be intravenous.

In patients who have had typhoid fever or recent immunization against typhoid this method is frequently unsatisfactory but, in the majority, good fevers may be obtained. Frequently after the first and second treatments, many patients have a prolonged temperature rise associated with considerable general malaise, muscle pains, anorexia, and vomiting. Subsequent treatments, however, are better tolerated.

A course of fever by typhoid vaccine consists of 16 to 8 paroxysms with rectal temperatures above 103° F. Results of this type of fever therapy are inferior to malaria and artificial fever.

Artificial Induction of Fever can be accomplished in several ways. There remains some difference of opinion in regard to the relative worth of artificial fever and malaria, but no doubt exists that in experienced hands artificial fever is comparatively safe and effective in the treatment of neurosyphilis. It has the advantage of being controlled as to elevation and duration. The general physical condition of the patient is improved almost at once. The equipment is expensive, and specially trained nurses and doctors are required for constant attendance during, and for several hours after stopping, the treatment. The dangers are burns, heat prostration or heat shock, and death from cardiac or respiratory failure. Adequately trained, cautious workers are able to recognize signals of danger and are prepared to meet them. It is customary with each treatment to prolong the fever at a level of about 105.6° F. for 2½ to 5 hours. A temperature of 106.5° F. should never be exceeded. Best results have been obtained by a total of 10 to 16 treatments given twice a week. This type of fever cannot be used in all persons. Some patients, although cooperative, unafraid, and anxious to receive treatment, are unable to withstand the heat. As the rectal temperature rises they become increasingly restless, agitated, mentally confused, and uncontrollable by safe amounts of sedation.

Hot baths, electric blankets, radiant heat, air-conditioned cabinets and high-frequency radio devices have been used for therapeutic hyperpyrexia.

Dosage in Fever Therapy.—In any method, a temperature approximating 105° F. rectally maintained for 4 hours is to be attained. This may be repeated on alternate days or twice a week for 10 treatments. The means for obtaining it are not important of themselves and artificial fever is probably as effective as malaria (Simpson et al. VDI suppl. 16 194..). The costs are less, the convenience and control greater, the hazards in expert hand fewer (Simpson et al. BJVD 1 1, 1941). The infrared cabinet is safest. Administration of therapeutic pyrexia demands the undivided attention of an experienced physician and a skilled nurse as well as adequate apparatus.

Artificial hyperpyrexia is well tolerated by patients with normal hearts, kidneys and blood vessels and is contraindicated by age over 60 years, cardiac or renal insufficiency, advanced arteriosclerosis, pulmonary tuberculosis, and late neglected dementia of neurosyphilis.

Complications of heat therapy include burns and vesicles; nausea and vomiting usually commencing toward the end of a treatment, controlled by oxygen inhalation and by intravenous injection of 1,000 cc. of 10% glucose; herpes labialis; tetany due to acidosis and hyperventilation, controlled by calcium gluconate intravenously or by carbon dioxide inhalations. An occasional patient put into the hot box rises in temperature abruptly, extremely, and perhaps with fatal outcome despite things done toward his rescue. Such a possibility can be prevented only by the utmost diligence in supervising the treatment, for if the temperature shoots up, the emergency must be recognized at once. Salt loss, too, is a danger: a gram 3 times a day should be given throughout the course of fever therapy in all cases.

Fever alone will render the dark field negative in 94% of primary lesions and produce recessions of secondary eruptions but it will not alter the positive blood test. Fever alone is inadequate (Simpson et al. AnnIntM 04, 1938).

Good results were obtained by artificial fever in all forms of neurosyphilis but the most satisfactory results were obtained in late meningovascular syphilis and tabes dorsalis. Artificial fever had the advantage over malaria of causing less debility during treatment. In patients with general paresis, the relapse rate was higher among those treated with artificial fever than among those treated with malaria.

Results to Be Expected From Fever Therapy.—*Asymptomatic Neurosyphilis, Early or Late.*—Excellent improvement is expected in terms of prevention of development of clinical forms of neurosyphilis. Especially in patients with group III fluids, some degree of positivity of the complement fixation reaction may persist for many years, even after fever therapy. Other spinal fluid abnormalities should disappear.

Acute Syphilitic Meningitis.—Results are usually clinically excellent, though some cranial nerve lesions such as extraocular muscle palsies and deafness may persist. In adequately treated cases the spinal fluid usually becomes normal, though in some with group III fluids changes may persist in the complement fixation test.

Diffuse Meningovascular and Vascular Neurosyphilis.—Results are variable, depending on the type of lesion. In general, most patients do surprisingly well both from clinical and laboratory standpoints. The spinal fluid STS after showi g some improv me t may remain positive for a lo g time. Ri ing cell count and protein content are forerunners of relapse. In assessi g the remission of clinical symptom in diffuse me ingovascular neurosyphilis, the physician mu t keep in mind neurological residuals which are prone to result from vascular occl sions cortical scar formations, etc. The development of epileptic seizures or the persist ce of painful paresthesia does not necessarily indicate advancement or persistence of the i flammatory process.

General Paresis.—From the standpoi t of its serious potentialities, both in regard to life expectancy an l to residual permanent nerve tissue damage thi form of syphilis constitutes a medical emergency. Years of experience have clearly demonstrated that fever is the form of therapy which can be relied on to arrest the progress of general paresis in the largest percentage of cases. The ultimate success of therapy is directly related to the duration of symptoms prior to the instit tion of adequat treatment. The disease p-pears to be arrested, with return to excellent functional condition in about one-third of patients treated. Varying degrees of incomplete remission with some degree of residual defect take place in about 60%. In about 10% ll forms of treatment are unavailing and death i inevitable. Following the terminatio of fever therapy cli ical improvement usually occurs reaching it maximum at about 6 months. Some cases respo d promptly; in a few cli ical improvement may be delayed a year or more. Improvement in spinal fluid cell count and red ction in protein co tent usuall occu within a few months. Other abnormalities, especially the positivity of the Wassermann test may persist for many years. In spite of maintenance of a satisf ctory clinical status, or t least without evidence of advance of the disease process the spinal fluid should be examined regu larly at 6-month intervals. The cell count and total protein are the first tests to reach normal levels and are the most sensitive i dicators of ctivity. Persistent elevation, o the return to abnormal le els, of eithe or both of these tests sually precedes the development of a clinical rel pse and i dicates the desirability of a second course of fever treatment. The spinal fluid complement fixation reaction and colloid l gold test are less sensitive. Their remaining ab ormal does not necessarily indicat impending relapse. A complement fixation test which remains tro gly positive or revert to positive in 0.1 cc. of fluid 18 months to years after treatment is to be considered an indication of pe sistent ctivity regardless of the other tests, and may foreshadow an ltimate relapse. *A second course of fever may be gi en to a patient with such a fluid examination.*

Tabes Dorsalis in whi h symptoms develop within the first 10 years of the disease, or in which symptoms come on acutely shows the strongest spinal fl id reactions. Paradox ically these are often the cases which obta n the greatest benefit from treatment. Conversely patie ts with a long history of visceral rises, light ing pains, and slowly developing ataxia show the least acti e spinal fluids and obtain disappointingly little benefit from antisyphilitic treatment.

Optic Atrophy.—The results of fever therapy depend on the degree of damage before treatment is instit ted. In general, in pat ents in whom visual acuity in the better eye is 20/40 or better there is about an e en chance of rrest of the atrophic process and the maintenance of useful vision.

Treatment of Optic Atrophy.—There is more exigency for fever therapy in this disease than in any other form of neurosyphilis. Malaria should be induced at once wrote Bruetsch (J 130 14, 1946) in all patients with failing vision. Malaria therapy appeared to have no value when visual acuity had diminished below 20/200 stated Blatt (abs AmJSyph 34 390 1950)

Optic atrophy call f at lea t 5,000,000 unit of pe cillin plus from 10 to 1 malari l bouts (W rst r Vrought BMJ 2 659 1947). Pe icillin therapy in 50 cases was followed by progression of isual d fect in 10 patients, 8 of whom became blind (Klander a d Gro AmJSyph 33: 234 1949). Penicilli alone seemed a effective as when combined with malaria in the experience of Horne and Curtis (AmJSyph 33 143, 1949). Penicillin seemed ffecti e in arresting the early st ges, but when vision was worse than 20/50 there ually occurred f rther loss despite the antibiotic, observed Dento and Harris (AOphth 48 449 1952)

Treatment of Tabetic Crises.—The agony may be almost insufferable and its relief a challeng g probl m Si ce th pinal fl d changes re gen rally slight, and ma even be absent, penicillin, capable of reversing CSF evidence of inflammation, seldom c complishes m ch. Fev therapy sometimes increases the pains. The vasodilator drug, Priscol was reported to be usef l (Rogers J 140: 7 1949) Chordotomy was required and was helpf l in a se of Mayne (BMJ 1 1309 1953) ACTH gave relief in a patient f Walner d Mendelsoh (J 152 03 1953) within a few hours.

Congenital (Prenatal) Syphilis

Prenatal Syphilis is a good name for diaplacental infection of the fetus. Infection occurs in utero In this stage it is usually curable

Immunity in the infantile type of disease is as variable as in the adult. Miscarriage stillbirth prematurity and actively syphilitic living babies are

the common results of infection yet normal babies may be born to syphilitic women. Infection in the fetus may be expected to damage structures while they undergo embryologic development. Nevertheless, congenital syphilitics may for many years show no sign of activity of the disease.

Colles (1837) noted that an apparently healthy man might marry and transfer syphilis to his wife without showing any evidence of the disease himself. Colles observed too that a woman without obvious venereal symptoms may bear a syphilitic child and nurse it with impunity even though others are infected by it. Profeta (1865) saw apparently healthy children being nursed by obviously syphilitic mothers without becoming infected. It is generally believed at present that if the child is diseased the mother must be infected, although her disease may be latent.

Spirochetes have never been demonstrated in fetal tissues earlier than the fourth month and rarely before the fifth. At term however the tissues are teeming with them, particularly the liver. The fetus can acquire syphilis from its mother shortly before or at the time of birth. It is generally true as Kassowitz law asserts, that there is progressively less likelihood that the successive children of a syphilitic mother may be infected for with the passage of time the woman's immunity is likely to prevail yet it happens that the disease may skip one pregnancy to damage the next a phenomenon explicable on the assumption of variations in the degree of immunity of the mother.

Showers of spirochetes occur from time to time in any syphilitic person, it is thought. If this happens in a pregnant woman, the fetus will be infected. Since it may happen it must be prevented from happening. Cole et al. (J 106 464 1936) concluded **The data show that congenital syphilis is practically a preventable disease. Its prevention is dependent on the routine, early and repeated use of the serologic blood test on every pregnant woman and on adequate treatment once the diagnosis of syphilis has been made.** Serologic tests should be repeated near term in order to detect syphilis acquired late in pregnancy (Heyman and McCain NEngJM 241 960 1949).

Some 25% of the pregnancies in syphilitic families result in miscarriage *or stillbirths, and fetal death is at least twice as frequent in syphilitic as in* nonsyphilitic families. The earlier in pregnancy that antisyphilitic treatment is given the greater the probability of its success in securing a nonsyphilitic offspring (Soloway J 129 500 1945).

Acquired Syphilis in Infancy and Childhood has *frequently* been observed (Creswell et al. AmJDisChild 66 611 1943). A newborn with a scalp chancre *presumably inoculated* in the birth canal, was [illegible] by Quiroga (abs ADS 42 601, 1940). Sad circumstances of transmission by nonsexual contact *were reported by Murrell and Gray (BMJ* [illegible] 1947). The age range in 35 cases of Waugh (AmJSyph 22 607, 1938) was from 5 months to 14 years. Epidemiology was emphasized in the extensive review by Smith (AmJSyph 23 165 1939). Four sisters [illegible] from 6 to 11 years of age were infected by one youth, reported Schoch and Long (AmJSyph 23 186, 1939). Overcrowding, ignorance and an infected member of the family [illegible] the [illegible] leading to nonsexual infection of 20 little children whose case histories were given by [illegible] et al. (JVDI 30 [illegible] 1949).

Reinfection with acquired syphilis has been described in congenital syphilitics; the *fifth known case* [illegible] *on record by Grimble and Hahn* (AmJSyph 36 439 [illegible]).

Twins.—Congenital syphilis affecting only one of a set of twins has been observed (Wile and Welton AmJSyph 22 544, 1938; Smith and Spence SouthMJ 34 147 1941; James [illegible] 61 359 [illegible]; Rakin AmJSyph 35 334, 1951). The twins may or may not be [illegible] in each case.

Third Generation Syphilis, the transmission of infection from a congenital syphilitic to his offspring possibly may occur although the difficulty of proving that it has occurred is evident (Brassel ADS 40 [illegible], 1939).

Early Symptoms.—Cutaneous Lesions may be present at birth, or may develop during the first 4 or 5 months. Syphilitic babies are generally marantic emaciated and feeble with thin wrinkled skins, and wizened senile faces. Coryzal symptoms often accompanied by rhinitis snuffles, and hoarse breathing may be among the earliest manifestations. Mucous patches and condylomas are likely to be present during the first few months, and these lesions often develop prior to the appearance of the general exanthem. The

Fig. 565.—Prenatal syphilis marasmus, snuffles, fissures radiating from the angles of the mouth. (Cole J 109 580, 1937)

Fig. 566.—Congenital syphilis. (Dr Sam E Sweitzer)

Fig. 567.—Prenatal syphilis etic syphilitic dermatitis nd bullous eruption on palms nd soles. (Cole J 109 580, 1937)

Fig. 568.—Osteitis in prenatal syphilis. Roentgenogram showing defects of ends f radius and ulna in syphilitic infant (Dr Galen Tice, U of Kansas Medical Center)

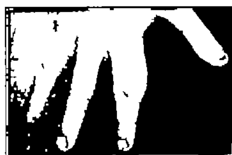
character of the cutaneous eruption varies. Bullous lesions may occur in hereditary syphilis. The blebs range in diameter from 1 to 5 cm., and are usually only partially distended, with eroded bases and flabby fragile walls. Such lesions may be generally distributed, but often they are limited to the palms and soles. They are likely to be intermixed with macules, maculopapules, and occasionally pustules. Lymph node involvement is often present, but is not a typical or characteristic feature The commonest types of eruption are the papular and maculopapular Fissures of the lips, angles of the mouth, and anus are present in some three-fourths of the cases. Pustular lesions like bullae usually indicate a grave infection. Tubercular and gummatous lesions seldom occur early in the disease See Cole et al. (VDI Supp. 7 1940) Wile and Mundt (AmJSyph 26 70 1942)

The early manifestations of prenatal syphilis (Cole J 109 580 1937) correspond to the secondary stage of acquired syphilis. Ordinarily they show up some weeks after birth. Prenatal syphilis can simulate any of the features of acquired syphilis, excluding cardiovascular manifestations. The child is restless, cries feebly but frequently and has snuffles. A reddish brown or coppery eruption is seen most frequently on the palms, soles, and diaper area It is comparatively easy to find *T pallidum* by dark field examination of material from the perionychium, rhagades, and moist papules or bullae Physical examination reveals a liver enlarged, even perhaps to the level of the umbilicus, and an enlarged spleen

Late Symptoms.—There is a late stage of prenatal syphilis, as of acquired syphilis, in which the disease shows a tendency to localize in certain parts or organs (Smith AmJSyph 24 755 1940) In the Cooperative Group study approximately 33% suffered from parenchymatous or interstitial keratitis 12% had involvement of the central nervous system and 7.2% had involvement of bones and joints.

DISEASE OF THE BONES is found in a fair percentage of the cases consisting of thickening at the end of the long bones, especially the radius and ulna. Owing to pain the child holds the limb as if it were paralyzed (Parrot's pseudoparalysis) X ray examination reveals the characteristic epiphysitis (Black JPed 14 761 1939) from which must be differentiated the lines caused by bismuth therapy given the mother (Whitridge AmJSyph 24 223 1940) Periostitis and occasionally dactylitis are seen. Roentgen findings thought most trustworthy in diagnosis by Black are (1) well-defined saw tooth metaphysis in well-calcified bones (2) multiple separation of epiphyses, with or without impaction in bones which are not rachitic (3) bilaterally symmetric osteomyelitis of the proximal mesial aspects of the tibiae (4) multiple circumscribed osteomyelitis of long bones showing patchy areas of rarefaction (5) multiple longitudinal areas of osteomyelitic rarefaction in the shafts of long bones sometimes resulting in fractures (6) foci of destructive rarefaction at the mesial or lateral aspects of the metaphyses and (7) multiple areas of cortical destruction generally seen within 1 cm. of the ends of the bones.

More osseous lesions are to be found in infants less than 5 months old and are of the form of generalized osteochondritis and periostitis after 1 year osteitis and osteomyelitis are usual and periostitis is seen (Russo and Shryock Radiol 44 477 1945) See Hill et al. (JPediat 30 547 1947)



Gross destruction of joints may occur and a rare example of Charcot elbow joint was reported by Denker and Kennedy (J 114 408 1940)

Symmetric, serous synovitis of the knee joints, with hydrarthrosis, is a manifestation seen in congenital syphilis and known as Clutton's joints (Klauder and Robinson J 103 236 1934 Clutton Lancet 1 391 1886)

Syphilitic osteitis and periostitis often affect the sternoclavicular joint the ensuing enlargement being known as Higoumenakis sign (Higoumenakis DZtschrNervenh 114 288 1930 AnnDD 8 939 1937 Dorne and Zakon ADS 32 602 1935) It was present in 30% of 64 congenital syphilitics observed by Dax and Stewart (BMJ 1 771 1939)

Gummas may affect the bony structure anywhere but are found most frequently in the tibia skull bones of the nasopharynx and bones of the upper extremities, especially the inner end of the clavicle Trauma is a factor in their localization. Saddle nose results from destruction of the bones of the nose Gummas may affect soft parts as well as bony structures. Late involve

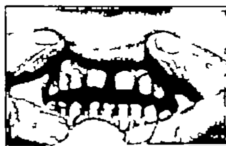


Fig. 569 —Saddle nose, in prenatal syphilis (Dr Jaques P Guequierre.)
Fig. 570 —Syphilitic periostitis of the finger
Fig 571 —Hutchinsonian teeth in a patient with entire Hutchinsonian triad keratitis, deafness, and dental defects. (Dr Grover W Wende.)

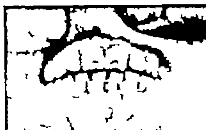

Fig. 572.—Rhagades in congenital syphilis. (Dr Robert Y Andrade.)
Fig 573.—Deformity of teeth, due t syphilis. (Dr D C. Smith.)
Fig. 574 —Hutchinsonian incisors. (Thoma Oral Pathology ed. 3, Mosby 1950.)

ment of the bones occurs most frequently in the form of diffuse osteitis or in a form of chronic hydarthrosis of the joints (Clutton's joints). The knees are most frequently affected (Loos AfDuS 181 549 1940). Osteoperiostitis is a diffuse hyperplastic process most often affecting the tibia. The periosteum is inflamed, and there is thickening from new bone formation leading to the "saber shin" appearance. The enlargement of one sternoclavicular articulation, Higoumenakis' sign, is as significant of the existence of late prenatal syphilis as are other important stigmas (Yang ADS 41 1060 1940).

The Teeth often show deformity (Karnosh ADS 13 25 1926). The variation of dental defects is wide, ranging from a complete failure to develop to a slight diminution of size or alteration of form, and these differences are largely of degree. The characteristic features are the undersized malformed appearance, the contracted appearance of mamelons, marginal ridges and cusps of incisors, cuspids and molars, and a peculiar open bite malocclusion (Anderson AmJDisChild 57 52, 1939).

Dwarfing of the affected teeth and lack of development of the premaxilla were the abnormalities stressed by Johnston et al. (Am. J. Orthodont. 27 667 1941) who could not demonstrate spirochetes in the dental structures. The effects of syphilis on the teeth depend upon the developmental stage during which the disease was active, and roentgenologic diagnosis from studies of unerupted permanent teeth can often be made according to Sarnat et al. (J 116 2745 1941).

The teeth especially affected are the permanent upper central incisors, the lower central and lateral incisors and the first molars (Sarnat and Shaw AmJDisChild 64 771 1942). Dental anomalies occur in approximately half of all heredosyphilitic children. The true Hutchinsonian incisor shows deformity of the developmental lobes of the permanent central incisor and is not due to transitory calcium deficiency. The upper incisors especially are narrowed and somewhat smaller than normal, are bowed out on their sides, and show a central depression of the cutting edge due to hypoplasia of the middle lobe. The true mulberry molar of syphilis is a permanent first molar characterized by enamel cusps showing crests of sound enamel on a base of hypoplastic deposits, the cusps being crowded together on a crown surface of dwarfed dimensions.

The budlike molar of Pflüger (see Kreyberg and Schwisow ZtschrNeurPsych 127 188 1930) was independently described by Karcher (ADS 31 661 1935) and is quite typical; the diameter of the crown is normal but the cusps are rolled in, giving the appearance of being clinched, and there is no defect of enamel.

The recognition of syphilitic dental dysplasias can contribute to public health case finding efforts (Beecher et al. JVDI 32 70 1951).

Ocular Manifestations of some kind develop in about 5% of all syphilitics sometime during their disease according to Woods (AmJSyph 27 133 1943). From birth until age 2 years, optic neuritis, choroiditis and retinitis are not extraordinary and the results may be either progression and atrophy or recovery. Between the ages of 2 and 8 years, interstitial keratitis is the usual ocular finding. After the age of 8 years occur interstitial keratitis, eighth nerve deafness, neurosyphilis and optic atrophy. Ocular examination may reveal diagnostic findings even when the changes are not conspicuous and when other signs of congenital syphilis are absent (Gross and Meyer AmJSyph 38 30 1954).

Interstitial keratitis occurred in a third of 1,010 cases of late prenatal syphilis surveyed by the Cooperative Clinical Group (Cole et al. ADS 35 561 1937). Patients less than 15 years of age did better than older patients, but there was a risk of the development of the disorder up to age 25 years. Adequate treatment strongly diminished the likelihood of its appearance. Interstitial keratitis appeared 5 years after antisyphilitic therapy had reversed the STS to normal in the case of Robinson (AmJSyph 36 92, 1952).

Of 637 patients with interstitial keratitis, 40% had dental stigmata, 35% bone and joint lesions, 10% labyrinthine disease, 8% chorioretinitis, 8% neurosyphilis (Klauder and Vandoren: VDI —: 307 1941) When one eye only was involved, the disease became bilateral within 1 month in 4?% and within 10 years in 9?% of the cases. Interstitial keratitis may appear any time from 4 or 5 years of age to 20 or 25 years. The cornea develops a diffuse ground-glass appearance different from the sharply defined phlyctenules seen in tuberculous keratitis There are extreme photophobia, lacrimation and circumcorneal injection of the ciliary vessels. These vessels may invade the cornea. In severe cases there may be iritic changes in the choroid and peculiar opacities in the vitreous.

Fig. 575.—Saddle nose resulting from prenatal syphilitic osteitis. (Dr Howard Morrow.)
Fig. 576.—Prenatal syphilis gummatous osteitis of the skull. (Dr Grover W Wende.)

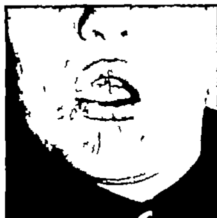

Fig. 577.—Interstitial keratitis early stage of clouding of cornea (Dr C. C Dennie.)
Fig. 578.—Syphilitic rhagades (Dr F Ronchese.)

It is common for the second eye to become involved, especially when therapy has been neglected, and blind eyes the result. Slit lamp examination of the cornea may reveal interstitial keratitis which is asymptomatic (Klauder and Cowan: J 113 1024, 1939)

The exact mechanism whereby syphilis damages the cornea is not known although spirochetes are plentiful in all parts of the eyes of the congenitally syphilitic fetus (Woods: AmJSyph — 133, 1943 Avitaminosis perhaps the lack of riboflavin may be concerned (Kruse et al. PHRpt 55 15 1940) Klauder et al. (AmJSyph 35 416, 1951) considered the endocrine aspect of etiology finding the BMR and the urinary 17 ketosteroid output lower than average in these patients.

Chorioretinitis in congenital syphilis may be classified in 4 types (1) salt and pepper fundus (2) oval pigmented yellowish red lesions occurring singly or in groups (3) light yellow peripheral lesions remaining small or undergoing confluence and (4) lesions simulating primary pigmentary degeneration of the retina and carrying a poor prognosis (Sidler Huguenin, cited by Klauder and Meyer AOphth 49 139 1953) Chorioretinitis is not statistically so important a cause of blindness as interstitial keratitis is.

DEAFNESS is a distressing result of late prenatal syphilis. It may be mild or total. It may come on slowly or at a certain stage progress with great rapidity If it has progressed far it does not respond well to therapy It usually reveals itself from the age of 6 or 8 years to the age of 20 or 25 Hutchinson s syndrome is not always evident in 25% all 3 symptoms—deformities of the eyes, ears and teeth—are noted. Changes in the internal ear and deformities of the teeth are present in about 10% involvement of the eyes and ears in 40% and involvement of the internal ear alone in 25% Histologic studies of the auditory apparatus in congenital syphilis have been given by Mayer and Fraser (JLaryngOtol 51 683 755 1936) and Carnevale (abs VDI 20 83 1939)

THE CENTRAL NERVOUS SYSTEM is commonly involved This seems more frequent in the earlier years of life than later An incidence of from 20 to 40% has been quoted. Syphilitic meningitis gives evidence of pressure symptoms the fontanel is tense acute hydrocephalus may be present and convulsions may occur The spinal fluid shows the usual changes. Paralyses of various types are also seen in these young patients. With parenchymatous involvement of the brain tissue juvenile dementia paralytica is encountered The symptoms may show up at any time from the age of 5 or 6 years to 20 or 25 In cases in which there is involvement of the posterior columns of the cord, the picture of tabes dorsalis presents itself often accompanied by optic atrophy The incidence of neurosyphilis in congenitally syphilitic children is higher among those born to neurosyphilitic parents than among an unselected group suggesting some credibility in the hypothesis of a neurotropic strain of the spirochete reported Quisenberry (HawaiiMJ 9 94 1949)

CARDIOVASCULAR INVOLVEMENT in congenital syphilis is rare, occurring in interstitial and nodular forms. Arteritis but not valvulitis may be caused (Hinrichson AmJSyph 27 319 1943)

Pathology—In the umbilical cord the inflammatory infiltrate is rich in polymorphonuclear leukocytes, which are not a usual feature of syphilitic tissue reaction. Dark-field examination of scrapings from the umbilical cord were positive in over half the cases of Ingraham (J 105 560 1935) The placenta is larger than usual with thickened rather avascular villi. Sometimes it exhibits little positive evidence of disease although the child shows much. Dippel (AmJObGyn 47 369 1944) did not find spirochetes in any fetus younger than 18 weeks in 67 necropsies of syphilitic infants. Spirochetes in large numbers are in the liver spleen, kidneys, adrenals heart muscle bone marrow and testes. Diffuse fibrosis is seen particularly in the lungs pancreas, heart and adrenals. The liver may show areas resembling gummas but infiltrated with enormous numbers of spirochetes. Congenital syphilis probably does not occur in the experimental disease in mice and rabbits (Kemp and Fitzgerald JID 1 353, 1938)

Diagnosis is usually easy when the disease is clinically in evidence Mucous patches and condylomas about the mouth and anus are characteristic features The occurrence of palmar and plantar bullae also is almost pathognomonic The cutaneous lesions are basically similar to those of the secondary eruption in acquired syphilis. Perioral lesions result in atrophic scarring of the elastic tissue and typical scarring rhagades, which are linear depressed pale furrows seen on the lips and extending radially in the perioral skin (Strakosch and Nelson ADS 43 664 1941)

Quantitative STS showing significant increases in titer of reagin in syphilitic infants after 4 to 8 weeks, aid in diagnosis (Ingraham ADS 43 323

1941) Practically 100% of persons with prenatal syphilis have positive serologic reactions. Early treatment is likely to reverse these but the longer the child remains positive and untreated the less likely is therapy to influence the blood test. The cord blood test is not a dependable guide as to the existence of syphilis in the newborn because his serum is likely to react as the mother's does, showing passive reaginemia even though the infant may be nonsyphilitic. Syphilitic reagin in the blood of the newborn is diagnostic of syphilis in the mother not in the child a fact known as Fildes law Such reagin, if the infant is not syphilitic, falls far toward zero even in the first week after birth (Faber and Black AmJDisChild 51 1257 1936) If physical and roentgen examinations of the infant are negative, quantitative tests at intervals of 2 weeks are indicated Persisting high titer or increase of titer for 6 to 8 weeks justifies treatment In the nonsyphilitic infant with positive tests at birth, titer is usually as low as 4 to 8 units within 3 weeks or negative but positivity occasionally persists into the third month. When the test is positive at the age of 8 weeks, there is 90% likelihood of the coexistence of positive x ray changes. It is inadvisable to give antisyphilitic treatment to infants of syphilitic mothers unless the infants are proved to have the infection

LANDMARKS OF TARDIVE HEREDOSYPHILIS (after Stokes)

MAJOR (strongly presumptive or diagnostic):

- Positive blood Wassermann.
- Interstitial keratitis.
- Hutchinsonian incisors.
- Mulberry molars.
- Eighth nerve deafness.
- Epiphysitis and osteochondritis.
- Saber tibiae.
- Osteitis of the nasal septum.
  - Snuffles.
  - Saddle bridge.
- Early dactylitis.
- Splenomegaly before the fourth month.
- Rhagades and scars.
- Roentgenographically specific changes.

SECONDARY (alone insufficient for diagnosis):

- Frontal bosses.
- Aplasia of incisor teeth.
- Scaphoid scapula.
- Marked enlargement inner third of clavicles.
- Disturbance of age-development ratio.
- Precocity and irritability
- Early epitrochlear adenopathy
- High narrow palatine arch.

MINOR

- Venous ectasia.
- Hypertrichosis.
- Ulnar deviation of middle fingers.
- Constitutional subnormality
- Backwardness.
- Hypertrophic frontal suture
- Craniotabes.
- Bilateral dacryocystitis in childhood.

DEBATABLE

- Carabelli tubercle.
- Retromastoid adenitis.
- Persistent infantile hydrocele
- Knock knee elbow
- Absence of the xiphoid process.
- Hypertrophic thymus and thymic abscess.

Roentgenograms are diagnostic in a higher proportion of cases than serologic tests (Evans J 115 197 1940) Roentgenologic diagnosis can be made in 95% of young patients in contrast with 30% diagnosticable by serologic methods, according to Parmelee and Halpern (J 105 503 1935) Within the first 4 months x ray examination discloses, when they exist, osteochondritis, epiphysitis, diaphysitis and periostitis (Holmes and Lingley NEngJM 217 983 1937) The involvement of bones in the fetus may be recognizable even before birth, by x ray examination.

Treatment.—Antenatal treatment of syphilitic women prevents syphilis in babies. Penicillin is the best therapeutic agent. While it is inadvisable to treat an infant for congenital syphilis unless he has been proved to have the disease (Ingraham AmJSyph 19 547 1935) it is highly advantageous to the syphilitic child to receive treatment early in the course of his infection (Smith AmJSyph 19 512, 1935 20 45 1936) and this should be done before the infant is born if possible (Foerster WiscMJ 36 987 1937)

PRENATAL TREATMENT DURING PREGNANCY —The value varies with the relative adequacy of the treatment, and in prepenicillin days it was observed that with increasing dosage of arsenicals and bismuth there was a steady fall in the number of fetal casualties (Dill et al. AmJObGyn 40 965 1940) Adequate therapy with either arsenicals and bismuth or penicillin gave equivalent results approximately 94% normal full term infants and 2% living syphilitic infants in the experience of Wammock et al. (AmJObGyn 59 806, 1950) When at least 2 400 000 units of penicillin had been given to the mother 95% of the babies were nonsyphilitic (Speiser et al. JVDI 28 108 1947) Not one syphilitic offspring appeared among the mothers whose STS became negative under treatment prior to delivery although syphilitic infants were born to 9% of the women who received less than 2,400 000 units of penicillin (Cole et al JVDI 30 95, 1949) Women who received 2,400 000 units or more bore syphilitic infants in only 2.5% of the instances.

Treatment should be begun before the fifth month of pregnancy If early syphilis appears late in pregnancy proper treatment carried through term will increase the likelihood of the birth of a healthy baby To ensure a *living nonsyphilitic infant it is necessary to treat the mother during each* pregnancy thought Peckham (J 117 1863 1941) It is now believed not necessary for a woman who has had syphilis to undergo treatment during every pregnancy provided that she has received 4 0 Gm of Mapharsen or its equivalent or 2 400 000 units of penicillin and provided that she is without signs of active syphilis and has negative STS or STS of 8 units or lower titer wrote Goodwin and Farber (AmJSyph 32 409 1948) Other authorities agree that it is not necessary to treat a pregnant woman for syphilis if she has been cured of the disease and has not been reinfected (Ingraham et al. AmJObGyn 56 340 1949 Tucker AmJSyph 33 1 1949 Goodwin JVDI 31 178 1950 Shaffer and Courville ADS 63 91 1951) The problem, obviously is to decide when the presumed cure is sufficiently secure to let the fetus carry the risk while retreatment with penicillin is not a great hazard to the mother and nowadays penicillin is cheap

Treatment with penicillin is remarkably effective in syphilitic pregnant women and is, in fact so superior for this purpose protecting the child even when started late in pregnancy that it supersedes all other possible choices of therapeutic agent (Aron et al. ADS 58 349 1947) Massive arsenical therapy is ill tolerated by the pregnant woman who is more liable than other syphilitic patients to the hazards of hemorrhagic encephalitis (Speiser et al. AmJObGyn 49 214 1945) *it should never be used* The reaction rate to arsenicals increases as the pregnancy progresses (Kennedy and Henington ADS 48 83 1943) The antisyphilitic superiority of penicillin is conspicuous and *results are equally good no matter what the duration of pregnancy at the time* treatment is commenced, thought Horne and Curtis (MichSMSJ 47 1006 1948) They recommended doses of 600 000 units daily for 10 days, using a preparation of slow absorption rate They stressed the necessity for adequate clinical and serologic follow up of both mother and child A dose of 600 000 units daily for 8 days seemed adequate to Bundesen et al (ADS 62 230 1950) See treatment in pregnancy (p 442) rapid treatment methods (p 449)

The occurrence of Herxheimer reactions was, in 2 instances among 182 cases of serious consequence to the fetus, reported Bowen et al. (ADS 58 735 1948)

GENERAL MEASURES include hygienic and supportive efforts. The nose should be kept clean, the folds of the skin should be free from moisture and dirt, and such mucous patches or condylomas as may develop should receive topical attention though they respond promptly to specific therapy Frequent baths, followed by the liberal application of a bland dusting powder are useful Hospitalization and expert pediatric care are highly desirable for many congenitally syphilitic infants suffer severe anemia dehydration hypoproteinemia and difficulties of salt and water balance.

PENICILLIN was reported effective in a total dose of 18,000 units per pound by Lentz et al. (J 126 408 1944) who at that time believed that the first doses should be cautiously small to avoid serious reactions. It is now known that such a total dose is much too small (70 000 units per pound being perhaps adequate) that caution in the first injection is not necessary that the antici pated cure rate in infants with early syphilis approaches 100% and that no adjunctive chemotherapy is necessary in the early period of treatment. Ex tensive studies of penicillin dosage and effects by Smith et al. (ArchPediat 72 12, 1955) indicated that the total dose should approximate 320 000 units per kilogram body weight 1 2 million to 4 8 million units according to the age of the child

When 0,000 units pe pound are given i 60 doses at 3-hour i tervals seronegativity does not promptly appear but the n mber of patients becoming seronegative increases monthly for at least 18 month (Pl tou et al.: AmJDisChild 7 433 1946) Larger doses continued over a longer period of time result in improvement in results (Ingraham et al.: J 130: 694 1946)

Following treatment the infa t should be examined at monthly intervals with titered serologic test as long a the tests show positi ity Intervals for re evaluation may be lengthened to 3 month aft r seronegativity i attained, a d the spi al fluid must be ex ami ed about 1 year late If infectious relapsing lesion occur at any time after the commencement of treatment or if the serologic test is still strongly positiv afte a year of postre tment observation, retreatment on an i dividualized basis is to be consi lered.

The dose of penicillin recommended by Platou et al. (J 133 10, 1947) on the basis of studies of .3 cases treated with penicillin in 5 university clinics, wa 100 000 units of penicillin sodium per kg body weight divided into 120 equal injections given at intervals of 3 hours in a period of from 12 to 15 days. Results i cluded dramatic clearing of active manifestations of infection, 0 relapses within 11 months, seronegativity i the majority of the patients within 4 to 1 mo the following the py and *7 death from ll causes. Result from a si gle course were satisfactory in 72% of the cases, unsatisf ctory in 9% per cent, and ncertain in 19% When spinal fluid abnormalities were prese t at the out set, they improved remarkably

PRIOR TO PENICILLIN which i the drug f choice because of its effectiveness, safety and col eidental val e gainst the intercurrent i fections debilitated infants usually suffer (QMN: J 131: 1535 1946) it was judged correct to st rt the ch ld who had active pre atal syphilis on arsenical treatment t once giving neoarsphenamine from 0.01 to 0.015 Gm. per kg Intra enous injection in infants require some skill; the fo tanel may be pu ctured to introd ce the med cine int the superio sagittal sinus. The drug was dis solved in cc. of distilled wate Moore at one time preferred sulfarsphenamine, from 0.010 to 0.015 Gm. per kg., administered i tramuscularly into the buttock in a con centrated solution. Ordi narily a course of 8 weekly injections of eithe preparation was employed, immediat ly followed by a series of weekly i tram scula injections into the b ttock of a preparation of bismuth, such as th oil suspension f bismuth salicylate 2 mg./kg (N ef and Vieth SouthMJ 33: 691 1940) Courses of the two drugs might be alternated until a yea of th rapy had been completed bout 25 injections of each preparation (Howard JPed 14: 220 1939) If th serologic reaction was still positive at the end of the yea furthe treatment for 6 month o a year was n orde Mapharsen and bismuth w re preferred by Astrachan and Corn ll (J 121: 746, 1943)

Acetarsone once popular because of the simplicity of its oral administration is a da gerous drug, although it ha cured many pat ents. Its antisyphilitic activity was demonstrated by Pillsbury a d Perlman (AJDC 39: 909 1930) who bserved its ability to reverse serologic test ; but serious reactions occurred in 4.6% of their 87 cases. Lyon and M (JPed 13 13 19 1939) consid red t a good a other arsenicals. The dose schedule of Maxwell d Glase (AmJDisChild 43: 1461 1932) consisted of 14 Gm. in 49 da s. Nephritis th serious reaction most to be feared. Acetarsone has been super seded by safe d more effect ve agents.

See Da kison nd Birt (CanadMAJ 34 33, 1936) acetarsone as improvement over previous medicines Cole (J 108 824, 1937) toxic and curativ doses too close together; Robinson and Robinson (AmJSyph 23 168, 1939) unsaf ; Nyhus (be J 144 1637 1950) as good as ny tisyphilitic drug.

In older children from 6 to 8 years of age are found osteitis periostitis, interstitial keratitis, and involvement of the central nervous system. Peni cillin is highly effective for the cure of specific inflammation (Yampolsky and Heyman J 132 368 1946) but interstitial keratitis remains a problem despite the antibiotic Around puberty interstitial keratitis eighth nerve deafness and involvement of the central nervous system are the serious haz ards. Any of these requires the care of an expert.

INTERSTITIAL KERATITIS.—The routine use of a cycloplegic fever therapy and full doses of chemotherapy are of great value (Klauder and Vandoren

AOphth 26 408 1941) In 42% of their 532 cases the eyes were involved either simultaneously or within one month of each other The second eye in 79% was involved by the tenth year The final visual acuity of both eyes was good in 64% of the patients treated continuously as compared to 47% of patients treated intermittently or irregularly Arsphenamine treatment supplemented with fever therapy either malarial or artificial successfully prevented relapse in all but 1 of 55 patients so treated by Klauder and Vandoren. Penicillin in a dose of 50 000 units each 4 hours failed to prevent involvement of the second eye in approximately half of 72 cases even when fever was used in adjunct (Klauder AmJSyph 31 575 1947) The addition of penicillin did not improve the results of adequate treatment entailing 20 doses of arsenical and 8 to 10 bouts of fever Fever therapy by means of typhoid antigen and concomitant penicillin comprised good treatment in the opinion of Forsyth (SouthMJ 41 1015 1948) but proved to be not highly satisfactory in terms of clinical results wrote London and Noojin (AmJSyph 32 483, 1948) who expressed the wish that better treatment were known. Their wish was not long delayed in fulfillment

Fig 479 —A girl blind eye congenital syphilis (Cole J 109 580 1937)
Fig 480 —Mutilation produced by prenatal syphilis (Dr H N Cole)

In estigating the effects of ACTH and cortisone on variou inflammator d eases of the ey Steffensen t al (AmJOphth 33 1033, 1950) observed that a patient with i ter st tial k atitis after rece ving these medicines parent rally contin ed to improve whe cortisone wa used locall whil other patient treated only topicall with cortisone did w ll Woods (AmJOphth 33 1325 1950) reported marv lous results confirmed soon b man others, in luding H rne (BMJ 1 1289 1951) Simpson et al (J\DI 32 116, 1951) Crane and McPherson (AmJSyph 35 525 1951) and Madd n and Danto (ADS 64 437 1951)

Cortisone acetate suspension, diluted 1-4 with saline making 6 mg /cc, may be dropped into the eyes approximately hourly while the patient is awake Improvement is dramatic visible within 24 hours, practically complete subjectively within 96 hours. Cases treated before corneal vascularization heal completely and recurrent attacks are as responsive as primary ones. The effects are especially good in early cases (Woods AmJSyph 35 517 1951)

Thyroid in conjunction with cortisone and fever therapy appeared to be beneficial in some cases of Klauder and Meyer (ArchOphth 51 435, 1954) who found the BMR regularly to be low and who insisted on the necessity for treating the patient early in the inflammatory stage of his disease

Fever therapy was asserted as being of some benefit by Okala (AmJSyph 37 549, 1953) but penicillin is not, and the benefit of cortison and ACTH are only transient

be felt. Their influence on inflammatory or allergic reactions diminishes vascular congestion, retards early fibrosi inhibits phagocytosis and reduces the formation of new blood vessels, but does not affect the underlying disease pointed out Ashworth (BritJVD 29: 3 1933) A hworth reported remarkable relief of photophobia red eye and distress with cortisone therapy in 28 cases, and believed that, if the drug is used early the disease may be halted before corneal vascularization takes place If its use is begun after vascularization has started, more time i required to bring the case under control. Concurrent heavy dosage with penicillin wa recommended, and tentative withdrawal of cortisone were depended on to 1 termine the time when its use could be discontinued. Corneal grafting he stated, might be considered afte activity of the disease had been in abeyance for years.

EIGHTH NERVE DAMAGE is extremely resistant to therapy It represents a form of parenchymatous neurosyphilis and requires appropriate adequate antisyphilitic treatment

THE SPINAL FLUID must be examined early and, if this shows evidence of involvement of the central nervous system suitable modification and intensification of treatment must be devised.

Juvenile neurosyphilis is estimated and attacked as adult neurosyphilis is, the spinal fluid findings being significant criteria of activity of the disease Penicillin and fever therapy are effective in the meningovascular varieties, but juvenile paresis and tabes dorsalis have a poor prognosis (Menninger Juvenile Paresis, Williams and Wilkins, 1936 Dennie AAAS publ. #6 p. 111 1938 Nielsen et al ADS 46 688 1942)

PENICILLIN THERAPY.—See Platou et al (J 127 582, 1945) Rose et al. (JPediat 29 667 1946) 36 cases, no death from syphilis, Neilson et l (ADS 53 625, 1946) 30 cases, 1 death Heyman and T mpolsky (AmJDisChild 71 605, 1946) 22 cases, 3 deaths, 2 relapses Olansky and Beck (AmJSyph 31; 61, 1947) penicill lone compared with penicillin, arsenical and bismuth, Platou and Kometani (Pediat 1 608, 1948) penicillin results, especially in juvenile neurosyphilis; Barker (JPediat 32 616, 1948) Rose et al. (AmJDisChild 77 729 1949) 55 cases, 7 deaths.

DERMATOSES DUE TO FUNGI

DERMATOMYCOSES

The Mycoses are the diseases caused by fungi. While bacteria the Schizomycetes, are botanically members of the fungi diseases caused by them are considered in the preceding chapter. Bacteria seem to be almost wholly unrelated to other groups of fungi although some of the higher forms are suggestive of Myxophyceae which have lost their chlorophyll.

Schizomycetes are typically unicellular plants the cells are usually small and relatively primitive in organization. Higher fungi form a large heterogeneous group of plants including all those lacking chlorophyll. In most of them the vegetative body is surrounded by cell walls and usually appears as septate filament called hyphae. The vegetative hyphae are collectively known as mycelium. Hyphae grow by the sprouting of small protuberances, which enlarge round off and are cut off from the mother cells by septums. Daughter cells or sprout cells, are known as blastospores. Among the yeasts this is the only type of vegetative body. When growth conditions are unfavorable resting cells are formed, called chlamydospores. When circumstances become favorable the chlamydospores develop normal vegetative mycelium. Hyphae generally are intertwined in silky masses which generally are capable of absorbing food at any point. Various specialized structures develop from them. Most fungi, at certain ages and under favorable conditions of nutrition develop reproductive structures on the mycelium. These are usually spores. Spores are cells or groups of cells characteristically formed and able to grow independently into new individuals. In many fungi there is a sexual function involving the two processes fertilization, comprising the fusion of two nuclei, and miosis, in which there is a return to the single chromosome number. Some fungi live without such reconstruction of their nuclei and propagate themselves by imperfect stages only. Such fungi with incomplete or with incompletely known life cycles have been called *Hyphomycetes* or *Fungi imperfecti* (Dodge C. W. Medical Mycology Mosby 1935). Fungus dermatoses are due to fungi imperfecti. The ability to thrive on keratin distinguishes the few pathogens from the many nonpathogens in general (Gregory: BiolRev 10 303, 1003)

Botanical Classification of Fungi.—Fungi are divided into five orders characterized by the form of their vegetative body or thallus, and by their mode of reproduction, according to Brumpt (Précis de Parasitologie ed 6 Masson et Cie 1949)

- Myxomycetales—thallus without membrane protoplasm amoeboid, reproduction with spores (the slime molds)
- Hyphomycetales—thallus with membrane (mycelium) generally septate nonsexual reproductive bodies conidia present or absent.
- Ascomycetales—mycelium septate reproductive bodies nonsexual *spore formation* in specialized asci ascospores.
- Basidiomycetales—features like those of Ascomycetales but spore formation on specialized organs supporting basidiospores.
- Phycomycetales—mycelium nonseptate reproduction both sexual and nonsexual.

Of interest in this chapter are members only of the Hyphomycetales, Ascomycetales and Phycomycetales.

Hyphomycetales are divided by Langeron (preferred by Brumpt) among:

(1) *Microsiphon types*, with extremely fine and continuous mycelium, including the genera Actinomyces Nocardia and Streptomyces.

(2) *Thallospore types* characterized by the formation of thallospores by constriction of the thallus without particular differentiation subdivided into (*a*) arthrospore genera, in which arthrospores are produced by *fragmentary* disarticulation from the vegetative filament (chlamydospores are a kind of arthrospore) including the genera Cladosporium, Geotrichum, Hormodendrum and Trichosporon (*b*) blastospore genera, in which round or oval globules bud either from the ends of filaments or from the globules themselves including the genera Candida, Geotrichoides Pityrosporum Torula and Torulopsis and (*c*) aleurospore genera in which the thallospores are aleuries forming like chlamydospores united intimately with the mycelium, including the genera Glenospora and (according to Langeron) the dermatophytes Trichophyton Microsporum, Epidermophyton and Achorion.

(3) *Conidiospore types* which form true conidia, subdivided into (a) sporotrichial genera, in which true conidia simple or septate are isolated and inserted directly upon the mycelial filaments, including the genera Rhi ocladium, Sporotrichum and Trichosporon, (b) sporophore genera, in which conidia are carried as ach or as leuries at the extremities of simple or composite filament named sporophores including the genera Alternaria Acremoniella, Acremonium Cephalosporium, Cladosporium, Hormodendrum and Trichosporon and (c) phialides genera, in which the sporophore entire if it i simple or with all it ramifications if it is composite i isolated from the sterile egetative mycelium by a basal partition including the genera Aspergillus Penicillium, Phialophora and Scopulariops s.

(4) *Genera f uncerta n syst matic position* Coccidioides Cryptococcus Histoplasma, Madurella and Malassezia.

ASCOMYCETALES contain highly differentiated fungi with septate mycelium. They produce asques (little sacs) and arious forms of conidia; their pleomorphi m is marked. The asques develop in the ends of certain filament spoken of a fertile and the cells of these differentiate into a number of spores ascospores, ranging from to 12 in number i various species. These ascospores are surrounded by an internal membrane and an external membrane which latter may present a germinative pore Fertile filament along with other filament form a pseudoparenchyma from which spring organs of fructification, or perithecia. The fruiting bodies of some organisms are well developed rounded and closed, as i Aspergillus. The ascomycetic parasites are classed l y Brumpt in the f llowing groups

(1) *Hemiascomycetes* lacking perithecium, the bare asques carried at the en ls of filament i cluding (a) th Endom cetales with well-developed mycelium and asq es disti ct from the filame ts exemplified by the genus Endomyces, and (b) the Saccharomycetales, with rudimentary mycelium and asques resembling other cells, xemplified by the genus Saccharomyces.

( ) *Plectomycetes*, with closed perithecium, including two orders (a) Gymnoascales, in which the perithecial envelope is formed with loose filaments, among which Brumpt places the dermatophyte genera Achorion Ctenomyces Epidermophyton, Microsporum and Trichophyton, admitting them to be aberrant never having been observed to produce asques o ascospores (Langeron put these in the order Hyphomycetales), a d (b) Plectascales, in which the perithecial envelope is compact inclosing the closed perithecium and containing asques not disposed in parallel series, exemplified by the family Aspergillacea, with it genera correctly named Eurotium (Aspergillus) Diplostephanus (Sterigmatocystis) Carpenteles (Penicillium) Microascus (Scopulariopsis) and Allescheria (Scedosporium)

(3) *Pyrenomycet s* characterized by a stroma presenting bottle-shaped perithecia and asques enmeshed in the false parenchyma forming a hymenium at the base of the perithecia exemplified by the genus Piedraia.

PHYCOMYCETALES are characterized by their white o pigmented thallus which present transverse divisions only at the point of formation of reproduct ve organs. Reproduction may be sexual or asexual. When asexual, conidia are formed, are motile and are called zoospores, which are borne in a zoosperangium. When sexual, th equal male a d female elements unite by isogamy t form one zygospore or two unequal sexual elements unite by heterogamy to form one oospore. In the family Chytridiaceae of the suborder of Oomycetes, the mycelium is rudimentary or absent, and the genera include Coccidioides Paracoccidioides and Rhinosporidium.

History of Knowledge of Fungus Diseases.—Hooke i 1677 m de a lens which enabled h m to see filaments of the fungus productive of yellow spot disease in the damask rose Malpighi knew of plants which grow on the plants. In 1720 Michel wrote about many fungi and described Aspergillus. Linnaeus (1752) collected all the facts then known and named many species. The first importa t human pathogen to be seen was observed by Langenbeck (1839) that of thrush, d in the same year Schönlein found that of favus. Charles Robin in 1843 named Langenbeck s organism *Old um albicans*. Lebert named Schönlein's fungus *Oidi m schoenlei* and Remak hanged this to *Achorion*. In 1844 Gruby found fungi f ringw rm and differe tiated the large spore type from the small spore (See Edit. JTropMed 37 377 1934.)

(AD 71 248, 1955) fine illustrations of lassification, diagnosis, mycologic technics and features of fungus infections

Cultivation of Fungi and Ecology of the Diseases They Cause.—Fungi appeared to have been demonstrated by direct examination in over 500 cases of tinea reported on by Lewis et al. (SouthMJ 39 246 1946) yet cultures yielded negative results in some 33% of these The fungi that were grown were *Trichophyton mentagrophytes* in 37% *Trichophyton purpureum* in 26%

and *Epidermophyton inguinale* in 4%. To increase the likelihood of obtaining positive cultures and of obtaining at least some of them free of contaminants, Curry (BJD 61 54, 1949) made multiple miniature cultures using droplets of inoculum on one Petri dish in many small areas. The value of hanging-drop

cultures has been attested by Blumenthal and Snow (J 107 1367 1936) and by Zimerinov and Rafalovich (ADS 61 94 1950) who obtained speedy out growth with mycologically diagnosticable features and described the features of the common pathogens.

Sabouraud's dextrose agar was amended by the addition of penicillin streptomycin and actidione by Georg (ADS 67 3.. 1953) who found these inhibitors of bacterial and saprophytic activity useful in obtaining fungus cultures from heavily contaminated material Success in isolating several pathogens from used shoes and from a shower stall was obtained by using a similar selective isolation medium reported Ajello and Getz (JID 22 17 1954)

The results of inoculations of human pathogens into animals were studied by DeLamater and Benham (JID 1 451 469 1938) Moore (Sci 89 514 1939) induced pathologic lesions of the chick chorioallantois, which provides a satisfactory culture medium for interesting investigations. *Trichophyton mentagrophytes* cultivated in increasing concentrations of pelargonic acid developed a tolerance of 6 times its original tolerance Murphy and Rothman (JID 12 5 1949) discovered. Solutions of the radioactive isotopes P^{32} and I^{131} are not self-sterilizing, for fungi lived in them unaltered as to cultural characters and pathogenicity reported Pearson et al. (JBact 56: 397 1948)

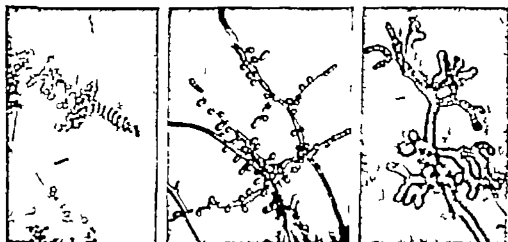

Fig. 557—*Trichophyton mentagrophytes (gypseum)* spirals are characteristic.

Fig. 558—*Trichophyton tonsurans* microconidia may be attached or unattached, singly or in clusters, and are seen in many species of fungi

Fig. 559—*Achorion schoenleini* favic chandeliers are characteristic.

Figs. 557-559 Courtesy of Drs. George M. Lewis and Mary Hopper

Species of *Trichophyton gypseum* were found on farmyard dung as a natural habitat on a farm where the calves had ringworm (Muende and Webb ADS 36 987 1937) while positive cultures were obtained from shoes, which apparently served to reinfect the wearers, by Jamieson and McCrea (ADS 44 837 1941) *Microsporum gypseum* infections (q v) and histoplasmosis (q v) may come from the soil.

In searching soil samples for *H capsulatum* with the membrane filter technic, *M gypseum* was obtained from the earth near a farmhouse in Tennessee by Gordon (JID 20 201 1953)

The incidence of varieties of fungus infections as related to geographic location was considered in a review of many cases occurring in St. Louis, Springfield, Mo., and Oklahoma City by Sisk et al (ADS 68 681 1953)

A study of British Army subjects indicated that when tinea of the body and the feet coexisted in a patient, they were usually due to the same organism the corporeal infection evidently being acquired from the patient's feet (Sanderson and Sloper BJD 65 362, 1953)

Methods of Cultivating Fungi and details of their botanical features are to be found in the treatises listed under general references notably those of Brumpt Conant et al Dodge Jacobson Langeron, Lewis and Hopper Moore et al., and Swartz.

See Weidman (J 60 499, 1928) 15 varieties of dermatophytes found in American cases, 50% of which were due to *T interdigitale*; Emmons (ADS 30 337, 1934) culture cell, bovine horn medium, formation of conidia, Davidson and Gregory (CanadJRes 10 373, 1934) organisms while normally parasitizing host produce hyphae and thallospores, while on detached tissues in vitro produce *highly differentiated spore forms*, a saprophytic phase of possible epidemiologic significance; Conant (ADS 33 665, 1936; 36 781, 1937) cultural studies of genus *Microsporum*; Shaw (JLCM 20 113, 1934; 21 244, 1935), classification and cultural characters, Williams (ADS 36 581, 1937) subsurface growth features of dermatophytes, Peck and Rosenfeld (JID 1 237 1938), pH of cultures and influence on growth, valeric acid inhibition not due to pH Williams (ADS 38 236, 1938), incorporation of dyes in medium to improve culture results; Epstein (JID 1 141, 1938), identity and range of variations of *T interdigitale* and *T gypseum*; Downing et al (NEngJM 222 363, 1940) demonstrable incidence of dermatophytes in suspected dermatoses, direct and cultural methods both necessary, Cornbleet and Meyer (NEngJM 230 604 1944) growth of fungi in sweat, Emmons and Hollander (ADS 52, 257 1945) speciation and mutation Duncan (BMJ 2 715, 1945) incidence of all types of *fungus disease in Great Britain*; *Lewis and James* (ADS 53 481, 1946) at pH 10.6 saprophytes are mainly inhibited but dermatophytes are not; Weidman and Glass (ADS 57 300, 1948) technic of demonstration by scrapings, Kimerinov and Rafalovich (BJD 60 238 1948) hanging-drop culture technic and features of common fungi so grown Nomenclature of Fungi Pathogenic to Man and Animals (Med. Res. Mycotic Diseases are by no means limited to the skin but their conspicuous manifestations are often cutaneous. See Lewis and Hopper (Introduction to Medical Mycology ed 3 1948)

Dermatomycosis includes all cutaneous infections due to fungi.
Dermatophytosis is applicable to superficial infections.
Epidermophytosis implies infection with an *Epidermophyton*.
***Trichophytosis** is similarly limited to parasitism with a Trichophyton.*

Bilateral, superficial, circumscribed, erythematous and scaly eruptions of the upper parts of the inner aspects of the thigh are commonly caused by *Epidermophyton cruris*. One may often correctly suspect that an infection of the scalp is caused by *Microsporum canis* from the history of contact with an infected animal, the short duration, the tendency to heal spontaneously and the inflammatory character of the lesion. Infection of the skin due to *Candida albicans* and the lesions of blastomycosis, actinomycosis and sporotrichosis are usually expressed clinically in fairly characteristic ways. One may often recognize a *Trichophyton purpureum* infection from clinical inspection alone (Lewis and Hopper ADS 35: 461 1937) However the diseases produced by closely related organisms may not be distinguishable clinically It is practical to discuss dermatomycoses according to their sites.

Human Pathogens, with their identifying features (Lewis and Hopper)

Direct examination in these descriptions, usually refers to the microscopic appearance of the organisms in a specimen mounted in 10% aqueous solution of potassium hydroxide.

Cultural characteristics are as seen after isolation on a solid medium containing 4% crude American dextrose 1% Fairchild's peptone and 1.8% agar

Culture mount refers to the microscopic appearance of a cultural growth as seen in a hanging-drop preparation, in a Henrici slide culture, or in a direct mount from a culture of material in 10% potassium hydroxide solution The last type of mount is not advisable for routine use because so prepared, the arrangement of fungus elements cannot be studied satisfactorily

Microsporum audouini (commonly causative of tinea capitis in children)

Direct Examination.—Short, broken-off hairs are extracted for examination. The spores are round, small, and grouped to form a mosaic sheath around the infected hairs There is usually no tendency to the formation of chains.

Cultural Characteristics—The colony is slow-growing, consisting of close-matted, velvety aerial mycelium, light gray to brown in the center with radiating furrows. The reverse of the colony is reddish brown to orange in color

Culture Mount—Fuseaux and microconidia are occasionally seen Chlamydospores and pectinate bodies are frequent

Microsporum canis (M lanosum) (commonly causative of tinea capitis in children)

Direct Examination—Hair infected with *M canis* cannot be distinguished from hair infected with *M audouini* In scrapings from lesion of tinea circinata, segmented mycelium may be noted

Cultural Characteristics—The growth appears first as a downy fluff, and it develops fairly rapidly After 1 week the colony is woolly and the aerial material is abundant The color is buff tan This development of yellow pigment on the undersurface of the colony is characteristic Grooves may be radial or concentric Pleomorphism begins after 4 or 5 weeks. The appearance under the filtered ultraviolet rays (Wood light) is distinctly lavender blue or shell pink toward the center of the colony the colors being bright and clear

Culture Mount—The feature of this fungus is the presence of large numbers of fuseaux of the tapering sort. Microconidia and some other forms may also be noted.

Microsporum gypseum (M fulvum) (Tinea corporis and capitis, often kerion)

Direct Examination—A hair infected with *M fulvum* may resemble in appearance hair infected with any other *Microsporum* Sometimes spores in linear arrangement may be observed

Cultural Characteristics.—The growth is flat, floury and cinnamon brown. A central umbo may be present Concentric furrows sometimes appear Pleomorphism is usually manifest after several weeks The reverse of the colony is reddish-brown to orange in color

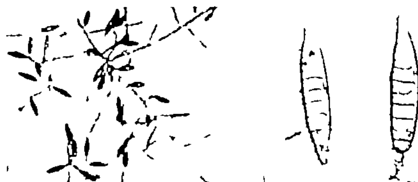
Culture Mount.—Numerous fuseaux are present. Racquet mycelium, nodular organs, and small round spores may also be seen.

Trichophyton sulfureum (tees rans) (nonfluorescent tinea capitis in adults)

Cultural Characteristics.—At first, the colony is velvety with a central red nodule the rest of the culture showing a delicate primrose color. Later it becomes powdery, folded with a small central crater and becomes sulfur yellow in color.

Trichophyton (Achorion) schoenleini (Favus)

Direct Examination.—Large spores in chains are noted in the substance of the hair. The presence of air bubbles is almost of diagnostic significance. Sporulated mycelium will be found in large amounts in scutula but such mycelia are few in number in infected nails or in superficial lesions of the smooth skin.



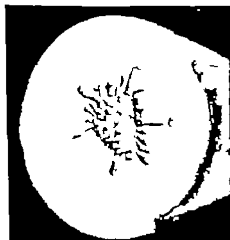


Fig. 590.—*M. gypseum* macroconidia, or fuseaux, attached to the hyphae indicate either *M. gypseum* or *M. canis.*

Fig. 591.—*M. canis*: detached macroconidia, showing septations. (Drs. George M. Lewis and Mary Hopper.)

Figs. 592 and 593.—*Microsporum gypseum* giant colony and culture mount stained with lactophenol-cotton blue. (Dr. Emanuel Muskatblit.)

Cultural Characteristics.—After 3 or 4 weeks the growth is smooth, compact and waxy. The surface shows numerous folds. Pleomorphism is rare. The submergence of the colony usually results in cracking of the agar.

Culture Mount.—Favic chandeliers may be noted. Chlamydospores in large numbers may also be observed.

Trichophyton mentagrophytes (gypseum) (Tinea especially of feet and nails)

Direct Examination.—In follicular infection, small, round spores in chains may be found external to the hair. In scales, macerated tissue, or in nail scrapings, chains of spores or segmented mycelium with little branching will be noted.

Cultural Characteristics.—There are 4 types of growth which Lewis and Hopper believe are closely related genetically.

1. The usual type. This begins as a white, fluffy growth. After about 2 weeks, the surface becomes velvety and buff-colored. There is usually a boss at the center and a few irregular folds.

2. *The granular variety.* The surface is powdery and is light buff or maize yellow in color. Fluffy changes develop with age.

3. *The T. interdigitale type.* This begins as a downy projection, developing into a white, fluffy, diffuse growth covering an agar slant within 2 weeks.

4. *The T. ... type.* This is white and fluffy at first, later becoming compact. Surface irregularities are present.

Fig. 594.—*T. schoenlei*, giant colony. (Dr. D. Muskatblit.)
Fig. 595.—*T. concentricum*, colony in test tube. (Dr. E. Muskatblit.)

Fig. 596.—*T. mentagrophytes*, slide culture, showing microconidia and fuseaux. (Dr. D. Muskatblit.)

Fig. 597.—*T. mentagrophytes*, slide culture, showing microconidia and spirals. (Dr. D. Muskatblit.)

Culture Mount.—

1. The usual type. Spirals may be seen. Small numbers of fuseaux and nodular organs, pectinate bodies, racquet mycelium, and chlamydospores may be noted. Microconidia are present.

2. The granular type. Numerous fuseaux are present and dense masses of microconidia are to be seen. Few spirals will be seen. Chlamydospores and racquet mycelium may be found in the subsurface growth.

3. The T. interdigitale and T. ... types. A large number of filaments and a few clusters of microconidia are observed. Nodular organs and racquet mycelium may be found. Spirals and fuseaux are usually absent.

Trichophyton rubrum (purpureum) (Tinea)

Direct Examination.—There is nothing characteristic in the microscopic appearance of the fungus in scrapings. While the amount of fungus material may be sparse, large numbers of organisms have been noted in an occasional specimen. The mycelium is about the same size as that of *T. gypseum* being 3 or 4 microns in diameter.

Cultures.—On dextrose agar primary growth at first is fluffy, pure white and hemispherical. The edge of the colony becomes less fluffy and at times is granular. The under surface of the colony shows the typical rose-purple color which gradually spreads to the edge of the colony and may be noted in varying degrees throughout the colony. Pleomorphism occurs eventually. Under filtered ultra violet rays (Wood light) the cultures show colors which are bright but hazy. The central half of the colony is mauve, the remainder is a light, soft blue-violet. There are many sterile (septate) hyphae and many microconidia in thyrses and in grapelike clusters in culture mount. Fuseaux are few. Chlamydospores develop in older growths. Inoculation of animals is occasionally successful. The index of sensitization is low.

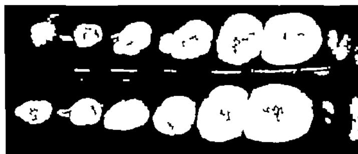

Fig 398.—*Candida albicans* cultures. (Dr. L. Moskatblit.)

Fig 399.—*C. albicans* culture mount, lactophenol-cotton blue stain, showing hyphae and blastospores. (Dr. L. Moskatblit.)

Fig 400.—*C. albicans* culture mount, showing hyphae, blastospores and chlamydospores. (Dr. L. Moskatblit.)

Trichophyton violaceum (Tinea)

Direct Examination.—Large spores in linear arrangement may be seen invading the shaft of an infected hair or in scales or nail tissue.

Cultural Characteristics.—The colony is compact, smooth, and shiny, and it has a typical deep violet color. The surface shows convolutions. Pleomorphism is rare.

Culture Mount.—The mycelium shows irregular and oddly shaped branches. No free or attached spores are developed. Chlamydospores are seen in older colonies.

Trichophyton tonsurans (crateriforme) (Tinea)

Direct Examination.—Large spores in chains are seen in the shaft of the infected hair usually in large numbers.

Cultural Characteristics.—The growth is compact, creamy white, and velvety. The central portion is broken and depressed, being yellow. Pleomorphism is rare.

Culture Mount.—Conidia in clusters (grapes) or on stalks (thyrses) are to be noted. Chlamydospores are common.

Candida (Monilia) albicans (Moniliasis)

Colonies originate by bipolar sprouting of blastospores and the pseudomycelium is composed of ellipsoidal cells. The colonies are creamy, thick and convex. *Candida albicans* is a "yeastlike" fungus, *differing from a true yeast in that a pseudomycelium is formed, whereas* true yeasts reproduce by budding, and the daughter cells do not adhere to the mother cell.

Cultures.—The growth is smooth, pasty and cream-colored, and it grows rapidly on dextrose medium. The central portion later appears honeycombed. On corn-meal agar mycelium, characteristic spore clusters, and chlamydospores develop. *Ascospores are not formed.*

Agglutination Reaction.—The organism agglutinates in a serum prepared against *Candida albicans* (Benham, J.Infect.D. 49: 183, 1931).

Animal Inoculation.—Benham (1931) found that the intravenous injection of 1 cc. of a 1:1000 suspension of a live culture killed a rabbit in 4 or 5 days. Abscesses in which *Candida albicans* may be recovered develop in the kidneys and other organs.

Differential Diagnosis.—Cryptococci do not develop mycelium, and other species of *Candida* may be distinguished from *Candida albicans* by the absence of chlamydospores when grown on corn-meal agar. *Mycoderma* may usually be recognized by its growth appearance in culture; a culture mount reveals arthrospores. *Endomyces* and *Saccharomyces* form ascospores; the former also develops mycelium.

Epidermophyton floccosum (Inguinale)

Direct Examination.—The scales contain chains of spores in which the elements tend to be flattened. The amount of fungus material is often plentiful.

Cultural Characteristics.—After 2 to 3 weeks the growth is apparent. It develops a velvety surface with irregular folds and is characteristically grayish olive drab or greenish drab in color. Pleomorphism develops early.

Culture Mount.—Fuseaux of the blunt-end variety are to be seen in groups. Chlamydospores and racquet mycelium may also be observed.

Fig. 401.—*C. albicans* in KOH preparation of a scale, ×770. (Dr. F. Muskatblit.)

Malassezia furfur (Microsporum furfur) (Tinea versicolor)

Direct Examination.—Fungus elements are usually present in profusion, and the picture is characteristic. They consist of round or ovoid, refractile spores in clusters. Mycelia, fairly long but fragile, occur in considerable numbers.

Culture.—Doubtfully successful. See Tinea versicolor.

Nocardia minutissima (Actinomyces minutissimus) (Erythrasma)

Direct Examination.—On examination with the high power of the microscope fine threads may be noted. If the oil immersion lens is used, the threads are visible, being *long*, tortuous, and interlacing. A few spores may be seen.

Cultural Characteristics.—There is not general agreement that this microorganism has been cultured.

Trichophyton concentricum (Endodermophyton tropicale) (Tinea imbricata)

Direct Examination.—Numerous segmented hyphae are noted.

Cultural Characteristic.—The growth is compact and gray to brown in color, and it shows an uneven surface. Superficial resemblance to *A. kerion schoenleini*.

Culture Mount.—Vegetative forms may be noted. Microconidia are not present.

Actinomyces bovis (Actinomycosis)

Direct Examination.—This is the most important laboratory investigation of a patient *suspected of infection with this microorganism.* The granules are seen to consist of one or more colonies in which in the mid-zone there is a mass of twisted mycelium, and at the periphery a palisaded arrangement of hyphae forming a fringe. These latter organs are enlarged at one end and are striated. The ray fungus is gram-positive. The central mycelium takes the basic dye and the periphery alone takes the acidic dye.

Cultural Characteristics.—There is considerable difficulty in obtaining a cultural growth, and it usually dies quickly. The colonies are pasty but of variable consistency and configuration.

Culture Mount.—Sterile mycelium without characteristic spore forms.

Monosporium apiospermum (Maduromycosis)

Cultural Characteristics.—Rapidly growing colony produces a white, cottony aerial mycelium which later turns gray or becomes buff to brown in color

Cultural Mount.—Ovoid and pyriform conidia, 3 to 10 microns long by 5 t 7 microns wide re produced singly t the ends of long conidiophores or from the ides of the mycelium on short conidiophores.

Figs. 402 and 403.—*F. floccosum* culture mount, lactophenol-cotton blue stain. Fig. 402 shows fuseaux. Fig. 403 shows chlamydospores. (Dr E. Muskatblit.)

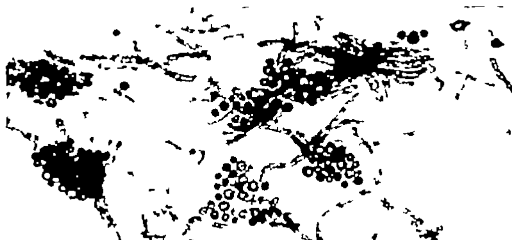

Fig. 404.—*M l vesse furfur* from tinea ersicolor polychrome methylene blue stain. ×770 (Dr E. Muskatblit.)

Rhinocladium (porotrich m) schenckii (Sporotrichosis)

Direct Examination.—Cigar-shaped cells may be noted, but fu gus material is usually absent.

Cultural Characteristics.—After 2 weeks, a moist growth is noted which is light brown in color but with age it becomes dark brown. The central portion shows irregula foldings. White excrescences form on the surface

Culture Mount.—Pea-shaped conidia re situated irregularly along the mycelium and rranged also as terminal triads and tetrads

Blastomyces dermatitidis (North American Blastomycosis of Gilchrist).

Direct examination.—Singly budding, thick w lled, round or oval, granula cells, 8 to 20 *microns in diameter* to be found.

Cultural Characteristics.—The central portion of the colony is gray and smooth becoming white and filamentous. A peripheral moist zone is usually present. Yeastlike growths are obtained on blood agar.

Culture Mount.—Microconidia, chlamydospores, and racquet mycelium may be noted. Budding cells may be obtained from the yeastlike growth.

Coccidioides immitis (Blastomycosis of Rixford and Gilchrist)

Direct Examination.—The microorganism is a sphere with a doubly contoured capsule from 5 to 60 microns in diameter and it contains 4 t 20 endospores.

Cultural Characteristics.—The growth is white and filamentous a brownish shade develops with age.

Culture Mounts.—Septate mycelium is profuse. Arthrospores and chlamydospores may be distinguished.

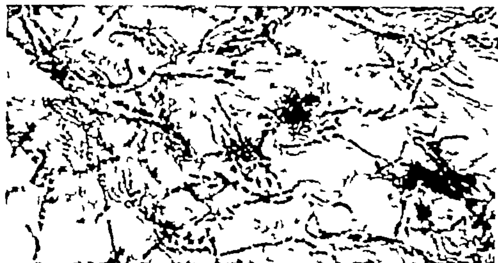

Fig. 605.—*Nocardia minutissima* from erythrasma, polychrome methylene blue stain, ×770. (Dr. L. Muskatblit.)

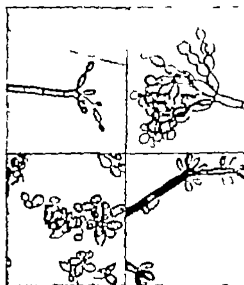

Fig. 606.—*Hormodendrum pedrosoi.* Above, Dendroid spore heads from corn-meal agar slide culture. *Lower left,* spores dissociated from conidiophore. *Lower right,* acrotheca type of sporulation. (Emmons, Hailey and Hailey J 116 25, 1941.)

Cryptococcus neoformans (Torula histolytica) (Torulosis)

Direct Examination.—Various-sized budding cells will be seen. A wet India-ink preparation reveals wide capsul

Cultural Characteristics.—The colony is moist and cream-colored, later changing to yellow and then to brown.

Culture Mount.—Round or ov l various-sized budding cells (India ink technic); no mycelium or ascospores.

Paracoccidioides brasiliensis (South American Blastomycosis)

Direct Examination.—Single and multiple budding, thick-walled yeastlike cells, 10 to 60 micron in diameter re found.

Cultural Characteristics.—Slow-growing, heaped, membranous or wrinkled colony with a short nap of white aerial mycelium which tends to become brown with age.

Culture Mount.—A few sessile oval to round conidia may be seen in culture at room temperature. Single and multiple budding, yeastlike cells may be seen in culture at 37° C.

Hormodendron pedrosoi (Chromomycosis)

Direct Examination.—So-called sclerotic cells of Medlar are present. These may be septate and are usually in groups. Small septate filaments may also be noted.

Cultural Characteristics.—The growth is compact, limited, and felty. Concentric zones may be colored brownish olive, olive black, olive gray and gray.

Culture Mount.—Olive brown spores are borne on conidiophores. Disjunctors are also usually present.

Phialophora verrucosa (Chromomycosis)

Direct Examination.—Single or clustered, round, thick walled, dark brown bodies which multiply by splitting, not by budding, not distinguishable from *Hormodendrum pedrosoi*.

Cultural Characteristics.—Slow growing colonies dark brown in color are found.

Cultural Mount.—Conidia arising from cups at the tip of flask-shaped conidiophores borne terminally or laterally singly or in groups, on the aerial mycelium.

Histoplasma capsulatum (Histoplasmosis)

Direct Examination.—The specimen, blood, urine, sputum or material aspirated from lymph node, marrow or spleen, should be mounted both unstained and stained by Giemsa method. The microorganisms, 2 to 4 μ in diameter are round, oval or yeastlike, usually budding, sometimes to be found in endothelial leukocytes.

Cultural Characteristics.—On dextrose agar incubated at room temperature, the colony is brown and glabrous, with an irregular surface, grows slowly and assumes a white cottony appearance with age, especially if the medium becomes dry.

Culture Mount.—Septate, branching hyphae with large, thick-walled chlamydospores showing tuberculate sculpturing of the outer wall, are found. These chlamydospores are best demonstrated in the mycelial cultures which develop on blood agar incubated in sealed tubes at 37° C. They best distinguish the organism from *B. dermatitidis*.

Rhinosporidium seeberi (Rhinosporidiosis)

Direct Examination.—Round to ovoid spores, 7 to 9 μ in diameter and spore-filled sporangia are found.

Pityrosporum ovale (? Seborrheic dermatitis, q. v.)

Direct Examination.—Flask-shaped cells of 2 to 10 μ, with or without budding, are seen.

Demonstration of Fungi.—One extracts a whitish hair stump or tears off the cap of a blister and immerses this in 10% aqueous potassium hydroxide. After maceration the bit is crushed under the cover slip and dim light is used in examination. Experience is necessary for distinguishing hyphae and spores from droplets of fat, epithelial cells, and detritus.

If 5% sodium lauryl sulfate is used as a clearing agent, instead of KOH, the material after direct examination may be used successfully for cultures (Mandel et al.: JID 18: 61, 1952).

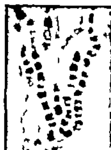
Fungi may be stained in paraffin sections of tissues, fixed by any fixative, by means of the Hotchkiss-McManus periodic acid-Schiff staining technic. As performed at the University of Kansas Medical Center this involves the following steps.

(1) Deparaffinize to water. (2) Immerse in 0.5% freshly prepared periodic acid solution for 5 minutes. (3) Rinse with distilled water. (4) Immerse in Schiff's reagent (water-clear, not pink) for 15 minutes. (5) Rinse 3 times for 2 minutes each time in sulfurous acid. (6) Wash with running water for 3 to 5 minutes. (7) Counterstain lightly with alum hematoxylin for 20 to 30 seconds. (8) Rinse with tap water, dehydrate through 95% and absolute alcohol, clear in xylol, and mount.

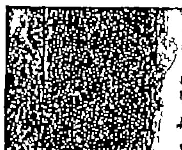
Preparation of Schiff reagent. Weigh 1.0 Gm. basic fuchsin and 1.0 Gm. anhydrous sodium metabisulfite. Boil 200 cc. distilled water, add the fuchsin while stirring. Cool to 50° C., filter, then add 20 cc. 1N HCl. Cool to 25° C., then add the sodium metabisulfite. Ripen for 2 days in the dark at room temperature until straw color, filter through activated charcoal to remove color. Store in refrigerator.

Preparation of sulfurous acid. Measure 6.0 cc. of 10% aqueous solution of sodium metabisulfite, 5.0 cc. 1N HCl, and 100 cc. distilled water. Mix, stopper tightly, store in refrigerator. This is good for only 1 week.

Crystalline periodic acid may be obtained from G. F. Smith Chemical Co., Columbus, Ohio.



The Hotchkiss-McManus Schiff stain was modified for applicability to scales and hairs by Moskowitz et al. (ADS 67: 507, 1953) as follows: (1) dry the material in a film of albumen-glycerin mixture on a slide for a few hours at room temperature; (2) immerse in 95% alcohol for 2 minutes, followed by (3) 5% aqueous periodic acid for 7 minutes; (4) rinse in water 2 minutes; (5) stain in Schiff reagent 7 minutes; (6) rinse in tap water 2 minutes; (7) dehydrate through 95% alcohol, then absolute alcohol, then xylol, for 2 minutes each, and mount.



Periodic acid serves to transform the polysaccharides of the cell wall of the fungus into polyaldehydes. Where these aldehydes are present, there develops a deep, red color in the presence of leukofuchsin provided by the Schiff aldehyde reagent. Fungus elements so stained stand out sharply against a pale pink or colorless background.

Fungi may be stained with cotton blue dye by heating the scales on a slide in a drop of the following mixture (Swartz and Conant: ADS 33: 291, 1936): lactic acid, 1.0; phenol crystals, 1.0; glycerol, 2.0; cotton blue (C4B Poirrier), 0.5%; water, 1.0.

Kligman (ADS 63: 25, 1951) suggested the application of 10% potassium hydroxide to the skin before scraping, for then it becomes easy to demonstrate the organisms. Kligman et al. (J 146: 1563, 1951) described improved technic for diagnosing ringworm infections, using basic fuchsin rather than KOH.

Berberian (ADS 36: 1171, 1937) used this staining technic. Cover scales in small bits with 50% glacial acetic acid in water and dry in incubator causing adherence of scales to slide; defat by flooding with ether several times, with acetone several times, with alcohol in diminishing concentrations; stain in Martinotti's toluidine blue; wash in water; differentiate with 0.5% acetic acid; dehydrate in absolute acetone; pass through xylene; mount in Euparal or balsam.

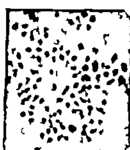


Fig. 607.—*Trich phyton* stained mycelium. (Dr B. B. Beeson.)
Fig. 608.—Tinea capitis, endothrix fungi in hair (Dr Stuart W y)
Fig 609.—*M* *and* ni, from tinea capitis. (Dr B. B Beeson.)

Figs 610 and 611.—Tine orga isms in KOH preparations of scales from dermatomycotic lesions. (Dr Emanuel Muskatblit)

Fig. 612.—*T rubrum* in scale from tinea cruris, stained with polychrome methylene blue ×850 (Dr E. Muskatblit)

An excellent method of staining fungi in scales or hairs is that of Muskatblit (ADS 59 1930 1949): Scales are broken into small fragment hairs are intact but separated from one another Raw egg white is applied to slide and the material transferred to the sticky surface while wet Dry in air or over a flame Defat and fix with Carnoy fluid (glacial acetic acid 10 parts, chloroform 30 and absolute alcohol 60) for five minutes; pour off fluid and dry Stain with polychrome methylene blue for 5 minutes, pour off and wash in water for 1 or minutes. Decolorize with 1% aqueous acetic acid for about 1 minute; this step is delicate and overexposure to acid will decolorize everything Wash with water minutes then absolute alcohol 5 minutes, and follow with xylol and balsam or Clarite

Hairs may be examined as follows The diseased stump is put on a slide, and washed with ether to defat It is then treated with aniline gentian violet solution for 5 minutes, blotted, treated with potassium iodide solution from 1 to 5 minutes, blotted, treated with aniline oil, then a mixture of equal parts of aniline oil and dilute hydrochloric acid to decolorize finally with aniline oil followed by xylol; then it is mounted in balsam.

See Keeteven (IJD 49: 500 1937) instead of KOH use 0.5% trinitrophenol in equal parts of phenol and oil of cloves; Bernhardt (ADS 48 532, 1943) permanent stained preparations, technic Wilson (ADS 52 207, 1945) permanent slides of cultures; Kligman and Mescon (JBact 60 415, 1950), modified Hotchkiss-McManus stain technic for tissues Hoffmann (DZtsch 76: 370 1936) staining of M. in tissue as Ajello (J 146 1581 1951), demonstration technics; Sharvill (BJD 64 329 1952) periodic acid Schiff stain Kligman et al. (AmJClinPath 21 89, 1951) Hotchkiss-McManus technic; Mescon et al. (Cancer 13 310, 1953) fungi in human neoplasms are saprophytes; Muskatblit et al (ADS 67 307 1953), Hotchkiss-McManus technic; Taschdjian and Muskatblit (ADS 68 570 1953) staining of KOH-cleared material; Lewis and Hopper (AD 7 302, 1936) histologic sections of colonies.

Mosaic Fungus, so called is perhaps not fungus at all, for it dissolves in ether absolute alcohol and phenol. It seems to be a degeneration product (Dowding and Orr ADS 33 865 1936) for mosaic material and *T gypseum* in transition forms appear in contiguity in mycotic scales. During healing of tinea, mosaic fungus increases and living fungus diminishes (Swartz and Conant ADS 33 291, 1936) The mosaic material after prolonged clearing in strong KOH appears to consist of notched crystals of cholesterol (Davidson and Gregory J 105 1262, 1935) It may appertain to imperfect keratinization (Cornbleet et al ADS 48 282, 1943) Finding it incapable of being cultivated and also soluble in various fat solvents Gotz (AfDuS 187 61 1948 188 104 1949) adjudged the mosaic substance to be a lipid present in various amounts normally in the palms and soles. Dowding (ADS 66: 470 1952) denied however that the mosaic substance is either cholesterol or something alive but thought it the product of the fungus, an extracellular deposit resulting from the dermatophyte It can be found on all normal feet sometimes on hands, and its presence is not necessarily secondary to the presence of mycotic infection stated Götz (ADS 70 119 1954)

Fluorescence in Demonstration of Fungous Infections.—Wood's light is ultraviolet light of wave lengths close to 3650 A.U which pass a Wood's filter made of glass containing nickel oxide. Exposed to this light in a darkroom the stumps of hairs infected with *M canis* and *M audouini* can quickly be differentiated by their bright, clear bluish-green fluorescence. Since these pathogens are the usual ones the test is practical (Lewis and Hopper ADS 34 681 1936) It affords an invaluable means for surveying numbers of children so as rapidly to identify the infected ones.

The fluorescent material in hairs infected by microspora can be extracted with hot water and is quenched by potassium iodide in 10% concentration, so that previous application of iodine may hide an infection without influencing the viability of the organisms (Fischer JID 13 139 1949) The fluorescent substance was extracted by boiling in water from which it dried as a white powder reported Robinson et al. (ADS 68: 129 311, 1953) The substance is destroyed by strong acids and bases. Its maximum fluorescence at pH 6.5 It is reversibly oxydizable. It shows a wide distinct band on spectrography maximum at 490° A.U It does not appear when fungi are grown on artificial media, even if various amino acids are added. Its presence is not proof that the fungus is viable for hairs long removed from the scalp and containing only nonviable fungi still manifest fluorescence.

TINEA

Symptoms.— Tinea (ringworm) is infection of the skin, hair or nails produced by various fungi Such infections are common and are at times serious. The ability of dermatophytes to grow on keratin forms the basis of their parasitic relationship with the human host. Sensitivity to dermato-

phytin in superficial mycotic infections, as well as in deep ones, is almost constantly present. There are analogies between the immunologic biology of dermatomycosis and of tuberculosis. Infectious diseases in general are characterized by the appearance of a primary lesion at the site of inoculation and

Fig 613.—Tinea corporis, due to *M can* the sort of "ringworm a hild is likely to contract from an infected pet

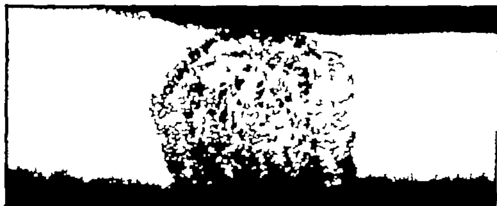

Fig. 614—Tinea of forearm. (Dr Robert N Andrad)

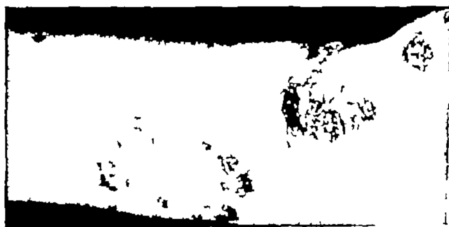

Fig. 615.—Tinea of forearm and wrist due t *T ment grophytes* (D J Lamb Calloway)

by the appearance of lesions of the skin under allergic conditions. Such latter dermatoses comprise the ids. Allergy is the sine qua non of their existence During the existence of a trichophytid the trichophytin reaction is positive

Environmental circumstances influence the equilibrium of the parasitic relationship so that the fungus may thrive or the tissues prevail. *Moisture*

warmth darkness and traumatic or chemical irritation favor the fungus. Ventilation coolness and dryness favor the tissues, as, of course do débride ment (washing) nonirritating antiparasitic chemicals and avoidance of in jury Clinical disease is often a composite representative of fungus infection and in addition secondary infection focal bacterial infection chemical damage from contactants, including medicinal substances, or the nutritional aberra tions which promote lichenification (p 870)

Clinical Classification.—In general clinical infections with fungi may be considered individually with clinical satisfaction without regard to systematic botany Pathogenic fungi causative of tinea damage only the skin even when they have been injected intravenously As a rule they damage the skin only superficially Nevertheless, their activity results in humoral alteration, and tinea, like many other dermatoses is by no means a purely cutaneous phenom enon.

Fig. 416.—Tinea corporis.

Fig. 417.—Tinea of axilla.

Clinical Forms.—One sees lesions of the following forms vesicular scaling macular macerated, fissured, papular callous, keratotic and lichenified (White ADS 15 387 1927) The nails are often infected and they may serve as a reservoir of reinfection difficult to eliminate.

Animal and Human Types of Tinea.—Fungi which are pathogenic principally to animals are likely to cause in animals lesions which are not very deep and inflammatory disease which is readily transmissible from animal t animal, lesions which contain numerous organisms easy to demonstrat lesions which are difficult to cure The same organisms in the human being may produce deeper and more inflammatory lesions, strong reactivity to trichophytin disease which is not readily transmissible, lesions in which organisms are few and demonstrable with difficulty and lesions which tend toward spontaneous cure or are comparatively easy to cure. Fungi which are pathogenic principally to human beings tend to cause chronic resistant, noninflammatory disease in human beings, and in animals to cause deeply inflammatory lesions. The distinction between animal and human infections is onl b rough analogy

Tinea Corporis.—Tinea of the glabrous skin usually begins with flattened, reddish papules. The lesions tend to spread peripherally and to heal in the center so that annular patches of dermatitis evolve In dermatophytosis, a state of resistance to inoculation with more of the same organism exists in the healed zone although areas outside the margins of these patches are vul nerable. The central portion is pinkish and has a superficially scaling surface. The margin is sharply defined, slightly elevated, actively inflamed, more or less scaly and often vesicular in places. The lesions gradually enlarge. Occasionally they coalesce, giving rise to arcuate figures. They may disappear spontaneously leaving no trace The tendency to undergo central involution

is lacking in some cases, so that the eruption may consist of solid reddish scurfy oval patches. Concentric rings of activity are common. The lesions range in number from a few to a dozen or more. Itching or burning of slight degree may be present, but symptoms are seldom prominent. *The sites of predilection* are the uncovered surfaces. Palms are sometimes attacked and tinea often affects soles and interdigital skin, fingers and hands being involved secondarily. Mucous membranes escape. Perianal skin is often involved and tinea constitutes *one cause of pruritus ani. Mycotic vulvovaginitis is usually monilial.*

Diagnostic differentiation from pityriasis rosea, seborrheic dermatitis, and psoriasis rests on demonstration of fungi in scrapings and cultures. In pityriasis rosea *the eruption is usually confined to the trunk and commonly* begins with the appearance of a herald spot; the lesions are numerous, develop quickly and pursue a relatively rapid course. In seborrheic dermatitis the sternal and interscapular regions generally are affected after the scalp, and

Fig. 618.—Tinea imbricata, Fiji case. (Dr. Harry M. Robinson, Jr.)

the lesions while often circinate are usually irregular. The scales are unctuous, and vesicles are not present except when secondary infection exists. The lesions in psoriasis at times are annular, but they are usually dry and never acutely inflammatory; on scraping off the superficial scales the typical bleeding points are exposed, and the extensor distribution of the eruption is more or less characteristic. See also Infectious eczematoid dermatitis.

Local deep tineal infection may be mistaken for carbuncle, from which it differs in being less acute and far less painful. Diagnosis should be positive by demonstration of fungi, rather than being made by exclusion.

Tender age does not exclude the possibility of mycotic infection. Cases of tinea due to *M. canis, M. gypseum, E. floccosum* and *T. rubrum* occurring in children ranging from 3 weeks to 12 months of age were reported and reviewed by King et al. (ADS 68: 664, 1953).

Tinea Imbricata (Tokelau Ringworm) is a variety of tinea corporis seen in warm, moist climates, due to various fungi of the genus *Endodermophyton*. Infection with *E. concentricum* is characterized by the widespread occurrence of scaly patches which often assume a concentric arrangement. The eruption may become universal and capable of being mistaken for ichthyosis. The

face scalp palms, soles and nails usually escape The health is unaffected Chronicity of the disease is notable It responds only stubbornly even to appropriate treatment and relapses are common. Castellani s fuchsin paint is fairly satisfactory Chrysarobin ointment may be useful.

See Castellani (BJD 25; 377 1913; JTropM 37 263, 1934) McCarthy (J 123: 449, 1943) Gomes (ADS 53 242, 1946); Sharville (BJD 64: 373 1952) *T concentricum* and *T rubrum* in same lesions; Poland (BJD 64: 378, 1952) wide distribution in Malaya

Tinea Cruris (Eczema Marginatum) —Tinea in the region of the groin is a clinical variety of dermatomycosis which may occur also in the axillae or beneath pendulous breasts. It is usually due to *Epidermophyton floccosum* (Wende and Collins ADS 3 1, 1921) but any of several species of fungi may infect these regions. Clinical distinctions independent of cultural identification are unsure I often find *T purpureum*

The infection at first may resemble intertrigo, that is, monilial or streptococcic dermatitis but usually the primary eruption consists of a few superficial, circinate patches which sooner or later coalesce to form confluent symmetric batwing-shaped inflammatory areas which have sharply defined, elevated borders. The margins may be straight, but usually they present a festooned appearance with more or less infiltration. The patches are generally located on the inner surfaces of the thighs, contiguous with the scrotum or labia and the intergluteal regions. In women the mucosa of the vulva is sometimes involved. In either sex the umbilical region may be affected

Extensions along the sagittal line anteriorly and posteriorly give rise respectively to involvement of the mons veneris and the perianal region and intergluteal fold. About the anus and over the coccyx fissuring is particularly likely to occur and distressing and chronic pruritus results. Marginal activity with central clearing and peripheral extension is the conspicuous feature when the lesions extend widely over the thighs and buttocks, and concentric circles of active disease are sometimes seen, as in tinea corporis.

The lesions of tinea cruris are usually moist at first, and they readily become macerated, secondarily infected and painful as well as merely itchy As they heal they become dry scaly and less edematous. Recurrences are common, for the eradication of all fungi is almost impossible while friction, sweating warm weather tight clothing and obesity combine to favor luxuriation of the organism

Tinea of the pedal interdigital spaces and of the nails commonly serves as the source of reinfection, and the feet, usually requiring treatment, must always be examined in cases of tinea cruris. Crural dermatomycosis due to Blastomyces is vegetative and papillomatous in contrast with the macular disease produced by the ordinary organisms of tinea

Tinea of the crotch may be confused with contact dermatitis, seborrheic dermatitis or erythrasma. The location and character of the eruption, its history and the presence of satellite lesions serve for recognition. In monilial vulvovaginitis, shallow pustules and mycotic dermatitis of the near by regions are likely to be present. Tinea of the crotch in women calls for an examination of the vaginal secretions. In erythrasma the patches are superficial and only slightly inflammatory and the causative organism *Actinomyces minutissimus* is readily differentiated by examination of scrapings from *Epidermophyton inguinale*

Tinea of the Hands and Feet.—*Epidermophyton Trichophyton Candida albicans* and other organisms are active here. Tinea of the hands often depends on the existence of tinea of the feet or nails. Dermatophytids of the hands are more common than actually demonstrable tineal infection, and many a case of tinealike pompholyx can be cured by applying treatment to the feet or to some other focus without particular regard to the hands. Streptococcic and staphylococcic dermatitis of the hands, recalcitrant perhaps because of focal infection, is likely to be the correct diagnosis when the hands alone are painfully inflamed in the absence of lesions of the feet (Mitchell: ADS 5 174 1922; 10: 659 1929 J 140 541 1951) The differentiation between mycotic

and coccic infections of the extremities is important, for the treatment of the one is not effective for the other

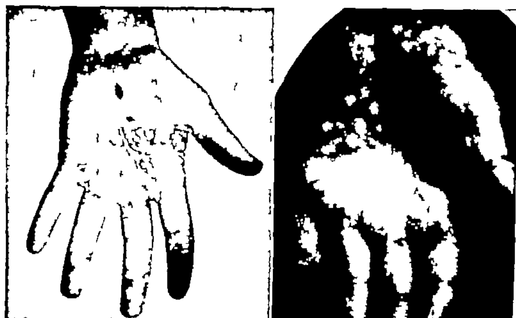

Fig. 426—Tinea of the volar skin. (Dr Fred Weidman.)
Fig. 427—Dermatophytid, vesicular due to active tinea of the feet.

Three principal varieties of cases are seen (White JCutD 37 501 794 1919 ADS 15 387 1927)

VESICULAR, in which the lesions are grouped and are accompanied by marked itching being characterized by sago-grain vesicles and occurring preferentially in warm humid weather;

SQUAMOUS, resembling scaling dyshidrosis, usually with a central primary lesion which results from the drying of confluent vesicles; and

PYOGENIC, resulting from secondary infection.

The essential lesions are usually vesicles, and these may be solitary or multiple grouped or widely scattered. The vesicle is deeply seated only slightly elevated, and has the appearance of a boiled sago grain embedded in the epidermis. Its content is usually clear and as a rule there is no erythema surrounding new vesicles. Within a few days the fluid is absorbed, leaving a brownish macule. Eventually the roof of the dried vesicle becomes torn, exposing a red smooth, shiny surface with a collarette of upturned scales. In acute cases the vesicles may be grouped and may become confluent even forming bullae In extensive acute bullous infections the patient is incapacitated (Ormsby and Mitchell J 67 711 1916) When vesicles are grouped *in a dry area such as the palm or sole desquamation occurs, leaving a circular* well-defined, shiny reddish area denuded of its corneum. This may heal spontaneously or new vesicles may continue to develop about the periphery and extension may occur in all directions. Groups of vesicles may appear in a dry or moist well-defined eczematous area.

The areas affected in their order of frequency are (1) the fourth interdigital space of the foot (2) the plantar surface of the arch, and (3) over the tuberosity of the fifth metatarsal. At the base of the fifth toe a fissure partly interdigital and partly plantar is commonly present Similar fissures may occur beneath all the flexural folds of the toes. Maceration of the exfoliated epidermis in the fourth interspace produces a white sodden thickened adherent mass of epithelium

Hyperhidrosis is usually an associated symptom The patient s complaint is of itching which may be moderate or severe Sensitiveness, *pain and in-*

capacitation occur in acute bullous cases, especially when pathogenic cocci add their effects to the situation.

Figs. 628 and 629.—Not all dermatitis of the feet is tinea. Fig 628 is a secondary syphilid. Fig. 629 is pustular psoriasis. (Dr Royal M. Montgomery)

Figs. 630 631 and 632.—*Trichophyton purpureum* infection of the soles, toenails and finger nails. (Drs. George M. Lewis, Mary Hopper and Royal Montgomery)

Trichophyton mentagrophytes infection in its early stage is acutely inflammatory with vesiculation; and scaling maceration and fissuring may proceed between the toes for months or years, noted Montgomery and Casper (J 128 77 1945 NYSJM 46 2038 1946) who were interested in distinguishing the clinical appearances of the diseases produced by specific fungi Ves-

icles deeply located, filled with viscid fluid and surrounded by not much erythema, characterize this type as it appears on the soles and sides of the feet. The vesicles may become pustular and then dry, become scaly and clear centrally, while vesicles perhaps recur in the central part of the lesions. As these dry there evolve brownish macules that desquamate. The domes of the ves-

icles contain easily demonstrable fungi. Infection of the nail plate is usually superficial, manifested by scaling or *small irregular white areas*. *Trichophyton purpureum* produces a noninflammatory dermatophytosis characterized by fine branny scaling and an absence of vesiculation. *In nail infections* this *fungus invades* the under portion of the nail, causing yellow undermined

areas, and the nail plate may be broken off or destroyed. *Candida albicans* infections of the feet are characterized by red and macerated areas usually involving all the interdigital webs. Nails show a paronychia and swelling with the lateral borders of the nail plate ridged and undermined. *Epidermophyton floccosum* infection of the feet causes maceration and severe scaling on the toe webs and flaky scales on the sole but nail infections are seldom due to this organism. Weidman and Glass (ADS 53 213 1946) did not consider *T purpureum* infections especially characteristic finding this organism in many cases with hyperkeratotic and macerated lesions. See *Trichophyton purpureum* infection (p 509)

Inguinal lymphadenitis occurs in many severe and acute cases involving the feet. *Trichophyton interdigitale* has been secured by culture from a swollen inguinal node, the same organism being recovered from the focus (White ADS 18 271 1928) Epstein (ADS 45 1113 1942) demonstrated that some cases of so-called dermatophytids of the hands are actually dermatomycosis, wherein one can find the organisms and obtain cure with parasiticidal medication. Regional lymphadenopathy is usual in kerion but it does not imply the presence of pathogenic bacteria or the need for penicillin injections.

Tinea of the palms and soles is to be distinguished from contact dermatitis, which is ordinarily not interdigital is manifest as severely pruritic patches with fading ill-defined margins, and is most intensely vesicular if vesicular at all, in the central part of the inflamed areas rather than at the periphery Impetigo and infectious eczematoid dermatitis are acutely inflammatory are interdigitally located when they complicate contact dermatitis or scabies, and spread rapidly with vesicles which are not multilocular Streptococcic or staphylococci dermatitis often begins from a specific and remembered minor injury upon which salves have been applied to the therapeutic detriment rather than betterment of the lesion. Coccic dermatitis is more painful and more speedy in its progress than mycotic dermatitis. It is, of course often secondary to tinea, but it must be treated first before fungicidal medicines are to be applied. Oozing, undermining, rapidly spreading tinealike dermatitis involving the dorsum of the feet or involving the hands and not the feet is usually coccic. Fungus infection of asymptomatic character often spreads swiftly and increases in virulence when eczematous dermatitis occurs. Mycologic studies are necessary for positive diagnosis (Mitchell: J 146 541 1951)

Tinea Albigena is an affection of palms and soles especially and rarely of the nails, arms and legs, seen in Java. Nieuwenhuis (AfDuS 89: 1 1908) described the disease with initial vesicles, the skin later becoming hyperkeratotic and fissured. Vitiliginoid depigmentation follows. The causative organism was originally classed as *Trichophyton albiciscans* but Brumpt concluded it belongs to the genus Glenosporella. The disease is said to be responsive to fungicides such as mercuric chloride, iodine or chrysarobin.

Tinea Nigra is a tropical chromophytosis characterized by the development of dark macules, usually on the palms and volar skin of the fingers, according to Carrión (ADS 61: 996, 1950) It was first described under the name Keratomycosis nigricans palmaris by Cerqueira Pinto of Brazil in 1916. The lesions range in color from black to gray some of them resembling the stains of silver nitrate, and are rounded macules of various sizes, sometimes slightly elevated and occasionally scaly They may be discrete or confluent and numerous or sparse The disease is not extremely rare cases having been reported from Asia, Java, Brazil, Cuba and the United States. See McCarthy (J 123 449 1963); Leland (ADS 61: 854 1950)

The infecting organism, *Cladosporium werneckii*, is constantly present in epidermal scrapings from the lesions, from which it is readily cultivated on standard mycologic mediums. The colonies are slow growing, black in color with centers that become raised and furry (Walsh: ADS 57: 722, 1945) Cases affecting the neck and upper thorax were noted by Neves and Costa (ADS 55 67 1947) The disease is asymptomatic and is presumably transmitted by direct contact. It responds readily to treatment with such fungicides as 3% alcoholic solution of salicylic acid, or an ointment containing benzoic acid, resorcinol and sulfur, of each 10%, according to Silva (AmdeD 6 923, 1935) Whitfield's ointment with 5% sulfur added to it promptly cured a case of mine.

Tinea of the Nails.—*Trichophyton gypseum* and *T purpureum* as well as *Candida albicans* and the organism of favus, are the parasites which commonly attack the nails (Rockwood: ADS 22 395 1930) Various aspergilli and other saprophytes are often cultivated too *M canis* is occasionally found in and about the nails (Lyons ADS 67 460 1953) These fungi are capable of living in the nail substance which they invade more or less deeply—*Trichophyton purpureum* attacks especially deeply (Montgomery and Casper NYS JM 46 2038 1946)—and so they cause the nail to become thickened, lusterless, friable and whitish or yellowish in color Progress of invasion toward the nail root exceeds the rate of nail growth so that eventually the entire nail plate may be supplanted by a scaling and horny malformed, infected mass.

The surface layers of the nail plate may be preserved while soggy stinking material accumulates beneath it or *the plate may exfoliate* as far proximally as the invasion of its deeper layers has progressed. Nails may be involved primarily or secondarily to cutaneous infection. Chronic interdigital tinea of the feet eventuates in infection of the nails almost invariably. When the nails have become infected they serve as foci responsible for the dissemination of parasites and for repetitions of ids (Williams ADS 18 730 1928)

Fig. 639 —Tinea of nails leukonychia trichophytica.

Fig. 640.—Tinea of the toenails and skin, clinically suggestive of T mentagrophytes infection (Dr J Lamar Calloway)

Fig 641 —Tinea of nails, clinically suggestive of T purpureum infection. (Dr J Lamar Calloway)

Invasion of the nail is gradual The free extremity of the nail, particularly at the side first is involved. Several nails may be infected, but the dates of onset are separate Sharply demarcated patches of opacity on and within the nail substance, asbestoslike and angulated in outline are known as *Leukonychia trichophytica* (Jessner AfDuS 141 1 1922 Sulzberger and Lewis MRec 146 305 1937) There may be no inflammatory paronychial disease. The organisms are on and within the nail plate and are readily demonstrable

In 2,764 cases of dermatomycosis, White (UOutRev 40: 562 1936) found the nails alone to be involved in 74 cases, and nails and skin in 346. The 3 main types were those d e to trichophytons, monilia and favus. Differential diagnosis was described: psoriasis produced punctate stipling, subungual undermining and partial destruction of the nail plate; avitaminosis produced transverse depressions and longitudinal striae and was benefited by vitamin therapy; and dermatitis of the terminal phalanges due to contactants, cocci verrucae or syphilis wa productive of secondary changes in the nail.

Histologic studies of mycotic nails were made by Alkiewicz (ADS 59: 395, 1949) and Sagher (JID 11: 337 1948) illustrating the fungi spreading within the plate at various levels. The white lines in the nail seen clinically correspond to air filled tunnels due to the invasion.

M. canis infection of the nail and digits is rare but perhaps not so rare as is indicated by the existence of a solitary report by L on (ADS 67 400, 1933) I identified 5 cases i 1949-1951 and, exhibiti g patients, reported on them at the February 193_ meeting of the Kansas City Dermatological Society In 4 cases the fingers and/or fingernails w re affected and in 1 there were lesions on the dorsa of the feet. Both staphylococci and streptococci secondarily infected 3 of the 5 patients in all of whom the disease wa chronic, extremel pruritic and recalcitrant to treatment. Episodes of vesiculation a d exudation occurred in ll of them, but when bateria were from time to time eliminated, the skin lesions were shallow circumscribed patches of dry, itchy dermatitis, more or less excoriated. One patient was a girl of L years, whose scalp was unaffected. Nails were infected in 3 of the 5 patients, and resembled *T purpureum* onychomycosis. While such cases appear to have epidemiologic significance I was unable to trace transmissions of infection. The patient with lesions f the glabrous skin of the feet wa cured but the others were not, despite the use of débridement various fungicides and x ray therapy One patient had radiodermatitis of the fingers, diseased for 1 years before I saw him.

See Kittredge (ADS 34 398, 1936) trichophytosis of all nails Bereston and Keil (ADS 44: 420, 1941) yellow onychomycosis due to *Aspergillus flavus*, Bereston and Waring (ADS 52 162, 1945) case showing *A* *ni* lans and *T rubrum* mixed infection Hem (ADS 54 182, 1946) cases pparently due to *A. glaucus* nd *A* *nid lans*, Moore and Weiss (JID 11 215, 1948) case due to *A. terreus* Kligman (JID 14: 67 1950) case due to a Basidiomycete, a ray fungus generally found on dead wood.

Mycotic Paronychia.—The paronychial tissues are susceptible to fungus infection, although many a rebellious paronychia is bacterial and dependent upon focal infection. The disease may be acute, subacute or chronic. Inflammation, maceration, vesiculation, and fissuring between and about the digits are frequently concomitant The disease tends to be an occupational one affecting individuals exposed to pathogenic fungi while their hands are wet at work (Kingery and Thienes ADS 11 186 1925) Manicuring may serve to inoculate the infection (Oláh DWehn 101 1035 1935) *Candida albicans* is the usual cause (Rockwood: NEngJM 209 295 1933) A Mucor infected orange workers in California according to Sutherland-Campbell and Plunkett (ADS 30 651 1934) Pustular cases accompanied by onychomycosis were ascribed to various organisms by Dósa (DWehn 102 582, 1936)

In the treatment of paronychia, cultures for both bacteria and fungi are helpful to the clinician in selecting appropriate medication. Prolonged exposure to moisture and maceration must be avoided The occasional application of 3% chrysarobin in chloroform is effective A paste of sodium perborate in water was recommended by Rockwood Soaks in $KMnO_4$ may help Gentian violet has been used beneficially X ray treatment 100 r weekly for a few doses, might be given. The elimination of focal infection and appropriate antibacterial measures are often curative

Trichomycosis (Tinea of the Hair)—Fungi parasitizing hair include microspora and trichophytons. Microsporum infections are described under Tinea Capitis. Trichophyton infections were long classified as endothrix and ectothrix, indicating predilection of the fungi for forming spores, respectively within the hair shaft or on it.

Endothrix parasites of importance are *T violaceum* *T sulfureum*, and *T crateriforme* (Levin and Behrman J 128 350 1945) These parasites cause black dot ringworm so called because infected hairs usually without fluorescence split off close to the scalp in scattered patches. The endothrix fungi provoke usually a clinical picture characterized by follicular pustules and small eczematoid patches. Wood s light may reveal dull white fluorescence exceptionally a bright white fluorescence confined to individual hairs and so distinguishable from the glisten of medication which is widely dispersed and can be wiped off with carbon tetrachloride. The KOH preparation shows large spores usually in chains throughout the hair shaft.

Ectothrix parasites are uncommon invaders of the scalp The two im portant ones are *T gypseum* and *T purpureum* The former usually produces pustular inflammation and kerion. Wood s light reveals no abnormality of fluorescence. The microscope shows chains of spores external to the hair shaft. Clinical resemblance to *M lanosum* infection is close but the lack of fluorescence should arouse suspicion Diagnosis requires cultural identifica

Fig 442—Tinea capitis (Dr George Miller MacKee.)

Fig. 443.—Kerion.

Fig 444—Tinea of the scalp fter roentgen epilation. (Dr George Miller Ma k)

tion. *T purpureum* rarely involves the scalp in North America yet it is the organism oftenest found in tinea of the scalp in adults in Peiping (Mu and Kurotchkin ChinMJ 55: 201 1939) Lesions due to it are likely to result in cicatricial alopecia.

Tinea Capitis in Children is a commonplace disease The earliest lesion is a small, rounded, scaly patch or a red papule perforated by a hair The dermis is somewhat hyperemic but the surface is scaly and whitish or grayish in color As the patch slowly widens, it shows no tendency to undergo central involution. Hair shafts become dry lusterless, whitish and brittle They break off and so occasion one variety of symptomatic alopecia. The patches range in size up to several centimeters in diameter and they may coalesce Itching is the principal symptom, and scratching may lead to secondary infection. Tinea capitis in children is an infectious, often seriously epidemic disease of consequence to economy and education It is transferred by barbers, the initial infection in the site cut by clippers, as well as by immediate contact from child to child (Schwartz et al. J 132 58 1946) Children are susceptible to infection while most adults are not. Extract from children s hair was more favorable as a culture medium than from adults reported Kingery et al. (ADS 40: 879 1939) and Rothman et al (Sci 104: 201 1946; JID 8 81 1947) showed that this is due to a relatively high concentration of fungistatic free fatty acids of 5 7 9 11 and 13 carbon atoms in adults hair The fat of adult hair containing normal aliphatic monobasic acids with an odd number of carbon atoms, does not kill fungus spores in hair but prevents their infecting new hairs which replace infected ones in the process of shedding (Rothman et al JID 8 81 1947)

Microsporum canis produces well-defined patches of alopecia, relatively frequently with marked inflammatory reaction, consisting of erythema scaling pustulation and crusting and this may lead to spontaneous cure It commonly produces lesions distinguishable from those of *M audouini* only by cultures.

Microsporum audouini infection is generally not inflammatory but produces gray scaly patches and is not readily curable *M audouini* infections are in fact so resistant that roentgen epilation is usually but not always, required while in other types of infection local applications alone are likely to suffice. The patient of Bereston and Robinson (ADS 68 682, 1953) was only 4 weeks old.

Diagnostically typical are the partly bald, well-defined, scaly areas marked by lusterless and brittle or broken hairs and dilated or débris-stuffed follicular orifices. Microsporum infected hairs are regularly brightly fluorescent although *M gypseum* cases are not (Wilson and Plunkett JID 16 19 1951) One must distinguish seborrheic dermatitis, contact dermatitis, infectious eczematoid dermatitis and alopecia areata. In alopecia areata infected hairs are absent, the bald region is in no way inflamed, and the circular patch of bald scalp is not scaly Compare Trichotillomania.

M audouini caused circinate and imbricated lesions of the vulva and near by skin of a girl 17 years old whose young brother previously was found to have this organism in an ordinary scalp lesion (Silverberg and Oseroff: ADS 69 245 1954 p 498)

Microscopic and cultural examinations are required to distinguish tinea from other diseases as well as to distinguish one kind of tinea from another, and this is of great practical importance. A broken whitish stub is extracted with an epilating forceps. It is placed in a drop of 10% potassium hydroxide solution on a glass slide and after a few minutes it is examined under the microscope. Fungi are ordinarily easy to find if they are present and a fruitless careful search is one criterion of cure

The organisms found in 288 Connecticut cases by Swartz et al. (ADS 60 486, 1949) were: *M canis* in 63% *M audouini* in 25% and *T schoenleini* in 8%; and there were occasional cases showing *M fulvum* *T mentagrophytes* and *T sulfureum*. While *M. audouini*

affected 3 times as many males as *females*, the incidence of *M canis* was equal in the sexes. X ray epilation proved necessary in 23% of the 283 cases. Of these epilations, 54% were performed because of *M audouini* infections and 3 % because of *M canis*.

Cultures from 170 cases in San Antonio by Lehmann et al. (ADS 61 483 1950) showed Microsporum in 68% (90 cases of *M canis* 10 of *M audouini* and 6 of *M fulvum* infection) and Trichophyton in 35% (23 cases of *T mentagrophytes* 18 of *T tonsurans* and 4 of *T violaceum* infection) and several were unidentified.

While clinical distinction between *M canis* and *M audouini* infections is not sure, suggestive differences were listed by Beare and Cheeseman (BJD 63 165 1951)

On a map showing the geographic distribution of cases, those due to *M canis* occurred haphazardly while *M audouini* cases occurred in localized areas. *Inflammatory reactions* were more common with *M canis*. Early *M canis* infections showed brilliant fluorescence but often lost this brilliance in a few weeks, while *M audouini* infections never diminished in the brilliance of their fluorescence If long hairs fluorescent throughout their length were present in an infection of short duration, the fungus was probably *M. canis*. Tinea corporis accompanied tinea capitis far more frequently with *M canis*. From three-fourths of the *M canis* infections a history was obtained of the presence in the household of a kitten having skin disease. Some *M audouini* infections cleared spontaneously and in those that did, there occurred early in the infection fluorescence of the distal two-thirds of the intrafollicular portion of the hair shaft which broke so as to produce partial alopecia, following which the hairs grew out fluorescent even to a length of 2 inches, while the number of infected hairs in the area decreased, fluorescence diminished and spontaneous cure ensued.

See Lewis and Hill (ADS 29 890, 1934), *M canis* and *M audouini* Lewis (AmJMedSci 189 364 1935), animal microsporons Smith (SouthMJ 28 610, 1935) microsporia Lewis and Hopper (ADS 35 461 36 821 1194, 1937), *M audouini* infection harder to cure than *M canis*, Moore and Conrad (ADS 42 610 1940), *M gypseum* case, Benedek and Felsher (ADS 49 120 1944) 140 Chicago cases, 81% *M audouini*, 12% *M canis*, not clinically distinguishable, Wilson and Plunkett (AnnWestMAS 1 93, 1947) review Montgomery et al. (NYSJM 46 679 1946), 2,457 N Y Skin and Cancer cases, 81% *M audouini*, Kinnear and Rogers (BMJ 2 854, 1948) Scottish statistics and epidemics Robinson (ADS 5 391, 1948) iodine, phenol and ammoniated mercury are as good as any antiseptics tested in vitro against *M audouini*, Franks and Mandel (ADS 62 54 1950), 3 members of one family including 2 adults with *M audouini* infection of scalp, Lewis (ADS 63 277 1951) *T craterriforme* kerion in child, Moore et al (ADS 66 382 1952) *T rubrum* ectothrix, produced scarring, Georg (PHRpts 67 53, 1952), *T tonsurans* health problem Bereston and Cohen (ADS 70 817 1954), quinacrine given for discoid L. E. induced green fluorescence of scalp hair Beare and Walker (BJD 67 101 1955) nonfluorescent *M audouini* and *M canis* scalp infections, exceptional, 3 cases.

Epidemic Tinea Capitis.—By 1943 reports from New York, Philadelphia and Pittsburgh indicated to the U S Public Health Service that an epidemic existed in this country and it spread during the subsequent 5 years for the most part fading out by 1949 See Lewis et al. (NYSJM 44 1327, 1944) In 1944 Hagerstown, Maryland requested assistance in controlling the epidemic which had come to involve about 600 of the 7 000 grade school children 98% of the cases being due to *M audouini* (Schwartz NYSJM 47 1782, 1947)

The control of this epidemic was described by Schwartz et al. (PubHBull #294 U S Govt.Printing Off 1946) the plan being based on the knowledge that the parasite is spread by contact with infected hairs and that the principal places of contact are in the home, in school on the playground, in motion picture theaters and in barber shops. Infected hairs were frequently found in the electric clippers of barber shops. All school children were surveyed with Wood s light at 3-month intervals, and preschool children in families with infected children were also examined. Strict quarantine could not be enforced so infected children were allowed to attend school provided they would wear closely fitting caps. Treatment centers were set up with trained personnel in 7 of the schools, and treatment was accomplished with topical medication and manual epilation after initially clipping the hair close Treatment was administered by the trained personnel. The 2 most effective fungicides of the many tried were (1) 5% salicylanilide in Carbowax 1,500 and (2) saturated solution of copper undecylenate in Carbowax. Of the 312 children cured, out of 403 treated about half were cured within 4 months, while 11% were treated for 10 months or longer

The Hagerstown experience is a model of Public Health Service assistance in such circumstances. Lee (PHRpts 63 261 1948) reviewing the problem stated that control requires early diagnosis and adequate treatment of every case. The disease should be reportable and treatment by qualified der

matologists should be made available In the Minnesota experience of Steves and Lynch (J 133: 306 1947) involving about 850 children, only 25% could be cured by manual therapy whereas 80% of those receiving roentgen epilation were cured. Of 208 patients epilated, 207 were cured by Carslaw (BJD 63 16 1951) who felt that fungicides are not necessary in adjunct to roentgen treatment.

EXPERIMENTAL INOCULATIONS of hairy scalp and glabrous skin in children and adults with *M audoui i* and *M ca is* were made by Kligman (JID 18: 231 195_; AD 71: 313, 1955) When infected hairs were rubbed onto the scalp with not too much trauma, takes occurred in about half the cases. On about the sixth day a narrow band of fluorescence developed in the newly infected hair some 0 75 mm. distal to it papilla, and this band lengthened as the hair grew out, reaching the follicular orifice about the thirteenth day Prior to this, by about the tenth day the hair could not be manually epilated because it broke off. Fungus did not invade dead hai It branched as it grew proximad toward the root of the live hair and by the twelfth day reached the cells of the keratogenous region forming Adamson's fringe but not growing i to the nucleated cells. If the hair was manually epilated, it broke off at Adamson s fringe leaving fungi in the intrafollicular st mp. Hyphae spread in the corneum during the stage of peripheral extension of infection, and tinea spreads on the scalp a it does on the glabrous skin. As it spreads on the scalp, the infection of hairs is incidental. The circular hape of the scalp lesion is secondary to the peripheral spread of hyphal invasion f the corneum, b t hyphae ca not be found in the corneum after the lesion has reached its maximum size, which takes about 3 months. At the periphery of a spreadi g lesion, newly infected hairs show a band of fluorescence proximally located. The detection of such hairs demonstrates that a lesion is in fact a spreading one for they do not occur at the periphery of lesions which are not spreading They are not found in a case which has become stabilized and in which new lesions will not develop. When hairs with banded fluorescence are found, the disease may be interpreted as of recent origin, less than 3 months in duration. After that time some sort of refractoriness apparently develops in the patient, but no explanation is known for this. Stabilization suggests that one might perform a local epilation, but this does not in experie ce turn out well. Local epilation should never be done.

Microsporum gypseum (fulvum) generally produces nonfluorescent inflammatory scalp infections. Of the 9 cases reported on by Dalton et al. (JID 15 421 1950) 6 affected the scalp and 3 the glabrous skin. All patients but 1 were children, all scalp cases were of the kerion type and these all resulted in atrophic depressed scarring The organism was an ectothrix. Its colonies on Sabouraud s dextrose agar were cinnamon in color flat and without radial or concentric furrows. The growth was suedelike with a white, powdery margin. On microscopic examination numerous microconidia were seen. The extremities of the fuseaux were rounded, the walls thin, and the transverse septations usually 4 in number

Wilson and Plunkett (JID 16 19 1951) too commented on the absence of fluorescence in their 7 cases, although fluorescence has been thought typical of other microsporum infections. *M gypseum* infections of the scalp are somewhat uncommon, but cause as a rule large boggy, crusted, sore kerions in children, which heal spontaneously after 2 or 3 months, little influenced by treatment unless perhaps an epilating dose of x ray therapy hastens involution. Cases have been noted by Sharp and Wegner (ADS 61 824, 1950) and Trice and Shafer (ADS 64 309 1951) Cawley and Grekin (ADS 60 435, 1949) reported a favoid lesion of the scrotum due to this organism On the glabrous skin, the lesions are usually inflammatory but cannot be distinguished clinically from other forms of tinea corporis. I identified 5 cases from Missouri and Kansas in the years 1930-1933 Brazilian cases were reported by Gonçalves (YBD 1953 p 209) Rare in Great Britain, the infection was observed as an epidemic involving 8 of 40 greenhouse employees by Whittle (BJD 66 353 1954) The lesions were annular and erythematous, with thick walled vesicles at the edges, and they were cured by applications of iodine and occlusive covering after about 5 weeks of treatment

M gypseum has a world wide distribution It has been isolated from soil samples in numerous localities by Ajello (JID 21 157 1953) to whom it appeared as a soil inhabiting fungus only occasionally parasitizing animals. It seems to participate in the microbiologic breakdown of keratin, for it is found by offering hair for it to thrive upon, the filaments becoming covered with a

yellowish white mantle of mycelium and penetrated to various depths by interesting perforating organs. The organism was found in soil samples from Cuba and was proved pathogenic in man and cat by Fuentes et al. (AD 71 684 1955)

Epidermophyton inguinale was found in a case of pityriasis of the scalp by Gjessing and Mossige (ADS 36 1154 1937)

T discoides (faviforme) is a fairly common cause of tinea capitis in England (Beare BMJ 1 356 1954) It was the cause of 3 cases of kerion in 1 family reported by Saunders (ADS 69 365 1954) See Kerion.

Tinea Capitis in Adults has been thought to be quite rare in Europe and America but common in Japan. It affects women more often than men and is usually of the noninflammatory type although kerions are occasionally reported (Cummer ADS 36 844 1937, Benson ADS 39 484, 1939)

Fowlkes and Fox (ADS 11 446 1925) collected 50 cases from the literature and added 3 of their own the majority of the infections being with endothrix trichophytons The elderly female patient of Mendelsohn and Muskatblit (NYSJM 38 803 1938) had *M canis* infection. The patient of Klumpp and Reiss (ADS 56 547 1947) was the mother of 2 children also infected with *M audouini* as was the patient whose scalp was cured by manual epilation and salicylanilide although her infected daughter required x ray epilation, reported by Morgan (JKansMS 50 231 1949) Kligman and Ginsberg (JID 14 345 1950) were not able to find an allegedly superior fungistatic activity of postpubertal sebum as compared with hair fat of children.

The excellent and comprehensive study of Pipkin (ADS 66 9 1952) demonstrated that tinea capitis in adults is not so rare as has been thought, especially in the Southwest, and that the clinical features frequently are diagnostically confusing Scalp disease inflammatory or not must be suspected of being mycotic whether or not fluorescence is evident.

T tonsurans infection of the scalp may be suspected when the involved plaques tend to be angulated or polygonal rather than rounded when the hairs are broken off so close to the scalp as to appear as black dots, and when the infection is unduly prolonged or continues after puberty wrote Howell et al. (ADS 65 194 1952) Fluorescence is almost uniformly absent, the direct examination shows an endothrix invasion and cultures yield the specific growth. On following the clinical course of a particular plaque there are 3 stages of evolution generally to be distinguished, although all stages are likely to be present in any given patient During the epidermal phase there are a few patchy areas resembling seborrheic dermatitis. During the phase of follicular invasion, there are broken hairs and small areas of resultant alopecia which areas are of unusual shape—finger like rectangular or oval with irregular borders—often only 2 or 3 mm in diameter seldom as large as 5 cm Folliculitis is present and, in children, kerion is frequent. The third phase is that of healing, without permanent alopecia

The *T tonsurans* group was responsible for 91% of the endothrix infections, 87% of all trichophyton infections and 73% of all cases of tinea capitis in adults in Pipkin's Texas series The diagnostic clue was the infected stub of the hair a dot speck or imbedded fragment which required careful seeking if it was to be found. Wood light was of no diagnostic help. Epilating x ray therapy was the only attack hopeful of success, and it must be followed by meticulous manual removal of residual infected material.

In the familial epidemic of *T tonsurans* infection described by Kligman and Constant (ADS 63 493, 1951) the endothrix trichophyton produced noninflammatory scalp lesions with fluorescence dull or absent and the trichophytin test remained negative. They cured the cutaneous lesions by x ray epilation and Whitfield's ointment but were unable to cure the nail infection in these patients. The extensive and recalcitrant case affecting an adult female observed by Cipollaro (ADS 68 226 1953) spread from the scalp onto the arms and hand Of 44 New York cases collected by Reiss (BJD 66 229 1954) the scalp was involved in 29 and the glabrous skin only in 11. Lesions of the glabrous skin were usually located on the nucha, cheeks or upper chest A forehead case resembled pityriasis streptogenes. Sometimes the lesions resembled chronic lichenoid eczema.

Fig. 645.—Kerion, spontaneously healing, seldom produces so much cicatricial alopecia as is seen here

Fig. 647.—Kerion of moustache. (Dr Gusta Riehl.)

TINEA CAPITITIS IN ADULTS.—See Fox (ADS 13 398, 1926) *M audoui i* case Levin and Behrman (J 126 360 1916) nonfluorescent tinea capitis, Lewis et al. (J 133 62, 1946) *M audouini*, Felsher and Finnerud (ADS 58 517 1948) *M audouini* 1 mother and children, Reif (ADS 59 662, 1949) *M* *adou* i in pregna t Negroes H rschmann and Olansky (ADS 61 122, 1950), *M audouini* case; Greenhouse (ADS 63 502 1951) *T violaceum* case Weber and Ulrich (ADS 66 624 1952) *T rubrum* case.

Tinea Barbae.—SUPERFICIAL TYPE.—Infection may involve several hair shafts to a greater or lesser extent but seldom to the extent seen in tinea capitis. Infected hairs become dry and brittle and can usually be extracted readily the diseased root-sheath often adherent to the shaft There are more or less infiltration scaling and itching Vesiculation and pustulation are commonly absent. The disease frequently remains superficial throughout its course.

DEEP TYPE.—Deep involvement characterizes many cases, either from the beginning of the attack or after the disease has been present for several days in superficial form. The lesions may be few or many Numerous, dissem inated lesions constitute sycosis as distinguished from kerion, in which the lesions are large carbunculoid and few These inflammatory tumors are flat or oval and reddish and are studded with dead or broken hairs or with gaping follicular orifices. Such nodules may ulcerate in the center but ordinarily pus and seropurulent material are discharged through inflamed, dilated

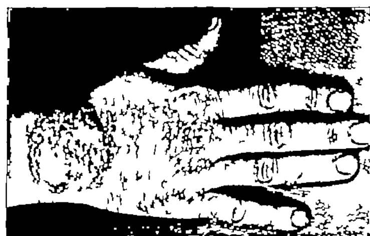

FIG. 441.—Agminat f lliculitis, n infection f animal origin (Dr M. L. Heidingsfeld)

follicular openings. The common site for the lesions is the skin beneath the jaw and in the cervicomaxillary fold. As a rule the upper lip escapes. This inflammatory form of tinea barbae usually exhibits a tendency to undergo self healing

Kerion may be caused by a y of several different f ngi, incl ding *M canis*, *M audouini*, *M fulvum* *T gypseum*, *T niveum* and *T crateriforme* (Birt and Wilt: ADS 69: 441 1954) *T fai forme* caused 1 of 39 cases of Carney (ADS 59 709 1949) and infected a mother and child reported by Muskatblit and Fisher (ADS 63: 723, 1952) *T sulfureum* caused a kerion of a child s scalp reported by Moore and Wool ridge (ADS 61: 460, 1950) A beard lesi n due to *T purpureum* was observed by Loewenthal a d Rein (ADS 63 19 1951) Upper lip lesions were discussed by Davidson and Dowding (ADS 61: 660, 1932) Similarity to bromoderma wa noted by Smith (BJD 50: 333, 1935) Agmi ate follicul tis, kerion, Majocchian granuloma a d tinea circinata were the configuratio of cattl ri g worm observed by Rook and Fra Bell (BMJ 1199 1954) whose cases were predom inantly caused by *T mentagrophytes* and *T discoides* *lbum*, respectively small spore a d large spore ectothrix parasites.

Cultures are best obtained from the pus. After an average duration f from 6 to 8 weeks the hair may be expected to regrow (Laymon MI M 29: 137 1946) and wh le expectant treatment i sufficient, manual epilation may help.

Kerion f the scalp l k keri n of the beard Sim lar carbuncular lesion on the dorsum of the hand or forearm may be called gminate folliculitis. S pporat ve ring worm contracted from cattle wa discussed by Fowle and George (ADS 56 90 194) Tinea barbae due to *Favotrichophyton alb m* was identified by Gammel and Wo k (ADS 33: 756, 1933)

Fig. 449.—Tinea of hair: section showing endothrix invasion of shafts within follicles. (Dr Fred Weidman.)

Figs. 450 and 451.—Fungus infections of hair. KOH preparations. Fig. 450 shows T. mentagrophytes causing ectothrix disease. Fig. 451 shows T. violaceum causing endothrix disease. (Dr Emanuel Muskatblit.)

Suppurative Tinea is a name designed to include kerion, sycosis, and agminate folliculitis. Variants of *Trichophyton gypseum* are the usual offenders. Many such cases occur in people who handle cattle. The trichophytin test is usually positive in suppurative tinea. Fowle and George (ADS 56 780 1947) reported 23 cases contracted from cattle and due to various trichophytons.

Of the 46 cases of suppurative tinea all occurring in farmers or cattle dealers, reported on by Davidson et al (CanadMAJ 31 587 1934) 10 were of kerion 29 of sycosis and 7 of agminate folliculitis, and all developed during the late winter or early spring months. Wood's light examinations were negative but the trichophytin test became positive in all. Immunity evolved slowly but self healing was in evidence for starch and boric poultices were satisfactory treatment.

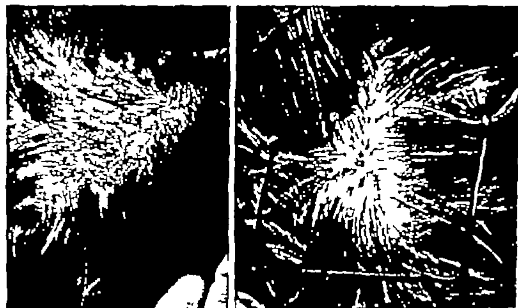

Fig. 652 and 653.—Tinea amiantacea. (Brown BJD 60 31 1948.)

Granuloma Trichophyticum is a type of deep ringworm differing from kerion chiefly in its chronicity and its milder degree of inflammatory intensity. It does not suppurate until late or unless it becomes secondarily infected. It occurs on the scalp and beard in connection with pre-existent fungus infection, and on the dorsa of the hands, forearms, and feet. The lesions are sharply defined and have smooth surfaces. They may persist for months or years. Sometimes they are acutely inflammatory sometimes hard and keloid like with deformed hairs at the periphery. They may occur on the leg and are readily mistaken for erysipelas, lichen chronicus simplex or stasis dermatitis. See *T. purpureum* infection (Wilson et al ADS 69 258 1954)

Tinea of the Eyelashes.—There may occur (1) folliculitis of the lashes and hair of the eyebrows with redness, swelling and perhaps purulent exudation, (2) edema of the lid margins without scaling or (3) scarring followed by loss of lashes noted Weidman (System of Medicine Appleton-Century 10 133 1937). The involvement may be unilateral or bilateral, and a child or an adult may be affected. The usual organisms are *T. sulfureum* or *T. violaceum*. The case of an 8-year-old boy reported by Silvers (ADS 49 436, 1944) was due to *M. audouini* was secondary to a lesion on the cheek showed classic fluorescence and was cured by manual epilation. *M. canis* infections of the lashes are quite rare according to Franks and Mandel (ADS 62 708 1950) who reported a case and reviewed the literature. See Montgomery and Walzer (ADS 46 40 1942) Costa (ADS 48 65 1943) Mitchell and Goodwin (ADS 64 655 1951)

Tinea Amiantacea, asbestos-like tinea, is a scalp disease wherein heavy scales extend onto the hairs, binding together the hair shafts. It may be circumscribed or diffuse. It is chronic It is not followed by atrophy scarring or alopecia (Becker and Muir ADS 20 45 1929) The condition was interpreted as a symptom complex which may occur in neurodermatitis or psoriasis and is responsive to an ointment containing 5% each of salicylic acid and oleate of mercury and to small doses of x ray therapy (Brown BJD 60 81 1948) Brown preferred the name Pityriasis amiantacea, believing that fungi are not causative The favorite prescription of Behrman (The Scalp in Health and Disease, Mosby 1952, p. 390) consisted of salicylic acid 6 ammoniated mercury 3 alcoholic solution of tar 1 water miscible base to 100 Chloramphenicol 0 6% in Vioform Cream is effective.

Piedra is a disease of the hair seen in some districts of South America and elsewhere It is characterized by the development of dark, nodular pinpoint to pinhead-sized, gritty masses on the shafts of the hairs of the scalp eyelashes or beard (McCarthy J 123 449 1943) Known also as

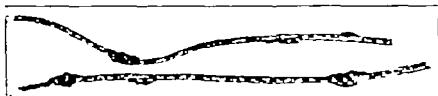

Fig. 411.—Piedra from an Indian girl of British Guiana. (Dr J. M. H. Macleod.)

Fig. 412.—Piedra KOH preparation. ×94. (Dr E. Muskatblit.)

trichosporosis or tinea nodosa, this fungus infection is limited to the shaft of the hair without involvement of the skin. The hard nodules (piedra means stone) adhere to the sides of the shaft like nits or form collars about it. White piedra is seen especially in Colombia, and is due to *Trichosporum beigeli* the spherical cells of which some are 10 µ in diameter and form a dense mat adherent to the hair because of a mucilaginous product of their growth. *Piedraia hortai* produces black piedra, affecting scalp axillae and beard a common and infectious disease of the scalp among Siamese children, according to Kneedler (ADS 39 121, 1939) A North American case was identified by Scott (ADS 64 767 1951) Cultural characters of the causative organisms are given by Moore (Clinical Tropical Medicine Hoeber 1944 p. 652) Shaving the head affords a quick cure but frequent shampoos followed by bichloride rinses or ammoniated mercury ointment will also succeed (Behrman The Scalp in Health and Disease Mosby 1952, p 341) The nodules can be dissolved off the hair with xylene.

Lepothrix (Trichomycosis, which may be yellow black, or red) is a dermatomycosis characterized by the occurrence of colored concretions on, or soft sheaths surrounding the axillary hair Adjacent skin is often infected. Concretions on the hairs are composed of masses and chains of micro-

organisms embedded in a homogeneous, chitinlike substance Species of Actinomyces mingled with certain cocci, have been thought to be the cause (Lane JCutD 27 387 1919)

The yellow type, allegedly due to *Actinomyces tenuis* is the commonest. Also due to *A tenuis* but with red pigment from the concurrent presence of *Micrococcus castellani* clumps of which grow in the gelatinous mass on the hair the red type is less common The black type is least common both in the tropics and in temperate regions, and is due to *A tenuis* and an associated pigment producing bacterium *Micrococcus nigrescens* (Castellani BJD 23 341 1911 25 14 1913) The nodules in the yellow type are homogeneous, soft and gelatinous, and added to them may occur clumps of red or of black cocci so as to produce the other types according to Moore (BJD 50 659 1938 ADS 37 967 1938) See Castellani and Wilkinson (BJD 34 255 1922 JTropM 26 186 1923)

Microbiologic studies by Crissey et al. (JID 19 187 1952) failed to confirm the nocardial nature of the causative organism which they believed to be a peculiar diphtheroid It fermented lactose and dextrose and grew best in an alkaline medium They named it *Corynebacterium tenuis*

The disorder can be cured by shaving the hair and washing the skin with benzine followed by 1 1 000 alcoholic solution of mercuric chloride

Otomycosis and Myringomycosis.—Many fungi are alleged to be capable of provoking inflammation in the skin of the external auditory canal and ear Itching dermatitis and impedance of hearing result On the tympanum parasites may form a coating of mycelium of blotting paper like consistency and bad odor Many different organisms, such as aspergilli generally considered nonpathogenic have been accredited with causing otomycosis. Branny desquamation or moist exfoliation with oozing is seen The truth is that the large majority of cases of dermatitis of the external ear are due to contactants, lichenoid dermatitis and bacteria working singly or in conjunction. Antibacterial therapy is more likely to succeed than fungicides, which often only irritate (Syverton et al AOtol 43 213 1946) *Pseudomonas aeruginosa* is a common offender which neomycin, chloramphenicol or polymyxin may eradicate (see p 327)

Otomycosis and myringomycosis do not undergo spontaneous resolution. They generally respond favorably to mild antiseptics along with careful débridement Recurrence is likely Ten per cent salicylic acid in 70% alcohol may be dropped into the canal Silver nitrate solution may be swabbed over the affected skin Metacresyl acetate has been highly recommended (Whalen J 111 502, 1938) Reeh (AnnOtol 51 146 1942) added 1% thymol. Sodium propionate 8% in propyl alcohol for swabbing twice daily followed by insufflation of 10% sodium propionate in talc was the recommendation of Duemling (ADS 52 75 1945) A wick moist with saturated aqueous solution of boric acid may be kept in the canal.

Rarely nowadays does one make a diagnosis of dermatomycosis of the ear My treatment of such cases many of which are referred by otologists whose fungicidal efforts proved futile or worse includes (1) prohibitions with respect to what may touch this region omitting toilet articles and cosmetics (2) attack upon seborrheic dermatitis of the scalp with Selsun or a lotion such as 1½% phenol 1 2,000 bichloride of mercury and 3% resorcinol in 70% alcohol (3) 2% sulfur and 0 8% Chloromycetin in Vioform Cream swabbed lightly on the dermatitis several times daily without filling up the canal (4) gentle syringing with 1 5,000 KMnO4 and (5) elimination of foci of infection in the stubborn cases. Cortisone by mouth and perhaps hydrocortisone ointment are helpful in cases which are primarily lichen chronicus simplex (q v) in this location

See Chronic Dermatitis of the Ears Dowling and Levey (CanadMAJ 41 336, 1939) Mucor causing obstruction deafness, Simon (WVaMJ 25 482, 1929) importance of treatment Dart AOtol 31 885 1940) Cresatin and thymol Minchew et al. (SouthMJ 33 1312, 1940) Cresatin and thymol Dunn (MJAustral 2 427 1941) carbol-fuchsin and sulf[illegible] powder Gill (SouthMJ 40 637 194[illegible]) Cresatin wick, zinc peroxide Dixon (JMoRMA 44 181 1947) clinical management of ear canal infections Hayes and Hall (AOtol 47 289, 1948) importance of Ps. aeruginosa Stuart (CanadMAJ 7[illegible] 334 1955) aspergillosis, 29 cases.

Trichophyton Purpureum Infection is sufficiently distinctive to be recognized from its clinical manifestations with some assurance (Lewis et al. ADS 37 823 1938) The lesions are likely to be solid, lichenoid plaques spreading at the borders with follicular papules, affecting the hands and feet groin back, thigh or umbilicus. They are superficial pruritic and extremely rebellious. Rarely granulomas are produced by this organism. Undermining and destruction of the nail plate are typical when onychomycosis is the case Hair involvement is exceptional, lesions being scattered follicular pustules and the organism behaving as an ectothrix (see tinea capitis in adults, p 500) Three cases of kerion of the beard due to *T purpureum* were reported by Sawicky et al. (AD 71 641 1955) See Figs. 630-632 In therapy potent topical agents must be used with persistence.

Extreme distribution and resemblance to dermatitis herpetiformis were reported by Tolmach and Schweig (ADS 41 732 1940) Experimental infection of rabbits interested Reiss (ADS 49 242, 1944) Cultural studies were detailed by Lewis and Hopper (ADS 41 893 1940) Swartz and Conant (ADS 42 614 1940) preferred the name *T rubrum*, and recommended inhalations of ethyl iodide in treatment A case of Baer and Muskatblit (ADS 60 445 1949) resembled erythroderma ichthyosiforme improved on Pragmatar eventually developed onychomycosis. The organism has been recovered from deep scrapings of lesions resembling chronic lichenoid eczema of the leg by Wilson (ADS 65 375 1952) see Cremer (Dermatologica 107 28 1953) Most of the patients of Wilson et al. (ADS 69 258 1954) were brunette women 19 to 50 years of age in whom usually solitary lesions assumed the form of chronic dermatitis of irregular outline showing cyanotic erythema, variable scaling and firmly indurated nodules. These were only slightly raised, not painful and only mildly itchy persisting for months but tending to undergo spontaneous regression with resultant circular atrophic scars. In late stages necrosis with ulcerations and crusting but not pustulation, sometimes occurred. Histologically the granulomatous infiltrate contained scattered fungus elements and the hairs showed globular spores externally and chains of round spores and short hyphae within. Wilson et al. obtained cures with sprays of 5% Asterol twice daily inunctions of Asterol ointment, potassium iodide 45 to 60 grains daily by mouth and small doses of x ray therapy

Involvement of the hands is clinically fairly typical, the infection of glabrous skin resulting from onychomycosis. Dry marginate chronic eczema is seen, usually unilateral often largely volar in distribution. Of 39 cases reported by Thompson (SouthMJ 47 130 1954) 30 were unilateral and males were affected 5 times as frequently as females. Thompson had good results with the antifungal preparation of Lyons et al. (USAFMJ 4 1175 1953) although no case of *T purpureum* onychomycosis was cured even by avulsion. The formula of Lyons et al, contained sodium propionate 2.0 sodium caprylate 2.0 propionic acid 3 0 undecylenic acid 5 0, salicylic acid 5 0 copper undecylenate 0 5 dioctyl sodium sulfosuccinate 0.1, water 20 0 propyl alcohol (91%) to make 100 0 The use of this prescription resulted, Lyons et al reported, in cures within a month in 15 of 17 cases, and in those that were not cured, cultures became negative. Lyons (pers. comm., 1955) had not changed his opinion of the value of his preparation (Verdefam Texas Pharmacal Co) after additional favorable experience The few cures I have secured resulted from the vigorous use of chrysarobin in an ointment or in chloroform solution.

A remarkable gyrate, urticarial and erythematous eruption due to *T rubrum* was observed by Waisman (JID 22 237 1954)

In 3 generalized cases of *T rubrum* dermatomycosis, there was coexisting lymphoblastoma, suggesting a relationship of unknown nature, reported Lewis et al. (ADS 67 247 1953)

See Castellani (JTropM 37 368 1934) permanent alopecia (scalp cases seen in Ceylon and China) Oertel (DWchr 102 166 1936) lesions of glabrous skin Morikawa (AfDuS 176: 364, 1937) nodular granulomas Ludwig (ADS 68, 310, 1953) sycosiform tinea barbae Lewis and Spoor (ADS 68 364, 1953) boy with widespread, gyrate, erythematous lesions;

Rothman (ADS 67: 239 1953) recalcitrant olar and nail cases, many of which showed increased glucose tolerance perhaps pertinent t pathogenicity cures of some skin, no nail infections, with concentrated lithium bromide and glucose solution.

Mixed Infections.—It is possible for a single host to harbor 2 or more pathogenic fungi at the same time. Several cases were described by Muskatblit (ADS 44: 631, 1941; 54: 658 1946) in one of which cultures from the foot demonstrated both *T interdigitale* and *T purpureum*. Mixed infections of the scalp interested Loewenthal (ADS 58: 27 1948) who found combinations of *T schoenlei* with *T violaceum* and with other organisms and one case with both *M canis* and *M audouini*. *T gypseum* on the face and *T violaceum* in the nails were present in the patient of Cawley and Horne (ADS 59 66 1949), while *E floccosum* and *T rubrum* were found on the hands and feet of the boy reported on by Franks and Rosenbaum (ADS 62: 439 1950) Four different pathogens were cultivated from the feet of a young man by Wooldridge (ADS 63 633 1951)!

Miscellaneous D ta on S perficial F gus I fections

T mentagrophytes—Dowding and Orr (BJD 49 298, 1937) hands, feet, beard, scalp Georg and Maechling (JID 13 339 1949), mutant with orange pigment from cases affecting skin and nails Franks and Frank (ADS 63 469 1951) case, astonishing erroneous dermatitis of feet.

T sulfureum.—Slaughter and Cawley (JID 9 63, 1947) lesions of child legs with —ld Samman (BJD 63 325, 1951) inveterat case forearms and nails with lichenoid lesions simulating those often due to *T. rubrum* Franks et l. (ADS 65 95, 1952) multipl kerion and erythema nodosum in a child.

A. gypseum. Shaban (ADS 36 335, 1937) caused scaly disease of guinea pigs, not of human beings.

T fluviale.—Szathmáry (ArDuS 181 192, 1940) occurrence in soil nea ri er infecting human beings.

T cameroonense.—Bernhardt (ADS 55 237 194) mycology of case showing itchy red spots.

Microsporum (Trichophyton) ferrugineum.—A common cause of tinea tonsurans in children in Japan, the organism was extensively studied a d so named by Ota (JapJ Dermat 21: 201, 830, 1921; BullSocPath Exot 15: 599 1922) because of the rusty reddish yellow to orange color of its colo ies. Soon Bong S h told me it is the most important causative agent of tinea capiti and tinea corporis in Asia, especially in Japan China and Korea, although *M sapporoense* is a common cause of tinea capiti in Hokkaido. *M. ferrugi eum* has been isolated in Uruguay and central Africa, a d an organism closely resembling it was found in children in India by Maplestone and Dey (I dMedGaz 74: 143, 1939) The clinical picture resembles that produced by *M audou* but the lesions are not fluorescent in Wood s light. Lesions of the glabrous skin are often located on the face where they resemble pityriasis simplex (see Reiss BJD 66: 239 1954) See Brumpt (Précis de parasitologie Masson, 1949 p. 1938); Dodge (Medical Mycology Mosby 1935, p. 545) thought it closely related to *M equinum*

Favus is the dermatosis due to infection with *Trichophyton (Achorion) schoenleini* or any of several closely related organisms. It is characterized clinically by saucer shaped yellowish scutula Infection may involve the *hair nails or glabrous skin, or all of these. The scalp is the commonest site.* A scutulum tends to enlarge peripherally and neighboring lesions coalesce to form thick, mortarlike masses which possess a peculiar characteristic odor like that of a mouse nest. The hair becomes dull, dry lusterless, and brittle In long-standing cases the follicles undergo atrophic obliteration, leading to cicatricial alopecia. The disease progresses tediously and it may endure over a period of many years. Favus is distinguished from tinea only by positive identification of the organism. Favids are the analogues of trichophytids.

Etiology —The disease may be transferred by handling infected animals, but transference from infected human beings is the usual route.

Treatment —The treatment of favus of the scalp is essentially that of tinea capitis. Roentgen epilation is highly desirable Morris (NEngJM 230 667 1944) was able to cure 2 Massachusetts cases in teen-age girls without epilation. Locally he alternated applications of 10% thymol in chloroform with 4% chrysarobin Carslaw (BJD 63 16 1951) reported that of 17 epilated cases, 12 were cured and 5 relapsed Parasiticides are those commonly used in tinea.

See Parker (JCutDis 3 44 1885) case, scalp of infant Way and Weidman (CalifWM 36 322, 1932) A quinckeanum case from California Siemens (Nederl TijdschrGeneesk 79 5140, 1935) treat 11 members of family simultaneously Barrett (ADS 33 126, 1936) 8 Kentucky cases Husk (DMtsch 70 125, 1937) 9 cases in one family several with f vids Aitken (EdinMJ 4 867 1938), 9 cases in Royal Infirmary in 20 years Montgomery et al (ADS 38 884 1938) nail only M and h rotchkin (ChinMJ 55 701 1939) 93 cases Muskatblit (MRec 151 187 1940) 6 New York t l rnty cases Machee et l (NYSJM 41 1722, 1941) x-ray epilation, salicylic acid and sulf followed by ammoniated mercury ointment; Swartz and Rockwood (ADS 41 415, 1943), in four generations; Kaplan and Hamblet cheek (Dermatologica 93 110 1946) 3 cases of f vic kerion on record; Russell (BJD 60 61, 1948) resemblance t folliculitis decalvans Robbins (ADS 58 180 1948) 3 New York cases Dobes (UCutRev 52 729 1948) 10 Georgia cases Upright and McCuiston (ADS 60

1202, 1949) endemic in Texas, Barrett (SouthMJ 43: 685, 1950) Kentucky cases, dull yellow green fluorescence Fishman (ADS 68 38, 1953) epidemic in nurses, contracted presumably from clinic patient in a New York hospital.

Tinea Versicolor (Pityriasis Versicolor) is a superficial dermatomycosis due to *Malassezia furfur* Yellowish or brownish macules are found usually on the chest and shoulders, although involvement of various regions, including

Fig. 66 —Tinea versicolor

Fig. 668 —Tinea versicolor

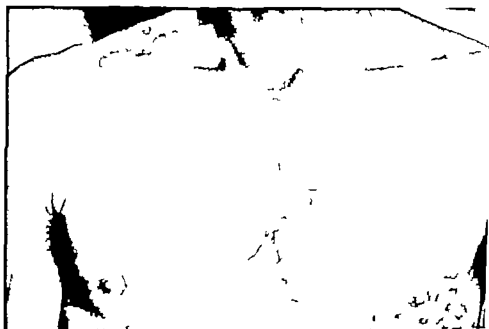

Fig. 669 —Tinea versicolor (Dr Ham) (F Itzer)

the scalp and even generalized cases have been seen by Costa and Junqueira (ADS 47 646 1943) In 47 cases of Bumgarner and Burke (ADS 59 192, 1949) 9 showed involvement of the scalp 2 of the face and 12 of the neck These authors believed that undiagnosed and untreated lesions of neck and scalp may serve as foci explaining persistency or relapse of the disease after treatment.

The patients are generally adult. The disease begins with one or more small, rounded, noninflammatory macules which enlarge slowly and may reach a diameter of 3 cm. or more their surfaces being covered with fine scales. Symptoms are almost wanting as a rule The lesions are usually followed by leukodermic patches into which pigment eventually returns (Adamson BJD 61 322, 1949) A peculiar musty odor is readily detected about persons who are extensively involved.

The lesions may clinically be practically invisible made manifest only by exposure of the skin to sunshine which induces pigmentation of the unaffected skin (Gougerot: BSocfrançD 43 1596 1936) Such lesions are miliary fixed and of minute dimensions. Despite their inconspicuousness they contain the parasites abundantly They may occur in patients with ordinary visible patches.

Fig. 470—Tinea versicolor unusual location. (Dr O G. Costa.)

Etiology and Pathology.—*Malassezia furfur* is easily detected in scrapings immersed in 10% KOH. Cellophane tape applied to a lesion pulls off readily identifiable fungus-laden material (Porto JID 21 229 1953) The parasite has been cultivated by Moore (AD&S 41 253 1940) Persons with moist warm skins, such as sufferers from tuberculosis, seem especially liable to infection There must exist some unknown susceptibility of the host for it is common to find the infection in one spouse and not in the other

Treatment.—The disorder is harmless and responds favorably though seldom permanently to medication. The skin may be swabbed with half saturated sodium thiosulfate solution and allowed to dry then swabbed with 5% vinegar this frees nascent sulfur and sulfurous acid (compare Scabies, treatment) Three per cent salicylic acid with 6% benzoic acid and 5% precipitated sulfur in petrolatum will serve well This should be applied over the entirety of the affected regions of the body twice a day for 2 days, then washed off The patient dons clean garments and sterilizes or dry-cleans contaminated ones. Such a course of fungicidal ointment therapy may be repeated after a month An ointment containing 5% crude coal tar is messy but effective.

Tropical Tinea Versicolor.—Yellow white and black forms have been described (Castellani: JCutD 20 393 1903) The neck and upper part of the chest are most often involved. Compare Lepothrix (p. 505)

ACHROMIA PARASITARIA.—Depigmentation may result from superficial fungus infections of a sort resembling tinea versicolor. There appear dirty whitish spots, slightly inflammatory at first but soon losing this aspect, becoming scaly and eventually becoming quite devoid of scales. After depigmentation has occurred, the lesions resemble those of vitiligo or syphilitic leukoderma (Pardo-Castello: ADS 25: 785 1932) See Vitiligo with raised borders; Pityriasis simplex.

PSEUDOACHROMIA PARASITICA is an interesting and by no means rare condition resulting from exposure to sunshine of a skin infected with tinea versicolor. This is followed by normal hyperpigmentation of the normal skin between the mycotic macules, while the fungi of the infected macules themselves are opaque to the tanning rays yet are destroyed by actinic energy, so that the lesions desquamate, fade and heal, leaving depigmentation in their places. The patient's appearance is then analogous to a photographic negative of his former appearance.

Fig. 671.—Achromia parasitaria. (Pardo-Castello ADS 25 785, 1932.)

Fig. 672.—Tinea versicolor after ultra violet irradiation, showing reddening of skin between opaque patches of dermatomycosis pseudoachromia parasitica.

See Lewis and Hopper (ADS 34 850, 1936) scales positive for fungi in pseudoachromia, lesions of which show typical fluorescence Marquardt (DWchn 104 177 1937) cultures of M furfur in Grütz' medium Jiner (ADS 27 870, 1933) scalp involvement, quotes Suzuki (JOrientM 8 97, 1928) on unusual locations Moore (ADS 38 349, 1938), pubic region Jiner and Barston (ADS 44 676, 1941) scalp Carpenter (ADS 47 251, 1943) face, in infant McCarthy (J 123 449 1943) tropical tinea

Erythrasma.—*Nocardia (Actinomyces) minutissimus* is a delicate fungus with spores and myceliums about 1 μ in diameter It has not probably been successfully cultivated It produces irregular but sharply circumscribed, reddish brown, slowly spreading finely scaling dry patches of slightly pruriginous, superficial dermatitis, located usually in the axillary genitocrural or pubic regions, rarely elsewhere The patches develop and spread slowly and give rise to slight symptoms. Interdigital cases with desquamation and maceration were identified by staining the scales by Rabeau and Guerra (BSocfranςD 43 464 1936) See McCarthy (J 123 449 1943) Charac

teristic bright red fluorescence is seen under Wood's light in most cases but not all and such examination is useful in diagnosis, especially when the location is atypical (Michaelides and Shatin ADS 65 614 1952)

The antiparasitic medicines used in treating tinea corporis are appropriate, and garments should be sterilized to avoid reinoculation. The 8% solution of chrysarobin in chloroform so effective in dry tinea and mycotic paronychia is good, but it must be used with circumspection, being capable of blistering the patient.

Etiology of Mycotic Infections.—These are common dermatoses. Moisture, warmth, and darkness are predisposing environmental circumstances. Infection may occur immediately or through contact with contaminated articles such as towels, slippers and bath mats. Mycotic infections of animals are readily transferred to human beings, sources being cats, dogs, horses, cattle, and even birds. Epidemics are commonplace, and schools, armies, and other communities where personal contact is close are subject to them There

Fig. 471.—Erythrasma. (Dr George Miller MacKee.)

are individual differences in susceptibility to infection, but lasting immunity apparently develops in no one and reinfections are common. Marital contact is not an important factor thought Sulzberger et al (ADS 45 670 1942) noting the paucity of reports of familial transmission.

The infection may lie dormant over long periods of time, only to flare suddenly when circumstances favor the growth of the organism. Autogenous reinfection was impugned as the principal mode of reactivation by Williams (ADS 18 730 1928) who demonstrated that nails often harbor inconspicuous but detectable infection. Shoes may be infected with epidermal scales which reinfect, and in such cases should, I believe be discarded rather than disinfected, for disinfectants like Formol are often irritating Inoculation with fungi occurs especially under conditions of close contact with infected persons, in sleeping quarters, locker rooms, swimming pools, showers, etc. The parasites find some individuals to their taste and others less attractive, and it is commonplace to observe a husband with chronic tinea pedis while his wife shows no trace of the disease and this is also notably true of tinea versicolor

TINEA IN INDUSTRY —The careful study of Peck et al. (ADS 50 170 1944) who surveyed the significance of tinea in 2,123 workers yielded no indication that infection with fungi and allergy thereto were related to the acquisition of dermatitis venenata. Tinea was not an important cause of loss of time in industry. There were three times as many cases in summer as in winter and about one third of all workers showed clinical evidence of the disease. See Downing (J 125 196 1944) Schwartz (OccupM 3 543 1947)

Dermatophytid.—In mycotic infections there may occur widespread, disseminated eruptions due to allergy to fungi (Low BJD 36 432 1924). Dermatophytid is the general name for such eruptions, which may differ widely in appearance. Epidermophytid, moniliid, and trichophytid are specific names applicable when the specific causative agent is known. The incubation period is about 10 days. The eruption may follow x ray or dermatomycin treatment. It may be violent or mild. During it the specific test is always positive and is generally accompanied by focal flare. It occurs when the primary site is actively vesicular or inflammatory. See Sulzberger (ADS 18 801 1928)

TYPES OF DERMATOPHYTIDS.—Lichen trichophyticus is the name applied to a dermatophytid occurring in tinea of the scalp, *in which the eruption is composed of scant* or numerous small red papules located on the back and shoulders, becoming scaly as they disappear (Williams ADS 4 353, 1921). Dermatophytic erythema multiforme and erythema nodosum have been seen. The commonest dermatophytid is pompholyx (q.v.) of the hands in vesicular tinea *of the feet* (Peck: ADS 22: 40 1930). If the focus is not con*trolled, the eruption may spread to involve the arms in scattered, discrete and confluent* patches of erythema, later becoming eczematous and scaly. The sides of the neck and the face may become involved. Erysipelas-like, recurrent dermatitis of the lower extremities was recognized as an "id" by Traub and Tolmach and by Sulzberger et al. (J 105: 187, 150 1937). Inflammation is less intense and more diffuse than in erysipelas. The lesions *recur in patches of constant size, shape, and location, as fixed drug eruptions do, noted* Walzman (ADS 53 10 1946). *His* patient manifested the usual immediate wheal reaction when trichophytin was injected within the area of the lesion. Hyposensitization was not successful when allergen was injected into normal skin, but was when injected within the lesion, following which the immediate reaction was reduced but not the 48-hour type *of reaction. Passive transfer of reactivity was demonstrable as is usual, in Walzman's* carefully studied patient in whom specific hyposensitization was obtained despite the persistence of positive skin reactivity and of Prausnitz Küstner reagins.

ETIOLOGY AND TREATMENT —*Dermatophytids are free from demonstrable* fungi. They depend on hyperergy to products of fungi (Sulzberger et al. ADS 34 207 1936). Dermatophytids tend to occur in showers and to disseminate symmetrically and the blood culture may be positive (Peck JIndianaMA 37 304 1944). Injections of trichophytin into the skin regularly reduce sensitivity and increase tolerance and hyposensitization so produced is sometimes accompanied by clinical improvement but there is seldom satisfaction in treating tinea and its allergy by means of trichophytin. One does better to attack the foci with appropriate means and in treating the "ids," to use bland nonspecific remedies such as 1:600 aluminum acetate for wet dressings or calamine lotion with phenol. Cortisone 75 mg daily accompanied by potassium chloride 30 gr daily for a few days may effectively counteract the patient's allergy during the period of time needed to bring the primary infection under control.

Dermatophytids, especially the pompholyx type are susceptible to secondary bacterial infection. Many a case of chronic dermatitis of the hands is of this complex nature to be cured by accomplishing elimination of focal infection, including mycotic infection of the feet and toenails, and using locally 2 per cent sulfur in Vioform Cream modest doses of x ray therapy and a program of avoiding contact irritants.

DERMATOPHYTID.—See Schamberg (J 61 1328, 1908), pinpoint whitish scaling of palms distinct from pompholyx; Bott (ArDuR 137 736 1921) lichenoid exanthem in case of kerion; Williams (ADS 4 357 1921) dermatophytids, like those described by Rasch (BJD 32 317 1920) and Bloch (Amsterd, Feb 1921); McGlasson (ADS 14 670, 1926) recurrent erysipelas of legs and bacterial infection of pedal tinea; Whit (ADS 20 316, 1929) perhaps transplantation rather than hematogenous dissemination in "ids"; Williams (ADS 21 437 1930 23 313, 1931) rashes complicating tinea of groin and beard; Idem (ADS 37 972, 1913) dermatophytids; Wise and Wolf (ADS 34 1 1936) dyshidrosiform rashes on hand and feet are not necessarily due to fungi or allergy to fungi; Waldbott and Ascher (ADS 38 314,

Fig. 474.—Dermatophytid causing pompholyx.

Fig. 475.—"Keratolysis," a common type of dermatophytid. (Dr. Grover Wende.)

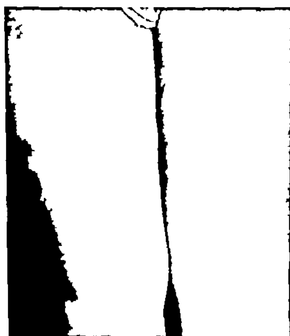

Fig. 476.—Urticarial and erythema annulare-like dermatophytid on the thighs of woman with acut vesicular tinea of feet.

1937) urticarial Reiss (JClinM 2, #1, 1938) relation of tinea of feet to inflammation of leg Yang (ChinMJ 57: 161 1940) recurrent erysipelas of legs Naide (AmJMedSci 20 : 82, 1941) fungus allergy and thromboangiitis obliterans Lasar (ADS 68 574 1953) erysipelas-like fixed eruption on leg.

DERMATOMYCOSES AND IMMUNOLOGY.—Vaccinal preparations of fungi have been studied with regard to their academic and practical significance. Reactions to trichophytin include the immediate urticarial reaction, the late tuberculoid inflammatory reaction to intradermal tests, and the eczematous reaction to patch tests. Efforts to obtain practical therapeutic results by the use of vaccinal agents may summarily be adjudged fruitless. Precipitins, agglutinins, and complement fixation antibodies circulate in human beings who are hypersensitive to dermatomycoses (Blumenthal: HandbHaG 11: 359, 1928). Thus vaccinal fungus materials can be used in diagnosis, much as tuberculin and luetin are used. Again the practical importance is slight because allergy from past infections, presently unimportant, may persist so that a positive test has no trustworthy significance as to the nature of the dermatosis at hand (Lewis et al.: ADS 38 713, 1938). The use of fungus vaccines in therapy, for immunizations, is recommended by some authorities, especially in attacking certain cases of pruritus ani, but I have found the measure disappointing. Of 65 patients treated with vaccines by Tolmach and Traub (ADS 33: 925, 1936) 9% were favorably influenced.

IMMUNOLOGY AND IMMUNOLOGIC THERAPY.— Brunsgaard (ActaD-V 3: 21, 1922) generalized nodular eruption following trichophytin injection in case of kerion; Fried and Segal (ADS 19 93 1929) T. gypseum injected intravenously into rabbits resulted in lesions only in scarified areas of skin, where local inflammation abetted pathogenicity of parasite. Peck and Jadassohn (ADuS 161 16, 1930) trichophytin allergy demonstrated in superficial tinea. Sulzberger and Kerr (JAllergy 2: 11, 1930), immediate reactivity to trichophytin passively transferrable. Ramirez (MJ & Rec 132 332, 1930), asthma from intradermal trichophytin injection. Sulzberger and Lewis (ADS 22 410, 1930), eczematous reaction to trichophytin. Peck (ADS 22 40, 1930), immunology. Wieder (WiscMJ 32 225, 1933), immunology. Sulzberger and Wise (J 99: 1759 1932) desensitization with fungus vaccine; Kerr et al. (JAllergy 5 238, 1934) immunologic treatment of tinea. Templeton (JAllergy 5 521, 1934), trichophytin therapy. Schols (DWchn 99 1342, 1934) reinfection with Epidermophyton ran shorter course than initial infection. Földvári (DZtschr 70: 260 1935) complement fixation antibodies in deep cases, titer not necessarily affected by vaccine or therapeutic response thereto. Robinson and Grauer (ADS 32: 787, 1935) autogenous trichophytin therapy. Traub and Tolmach (ADS 32 413 1935), trichophytin hyposensitization not clinically valuable. Ehler and Kanarijian (NYSJM 36 Dec. 1, 1936), no great therapeutic value. Jadassohn et al. (JImmunol 3 93, 1937) antigens in trichophytin, Schultz-Dale experiments, no pure, single antigen found. Marcussen (ADS 36, 494, 1937) antibodies same in immediate and delayed reactions. Traub and Tolmach (NYSJM 38 365, 1938) vaccines valueless. Council Rpt on trichophytin and Oidiomycin (J 107 665, 1936 113, 1735, 1939). Lewis et al. (ADS 38 618, 1937) long delayed reactions representing induction of sensitivity by performance of test. Henrici (Third Internat. Congr Microbiol. 1939 p. 567) protein and polysaccharide fractions of T. mentagrophytes produce different effects in experimental animals, and polysaccharide appears to be antigen responsible for human blood-borne id. DeLamater (Third Internat. Congr Microbiol. 1939 p. 575) immunity in experimental tinea reaches climax in 5 months and disappears in 11 months, and tissues of healed animal are relatively immune to reinoculation, more so within actual site of previous, healed disease. Peck et al. (ADS 42 428, 1940), slight fungistatic property of blood serum of infected person. DeLamater (JID 4, 143 1941) allergy to T. gypseum in guinea pig rises to peak after lesions have been healed 2 or 3 weeks, then diminishes, while immunity develops and wanes similarly. Peck and Glick (ADS 43 879 1941), preparation of trichophytin. Miller et al. (ADS 44 904, 1941) preparation. Peck et al. (ADS 44 816, 1941) preparation. Fancher et al. (JImmunol 48 193, 1943) histology of trichophytin and Oidiomycin reactions not tuberculoid. Kattenstein (JID 8 240, 1947) specificity of skin tests with histoplasmin, coccidioidin, sporotrichin and blastomycin, no false positives in persons lacking deep mycotic infection. Jillson and Huppert (JID 12 179 1949), urticarial reactivity to trichophytin in T. rubrum infection and in patients with history of atopy or recurrent lymphangitis not abolished by hyposensitization injections, though tuberculoid reactivity was. Jadassohn and Suter (ActaAllerg 4 150, 1951), tuberculoid reactivity lacks demonstrable antibodies. Gotz and Three (DWchn 124 1102, 1951) trichophytin test of limited value.

Prognosis.—The outlook in mycotic infection varies with the location, extent and duration of disease, the specific cause, the reactivity of the particular patient and the effectiveness of treatment. Tinea corporis usually responds readily and favorably although *T. purpureum* infections are exceptions to this rule. In extensive cases of tinea of the scalp the infection is extremely rebellious in some cases, especially in *T. tonsurans* infections, and easier to cure in others, depending on the infecting organism. In cases in which kerion occurs, baldness due to scarring may result. Great care must be exercised in examining a case before discharging it as cured. *Good treatment, which implies attention to detail and to the following of correct broad principles is materially advantageous.* In World War II experience a wet tropical climate rendered cure without evacuation sometimes impossible. All infected areas must be treated simultaneously so that dissemination cannot occur. *Fungi, like bacteria, propagate fast* under suitable conditions. Animal and human sources of reinfection along with inanimate sources such as clothing and shoes must be recognized and dealt with. *Dermatitis venenata* due to medication must be recognized and avoided. Secondary coccic infection is commonplace and *focal infections must be eradicated* in many a patient before cure of what appears to be chronic *tinea of hands or feet can be achieved.*

Treatment of Tinea.—Correct diagnosis is essential. The distinction of tinea from dermatitis venenata and from coccic disease is important. Tineal dermatitis is due to moldlike fungi which primarily parasitize the dead horny cells of the epidermis and secondarily provoke inflammation allergy anti body production and eczematous dermatitis. In regions where the fungi are treatment aims at eliminating them by removing some mechanically and in hibiting the others with chemicals that do not injure the skin. In the lesions due to allergy the aims are (1) attacking foci whence dissemination originates and where fungi are present and (2) soothing the inflamed skin where pathogenic fungi are not present, so as to give the patient symptomatic relief.

Many chemical substances are serviceable and none of them is specific (Kingery et al. JLabClinM 20 950 1935) The physician undertakes not to exterminate parasites, but rather to tip the equilibrium between host and parasite in favor of the host while one trusts to the natural responses to attend to the healing.

The antitheses of moisture warmth and darkness are prescribed, while suitable débridement may deprive the parasite of its cultural medium and mechanically remove large numbers of them

In acute vesicular lesions, astringent soaks and antiseptic powders are serviceable. Vesicles should be opened widely so that antiseptics can get into them Inflamed skin treated with soaks and without grease readily becomes cracked and fissured if it is flexed but it regains its normal flexibility when the inflammation disappears. The use of unguents, while comforting is here likely to disappointment. Medicines must be stopped before they do harm. The plan of treatment must be individualized.

Obesity predisposes to mycotic infections. In diabetes the sweat is laden with sugar which serves as pabulum especially for Candida. Tight clothes keep the crural regions continually moist and ill ventilated so that tinea of the crotch may be impossible to cure until these conditions have been altered Shoes which are tight across the toes, holding them in continuous juxtaposition, make it next to impossible to cure interdigital tinea.

Internal remedies of value are few indeed. Arsphenamines are decidedly dangerous as well as useless, for the sensitivity of the skin is precarious during mycotic infection. Vaccinal therapy has been disappointing see Dermatomycins. Prantal given in suitable dosage to inhibit volar hyper hidrosis, may contribute materially in handling some cases, 50 mg 4 times a day sufficing for most adults.

Roentgen therapy in treating tinea must be used with greater wisdom than in most other conditions for which it is useful. X ray energy does not kill the fungus. It may reduce hyperhidrosis, and it abets dissolution of in flammatory reaction and helps to cause vesicles to resorb (Brundage South MJ 31 1097 1938) It inhibits the ability of the skin to respond to the presence of the fungus, and its use is generally followed by several days of remission. When roentgen therapy is used time after time as the disease repeatedly reappears the result is atrophy or burn.

USEFUL CHEMICAL AGENTS

Soap and water along with a scrubbing brush sometimes perhaps rei f rced with sandpaper for attacking thick collections of scales in chronic squamous tinea f the feet.

Soaks and Compresses such i

Potassium Permanganate (3 grains to the gallon of w ter)

℞ Pot sium permanganat 0
W ter 100.0
Sig.: 1 teaspoonful to 1 quart water for soaks, douches or compresses.

BICHLORIDE OF MERCURY 1:10,000:

℞ Bichloride of mercury 1.0
Water 20.0
Sig: POISON 1 teaspoonful to 1 quart water for soaks or moist poultices.

ALUMINUM ACETATE (half a teaspoonful to the quart of water)

℞ Aluminum acetate powder 2.0
Put equal portions into 10 capsules.
Sig 1 capsule to 1 pint of water for moist packs.

CHRYSAROBIN 1% dissolved in chloroform, especially serviceable for tinea of nails after débridement, and on dry superficial tinea of crural or axillary folds, between the toes, or (with caution—it is hot!) about the anus.

SILVER NITRATE, 5% in water for occasional topical application, serving as a protein precipitant capable of rendering the epidermis uninhabitable

IODINE, the tincture, for painting infected nails.

SALICYLIC ACID 3% in 1 1 000 tincture of Merthiolate is useful for chronic vesicular tinea. The 10% alcoholic solution of salicylic acid is popular It causes scaling not to be confused with tineal disease

GENTIAN VIOLET *% aqueous solution, is fungicidal for gram positive organisms, not toxic, and astringent Methylene blue, 1% aqueous, yields a more flexible crust than gentian violet. Brilliant green and acriflavine have been advocated (Loos AfDu# 170: 602 1934 McCrea: Mycologia *6 449 1934) Gentian violet may irritate mucosae severely

DUSTING POWDERS such as:

(1) ℞ Camphor 1.0
Salicylic acid 1 0
Zinc oxide
Cornstarch
Zinc stearate .... of each sufficient to make 100.0
Sig: Dust between toes and into shoes to keep feet dry

( ) ℞ Salicylic acid
Menthol .... aa 1 0
Thymol iodide
Boric acid
Zinc oxide
Talc .... aa 10 0
Sig Antiseptic powder (favorite of Duemling: ADS 5.: 75 1945)

(3) Desenex Powder a proprietary zinc undecylenate preparation recommended in interdigital and intergluteal or crotch infections. (See Fatty acid therapy)

WHITFIELD'S OINTMENT (see BJD 56 .3 1944 59 173 184)

℞ Benzoic acid 5 0
Salicylic acid 3.0
Soft paraffin 5.0
Coconut oil .... t 100.0

Modification of Whitfield's ointment include the National Formulary one:

℞ Benzoic acid .... 1..0
Salicylic acid 0.0
Wool fat 5.0
White petrolatum .... to 100 0
Sig Whitfield ointment NF full strength.

Practical modifications of Whitfield's ointment NF include the addition of 1% phenol perhaps dilution with petrolatum or Lassar's paste to half strength or the incorporation of from 3 to 10% precipitated sulfur

SCHALEK'S PASTE an excellent antiparasitic agent

℞ Phenol 0.3
Salicylic acid .... 1..
Precipitated sulfur 1 6
Zinc oxide
Cornstarch .... of each 4 to 8
White petrolatum .... to 30.0
Sig: Rub in twice daily wash off with soap once daily

DENNIE'S ORANGE OINTMENT a potent mercurial analogue of Whitfield's:

℞	Red sulfide of mercury	0.1
	Salicylic acid	3.0
	Benzoic acid	6.0
	Sulfur precipitated	2.0
	Lanolin	20.0
	Petrolatum	to 60.0

Sig Dennie's orange ointment fo fungus infection.

CASTELLANI'S FUCHSIN PAINT (BMJ 1 235 1943), a valuable parasiticidal lotion, the potent ingredient of which is resorcinol, and basic fuchsin inhibits monilia:

℞	Basic fuchsin, sat. alcoholic sol.	10.0
	5% aq. sol. phenol	100 0
	Mix, filter then add	
	Boric acid	1.0
	Acetone	5.0
	Resorcinol	10.0
	Filter	

Sig: Apply by swabbing several times a day

There are few cases of tinea which will not respond to one or a combination of the preceding correctly used. In the following list brief comments are offered regarding the virtues (or lack of them) of numerous therapeutic agents, and the tabulation with its references may be of service

Ammoniated mercury ointment (1 to 10%): parasiticidal, often irritating

Anthral (Dihydroxyanthranol) effectiveness m ch like that of hrysarobin (q v); useful, with caution, in 1% ointment or chloroform solution.

Antibiotics discussed under Treatment antibiotic, antifungal.

Antihistamine compounds: some fungistatic powe but their generally considerable tendency to irritate or sensitize has kept them from being acceptable (Carson and Campbell: Sci 111 689 1950 diphe ylpyraline; Sokoloff ADS 64: 764 1951 diphe yl pyraline; Carter and Sutton: JKansMS 52: 119 1951 Chlor trimeton; Seneca: Sci 115 48 195_) Fahlberg (JID *0: 171 1953) di Paralene best.

Asterol dihydrochloride: alleged to make x ray epilation unnecessary in treatment of tinea capitis (Stritzler et al. ADS 63: 606, 1951; Ravits: J 148: 1005, 195_) Parent neous absorption ha ca sed convulsions in infants (Wallach: ADS 67: 517, 1953; see Dermatitis medicamentosa) must be used correctly (Pirk a d Sevringhaus: ADS 67: 519 1953)

Benzoic acid (5 to 15%) a tiseptic antimold agent, apparently harmless as food preservative in 1:1,000 dilution, valuable with sali ylic acid n Whitfield's ointment and t modification (q v)

Betanaphthol (3 to 10%) parasiticidal.

Campho ph nol fungicidal(?) dangerous (Gle and Hailey: ADS 47: 259 1943, nfavorable Phill ps BJD 56 19 1944 favorab le)

Chlorine (hypochlorite, Cl rox, etc.) hazardous an l u reliable

Carvacrol a creosote-lik substance obtai able from campho l combin tion with chlorine and mercury (monochlormercuricarvacrol): fungistatic (Geo gi: ADS 48 497 1943)

Citric cid and i egar have practical utility: a good home remedy is to rub in fected ski with cut surface of a lemon (Alderson ADS 39 706 1939)

Chrysarobin 1 to 10%—da gerous about the eyes—potent, exfoliative rubefacient, reducing gent. Dihydro ya thranol (Anthralin) may be substit ted (Molitch: J 106: 1563, 1036) Useful i chloroform sol tion r l tment ehicle.

Cl icin (Herrick: PSExpBiol 59: 41, 1945): 0.5% topical, lethal to pathogens. See Antibiotics, a tifungal

Coppe sulf t : 1:5,000 aqueous, a good antiseptic soak. Copper undecylenate i Carbowax for se lp cases i good (Combes et al.: JID 10: 447 1948)

Copper sulf te iontophoresis (Greenwood and Rockwool ADS 44 800 1941; Haggard et l: J 11_ 1229 1939) 0.2% aqueous solution of copper sulf t i pans to immerse extremities to be tre ted, othe tremities t be immersed i simila pans containing isotoni saline sol tion Th pos ti lectrode is connected t the coppe solution, the negativ t the sali A curre t of bout 5 milli mperes i used to treat on ha d or foot 5 t 10 mn. if both hand both feet are treated sim ltaneou ly Iontophoresis is so carried out for periods of bout 30 m tes, 3 times week. Best result obtained i active, vesicular cases. Fi l trate b iontophoresis, see Harpuder (NYSJM 39: 176 1939)

Crud coal t : t 50% in lan lin and petrolatum messy but effectively antiparasitic, rarely irritating

Dithiocarbamate derivatives: fungicides not inactived by blood (Kligman and Rosensweig: JID 10: 59, 1948)

Essential oils: most effective include those of neroly geranium, linalool, citronella; particularly derivatives of phenolic type and the doubly unsaturated acyclic terpenes (Vilanova and Casanovas: JID 20: 447 1953)

Ethyl chloride spray: defatting desquamative rubefacient (Lewis and Morginson: ADS 50: 243, 1944 Bograd ADS 48: 511 1943)

Ethyl iodide inhalation (Swartz: ADS 40: 962 1939)

Ethylparaoxybenzoate and allied fungicidal substances: investigated by Bonnevie (ActaD-V 17 576 1936) who commended them and also thymol, and benzoic, salicylic and cinnamic acids.

Fatty Acid Therapy—See Sulzberger and Kanof (ADS 55: 391 1947); Muskatblit (ADS 56: 256, 1947); Keeney et al. (BullJHH 73 479 1943, 75: 377, 393, 410 417 1944; 77 421, 1945) sodium caprylate ointment Peck and Russ (ADS 56: 601, 1947) propionate-caprylate mixtures, review and bibliography Bereston (JID 8: 227 1947; 9: 243, 1947) propylene glycol dipropionate useful for tinea of the feet but not superior to other agents in common use, and ineffectual in M audouini infections of the scalp; Nettleship (ADS 61: 609 1950) propionate-caprylate ointment and powder good. Undecylenic acid derivatives (Shapiro and Rothman: ADS 5_: 166 1945) Desenex ointment preferable to Sopronol zinc undecylenate enhances fungicidal activity (Sullivan and Fishbein JID 10: 293 1948) See T purpureum infection (p. 509)

Formaldehyde: 3% for soaks; hazardous, often irritating; has been advocated to sterilize shoes. See Salsbury (CanadMAJ 36: 515 1937)

Iodine the tincture—incompatible with sulfur and mercury—antiseptic (Sharlit: ADS 40: 663, 1939)

Iodocholeate, a crystalline bile salt of iodine, 10% in a water containing vehicle (Lever: ADS 40: 19 1939)

Mercurochrome followed by ultraviolet light (Gomez Vega ADS 34: 961, 1936)

Mycostatin: antifungal antibiotic valuable in *Candida albicans* infections (see p. 530)

Naftalan a tarry antiseptic approved by Ormsby (NEngJM 224: 673, 1941)

Parabens, methyl and propyl: low in toxicity not interfering with antibiotic action of Aureomycin or penicillin (Siegel: AntibiotChemoth 3 478, 1953)

Perchlormethyl Mercaptan reacting with alkali metal salt of imides and amides: mainly colorless, odorless crystalline compounds, some apparently effective (Kittleson: Sci 115 84 1952)

Phenol: 1% antipruritic, mildly antiseptic.

Phenyl Mercuric Compounds usually irritating, of little clinical value despite in vitro effectiveness (Goldman et al.: ADS 47: 569 1943)

Resorcinol 3 to 10% similar to salicylic acid.

Salicylanilide with TCAP in Carbowax good in tinea capitis (Schwartz et al.: IndustM 18: 257 1949; Hopkins et al. ADS 67: 479 1953)

Salicylic acid 2 to 10% provocative of desquamation not strongly antiseptic it self Valuable in combinations with benzoic acid and sulfur Salicylic acid in alcohol is often used to induce exfoliation The formula favored by Albert and Zeigler (SouthMJ 3 348 1944) was

℞ Salicylic acid — — 10.0
Acetone
Ethyl alcohol (85%)
Glycerol — — of each to make 100.0
Sig Swab on fungus infection daily for a few days.

Silver Nitrate: 5% aqueous for occasional topical application; soaks 1:5 000, astringent and parasiticidal. Saturated alcoholic solution for nails. Ammoniacal silver nitrate allegedly penetrant, disappointing

Spergon (tetrachloroparabenzoquinone): 5 to 50% in ointment bases tested by McGavack et al. (ADS 59 94, 1949) with cures of tinea capitis. Its in vitro effectiveness is high (Gordon: ADS 66 573, 195_) It obscures fluorescence of infected hairs and produces false cures, according to Moore (ADS 66 621 1952)

Sodium Borate: 2% soaks or as powder for feet See Ingels (CalifWM 54: 129 1941); Dóza (AfDuS 176: 281 1937)

Sodium Thiosulfate isotonic to saturated solutions, weakly antiparasitic sometimes irritating, usefulness overestimated.

Stilbamidine and related compound see Blastomycosis, treatment. Propamidine in treatment of tinea was investigated by Fison (JInfectDis 76: 193, 1945); salicyl and related benzestrol and diethylstilbestrol show antifungus activity (Heinemann JID 9: 277 1947)

Streptothricin 10 unit per gram in greaseless ointment base for anterior genital tinea (Greer ... J 129 101_, 1945)

Sulfonamide sulfanilamide best inhibit T gypseum not C albicans to be given internally not to be applied topically for actively inflammatory disease (Lewis and Hopper: ADS 44: 1101 1941)

Sulfur: 3 to 15%, excellent fungicidal agent activity enhanced by combination with salicylic acid. Vioform ointment is a good vehicle adding antibacterial effect.

TCAP (trimethylcetyl ammonium pentachlorphenate): with undecylenic acid is active and effective, according to Foley and Lee (JAmPharmAssn 36: 1?? 1947; JID 8: 1 1947 10: 49 1948)

Tetrachlorphenol sodium: ?% with 3% salicylic acid added to the ointment, effective (Wieder: ADS 31: 644 1935)

Tetraiodomethenamine in collodion releases iodine slowly (Sharlit: ADS 40: 603, 1939)

Thymol: 0.5% or weaker fungicidal, apt to irritate

Undecylenic acid derivatives: see Fatty acid therapy

Vioform: 3% cream or ointment adding 3% precipitated sulfur; valuable in monilial disease and secondarily infected tinea.

Zephiran: antiseptic recommended by Hopkins et al. (BullUSAMD June 1944, p. 43)

Zinc chloride: 1/100 molar (1.7 Gm. per liter) permanently inhibits respiration of fungi (Nickerson: Sci 103: 484 1946)

Evaluation of Fungicides.—The methods of testing have received extensive consideration. To effect clinical benefit the vehicles are likewise of concern. While fungicidal agents can diffuse from collodion films, fluid vehicles seemed preferable to Sharlit (ADS 31: 17 1935) Ointments were of especial interest to Burlingame and Reddish (JLabClinM 24: 65, 1939)

See Kingery et al. (JLCM 20, 950 1935) phenol derivatives Weidman et al. (J 128 ???, 1945); Horsfall (Fungicides and Their Action, Chronica Botanica, Waltham, Mass 1945); Kligman and Rosensweig (JID 10 15, 1948) Peck (abs YBD 1949 p. 443); Bumby and Stewart (BJD 61 318, 1949) China et al. (JID 20: 177 1953) halogenation of test substances fungistatic activity increased by chlorination and bromination, not by iodination or fluorination, Rebell and Lamb (JID 21: 331, 1953) in vitro study of several blocked steroids, Lyons and Livingood (ADS 68 ???, 1953), improved method of evaluation H et al. (ADS 70: 1, 1954), tissue culture technic intended to duplicate in vivo conditions Curtis et al. (ADS 70 7??, 1954) antifungal activity of many compounds related to stilbenes; Barlow and Chattaway (JID 24: ??, 1955) effect of fungicides on keratin cross linkages and so on susceptibility to fungus attack.

TREATMENT OF REGIONAL TINEA

TINEA CORPORIS.—The disease as a rule responds to any of the parasiticides, such as Whitfield's ointment or Schalek's paste. This may be rubbed in repeatedly until the skin becomes slightly sore and scaly then treatment should be stopped for several days while one waits to see whether more is required. A single application of 3% chrysarobin in chloroform or of 0.5% Anthralin ointment may vigorously irritate and peel off the disease.

TINEA OF THE FEET AND HANDS.—Not a high proportion of what one sees called tinea of feet or hands is fungus infection in whole or even in part. Whitfield's ointment is unsuitable for coccic infection, dermatitis dependent on focal infection or contact, atopic or lichenoid dermatitis, which are of frequent incidence. However when tinea is the correct diagnosis, circumstances favoring the organisms may be altered by washing the feet with soap each night, rinsing them well and wiping away scaly accumulations. The toes should be dried carefully after bathing. A dusting powder is then useful. The shoes should be loose particularly at the toe. Vesicles should be opened and the feet soaked in some antiseptic foot bath such as 1:5 000 potassium permanganate or 1:10 000 bichloride of mercury. The soaks may last 10 minutes 2 to 6 or 8 times a day using cool water. In severe cases the patient should be off his feet which between soakings should be elevated dry and exposed to the air.

In chronic infections, with interdigital maceration and scaling about the toes and on the soles, daily washing and dusting are advisable. Silver nitrate is useful the 5% aqueous solution being occasionally swabbed over the involved areas. Ointments which provoke scaling such as Schalek's paste or half-strength Whitfield's ointment may be rubbed in once a day after the feet have been washed with soap and water. Scaling provoked by medicament must not be mistaken for scaling provoked by infection. The ointment should be used for several days, then omitted for several days.

Nails must be examined and treated appropriately. See Onychomycosis.

X ray therapy directed at the entire sole for control of hyperhidrosis may be advisable but it will not cure psychosomatic excessive perspiration. Prantal 50 mg q.i.d. may reduce sweating markedly while it is given and so aid in tinea associated with hyperhidrosis.

Medication of shoes or socks results in more harm than benefit, I believe. Reinfection comes from infected nails or other sources and permanent cure is not to be promised or indeed even sought. Physicians themselves often carry tinea of the feet for years, neglecting it when it is not bothersome.

In so-called fungus infections of the hands, *Ayres and Anderson* (CalWM 56 63 1942) demonstrated fungus organisms in only 12% Monilia comprised about one-fourth of these. Kerion is seen in persons who handle animals.

Prevention of pedal dermatomycosis may be accomplished by keeping the feet clean and dry wiping between the toes after bathing and using a nonirritant fungicide such as Desenex powder (Schwartz OccupM 3 543 1947) In the tropics, Jolly (BMJ 1 726 1948) prevented spread of the disease by *supplying each soldier with 2 clean towels, wooden clogs and a foot powder* treating bodily lesions as they were discovered with 1% chrysarobin in Lassar s paste and interdigital lesions with 1% brilliant green plus 3% salicylic acid in alcohol.

Tinea of Hands and Feet.—Peck (ADS 33 40 1936) epidermophytosis Osborne et al (NYSJM 34 1270, 1934), sodium hypochlorite as prophylactic Gray (BMJ 2 541 1934) feet Wilson (ADS 30 641 1934) cleanliness Wise and Wolf (J 107 1126, 1936), favorite prescriptions Elson (UCutRev 40 737 1936) sodium perborate in acute cases, 12% balsam of Peru in subacute Hein and Rosenblum (MRec 145 363, 1937), phenyl mercuric nitrate, frequently irritating but effective Jamieson and McCrea (ADS 35 201, 1937) pathogens cultivated from shoes Moloney (IANDIII 35 440, 1937) 20% $CuSO_4$ in glycerol; Trebs (J 111 686, 1938) 5% salicylic acid, 2% menthol, 5% camphor in starch and boric acid powder Goldman (OhioSMJ 34 408, 1938) favorite prescriptions, bibliography Metedy (MilSurg 83 260, 1938) sodium thiosulfate Epstein, Lewis, Loveman, Pillsbury, Schoch, Shelmire, Smith, Swartz, Wieder (JID 2 423, 1940) methods and prescriptions Peck and Schwartz (PHRpts 59 337 1944) favorite prescriptions Wallace and Moorman (ADS 47 814, 1943) in high school children Crittenden and Joiner (JLCM 29 898, 1944) rinse hose in copper acetate solution Pardo-Castello (ADS 49 222 1944) 100% coal tar for interdigital maceration Caro (J 124 761 1944) clinical features of *T gypseum T purpureum* and *E floccosum* infections, Sulzberger and Kanof (USNMB 46 821, 1946), undecylinic acid prophylaxis Rees (CalifM 69 28 1948) 3% salicylic acid 4% benzoic acid in 40% alcohol

Onychomycosis is an extremely persistent disease. The infection may be only superficial, but it is usually deeply situated where fungicides cannot reach the organisms. Thus the main dependence in treatment is upon mechanical removal of infected nail substance Nail nippers and an electric grinding tool are indispensable and as much infected tissue as possible should be removed once or twice a month. *After débridement one may apply* silver nitrate in saturated alcoholic solution or tincture of iodine or 3% chrysarobin in chloroform *During intervals between débridement procedures*, the nail *may be treated with Whitfield s ointment or a modification of it to include* sulfur but a patient seldom performs débridement for himself correctly

A nail grows distally about 1 mm per week while the fungus invades proximad If it can be brought about that the rate of invasion of the pathogen is less than the rate of growth of the nail success is eventually obtained, but it is tedious and hard won If cure is achieved in a year the treatment may be considered good Some cases especially those caused by *T purpureum* are practically incurable by methods presently in use Even avulsion is seldom *advisable* (White J 103 1370 1934)

Removal of Nail.—While Wigley (BMJ 2 390 1943) and Taylor (J 1 8 750 1945) have described the technic of surgical ablation of a nail, Montgomery (J 120 647 1945) advised conservatism using painstaking débridement and strong fungicides. Ablation of all nail substance is difficult, but avulsion is simple and is sometimes appropriate *T rubrum* onychomycosis is hardly curable otherwise so is chronic onychial moniliasis.

The digit is anesthetized by procaine injection subcutaneously into both sides of the proximal phalanx A rubber band is wrapped about the middle phalanx after anesthesia is achieved, in order to secure hemostasis. A No. 15 Bard Parker blade is pushed under the nail and *from* side to side working proximad under the proximal nail fold. The loosened nail is grasped with a strong hemostat and gently pulled forth while it is being lifted up Epidermis adherent to the root of the nail is thereby stretched, and it should be separated from the edge of the proximal nail fold to which it attaches. The nail bed is carefully scraped free of all infected epidermal material. The rubber band

is then removed from the digit, and a dressing of bland grease is applied. Little pain ensues, and soft nail substance covers the nail bed within two weeks. The nail root is unharmed, and normal regrowth may be hoped for. Avulsion may be repeated six months later if the previous effort failed to accomplish a cure.

Onychomycosis due to *T. purpureum* where little or no vesiculation of plantar skin appears, was discussed by Montgomery and Caspar (J 128 77 1946). The free edge of the nail is first affected, then yellow streaks extend longitudinally under the plate enlarge and render the nail yellow brittle and dystrophic so that it may detach. They used repeated débridement with an electric drill and applied 40% salicylic acid plasters to be changed weekly later tincture of iodine or 1 to 2% chrysarobin ointment. This disease is one that is really discouraging. A competent dermatological friend of mine has given up trying to cure himself.

NAILS.—Nickerson and Whit (AD&S 57: 926, 1948) ammoniacal silver nitrate. Fischer (Dermatologica 98: 237 1949) dissolve nail plate with calcium thioglycollate paste then reach parasites with fungicide. Franks and Sternberg (AD&S 62: 787, 1950) ammoniacal silver nitrate. Rothman (AD&S 67: 230 1954) hypothetic relation of glucose metabolism and susceptibility lithium bromide-glucose applications. Kesten et al. (AD 71 52, 1955) modified Rothman method, using lithium bromide and Asterol, 2 of 12 cases claimed cured.

TINEA OF THE CROTCH AND AXILLA commonly depends on the presence of infection elsewhere, particularly of the feet, which must be examined and treated appropriately. Chrysarobin in chloroform is my favorite remedy but its use must, in hot cases, be preceded by a day or two of boric acid or $KMnO_4$ compresses. Desenex powder may work well. The application of 5% silver nitrate and the use of 1:10 000 bichloride of mercury as cool wet poultices, applied for 10 or 15 minutes 2 to 6 times a day generally serve to control the infection. The underwear and trousers must be loose so that the parts are well ventilated. Schalek's paste may be rubbed in, left on overnight and washed off with soap and water the next morning. In women mycotic infection of the crotch is often due to mycotic vulvovaginitis, and 1:5 000 potassium permanganate douches twice a day should supplement external medication. X ray therapy in 100-r doses often helps greatly.

TINEA OF THE BEARD.—Localized inflammatory mycotic infection, kerion, is treated by the removal of loose hairs, the application of wet packs of 1:10 000 bichloride of mercury and small doses of roentgen therapy. Sulfadiazine by mouth may be helpful. When the infection is disseminated and chronic rather than deeply inflammatory and localized, the problem is more difficult. Then roentgen epilation and 2% sulfur in Vioform Cream may prove successful. Disseminated chronic tinea of the beard is a very rare disease not to be confused with sycosis barbae.

TINEA OF THE SCALP is often epidemic among children. Prophylactic measures are essential, and this involves isolation and control of tonsorial sanitation. The hair should be closely clipped, and a snugly fitting cheap cap should be worn continually. The scalp should be washed with nonmedicated soap and water once a day or once in 2 days, depending on its soreness. Infections with *Microsporum audouini* are highly resistant as a rule but not always. Livingood and Pillsbury (JID 4 43 1941) cured 70% without x rays. These are only sometimes inflammatory and are often hard to cure unless x ray epilation is done. *M. canis* infection may be treated successfully by showing the mother how to remove all infected hairs with a good forceps, with instructions to shampoo the head daily and to follow drying after the shampoo with a thorough rubbing in of 4% salicylic acid and 6% sulfur in petrolatum. Alternate use of 10% ammoniated mercury and 5% Mercurochrome served well for Cleveland (CanadMAJ 36 38, 1937). MacKee et al. (JID 7 43 1946) reported a topical method involving trimethyl cetyl ammonium pentachlorphenate, citric and propionic acids, and a detergent vehicle. Salicylanilide 5% or copper undecylenate saturated solution in Carbowax was effective in the Hagerstown, Md. epidemic of 1944-1945 when properly used (Schwartz et al.: J 132 58, 1946).

Roentgen Epilation may be judged safe if performed expertly with a reliably calibrated x ray machine. A tinea marker is simple and convenient. It consists of a flexible plastic band which fits about the head equatorially and has two bands attached to it which cross the scalp in great circles at right angles to the circumferential band and to each other. The circumferential band is located 5 inches, plus or minus ¼ inch or so, from the vertex intersection of the perpendicularly crossed bands which are placed so that one of them lies in the medial plane. Five points are thus marked by the vertex point and the four points 90 degrees apart on the circumferential band. The point over the middle of the forehead is placed about 1 inch within the hair line and the nuchal point falls about 1½ inches within the scalp line. The epilating dose of 350 to 400 r at about 100 KVP unfiltered is delivered with care that the center of the beam is accurately perpendicular to the scalp at each of the five points nonhairy skin being adequately shielded (MacKee et al. ADS 53 458 1946). The hair loosens and begins to fall on about the seventeenth day. Its regrowth eventually has never disappointed me.

During the defluvium, abetted by manual epilation, energetic fungicidal therapy is employed. Buried and broken hairs may be encouraged to come out by a detergent grease such as Carbowax 1,500. Local rather than whole scalp epilation is not adequate and leads frequently to disappointment and trouble with relapses. Cure is controlled by careful examination in Wood's light. Isolated, stubborn fluorescent hairs may be picked out or removed by electrodesiccation, so hastening cure (Costello ADS 54 210 1946).

X ray epilation without any other treatment is dependably curative in my own experience and that of Lydon et al (BMJ 1 523 1949). I treat tinea capitis by epilation as soon as the parents allow me to. It is the most effective, and sometimes the only effective treatment for the disease (Eichenlaub and Osbourne MAnnDC 15 596 1946). The efficacy of x ray epilation was confirmed by reports of Cofano (Dermatologica 4 110, 1953) and Thorne and Orange (PostgradMedJ 30 423 1954). Partial epilations should *never* be done.

If Wood's light shows fluorescence and direct examination shows fungi and if epilation is done at once the head is bald at the end of 3 weeks, the child is cured in 6 weeks, and hair has regrown at the end of 12 weeks from the time the patient was first seen. I do not like procrastination.

Early reactions following x ray epilation are more likely to affect the apprehensive uncooperative child who can be prepared for the tiresome and somewhat alarming experience with a grain or two of Sodium Amytal. There often occur nausea, headache and slight fever some 1 hours after the x ray dose is given, but all such phenomena end within [illegible]4 hours. High voltage and filtration increase the immediate reactions both in percentage incidence and severity (Zugerman ADS 60: 722 1949). Graying of the hair at the time of its regrowth is occasionally noted (Zeligman ADS 66 627 1952). Previously straight hair has been known to grow back curly.

Roentgen epilation may be repeated probably with safety if the interval between the treatments is not less than 3 months. If a third epilation is performed, permanent damage and hair loss are expected (Hazen ADS 56 539 1947). There is of course no hazard to the child's brain, regarding which the parents frequently require reassurance.

Epilating Wax. A good one is made of beeswax, 1 part by weight, and powdered rosin 4 parts (Pusey J 87 665, 1926). The first is melted and the second added with stirring. While warm, the wax is smeared thick on muslin, the strips are applied to the clipped scalp, the wax is allowed to cool and the muslin strips are jerked off the child's head against the grain, removing all hair cleanly (Davidson et al. CanadMAJ 30: 620 1934).

Thallium Epilation. Thallium acetate, a deadly poison in overdosage, may be given by mouth to loosen hair and cause temporary epilation in the treatment of tinea capitis. The drug must not be administered to a patient older than 11 years. A single dose is given and it may not be repeated for several months. The dose is meticulously calculated at 8.5 mg per kg body weight. This dose accurately weighed and the weight most carefully checked, is swallowed by the child with milk at a meal. Hair begins to fall about 13 days later, can be epilated with adhesive tape or epilating wax during the next few days, and generally begins to grow back in about 25 days.

Thallium poisoning has been fatal, most fatalities having resulted from overdosage usually from the careless handling of decimal points in the calculation. Such misad-

venture i abhorrent as well as preventable It appears that BAL, given as for any heavy metal poisoning, is effective in thallium poisoning Perhaps iodide by mouth would serve as an antidote for thallium iodide is extremely insoluble See Dermatitis medicamentosa.

ESTROGENIC SUBSTANCES loosen the hair Dobes (AD 7 : 32 1935) told me He found Amniotin especially suitable giving children under 5 years of age 10,000 units weekly for 4 to 6 weekly doses, and children over 5 years 20,000 units. When the hair loosened, he applied collodion to the areas, and this enabled him to pull out the infected hairs without breaking them off

KERION OF THE SCALP —This heals spontaneously Manual epilation helps. One must patiently temporize using gentle measures for simple cleanliness. No medicines help the condition. Rarely an abscess develops under the lesion and requires incision and drainage Some scarring with partial alopecia, is likely to result. Kerion development is not preventable It takes two months or more to heal. It is erroneous to overtreat, over irradiate or incise but correct handling is regularly followed by regrowth of hair and little or no cicatricial alopecia (Keim pers. comm., 1955)

TINEA CAPITIS.—See Lario (ADS 18: 119, 1939), thallium; Buschke (DZtsch 77: 186, 1938) thallium, Poth and Kaliski (ADS 45 121 1942) estrogenic substances given to change susceptibility of host Miller et al. (J 132 67 1946) M audouini cases cured probably by manual epilation rather than any fungicide tried; Carrick (J 131 1189, 1946) copper oleate and fatty acid derivatives second choice when x-ray epilation not available for M audouini cases; Montgomery (JID 9 1, 1947) facilitate electrolysis of isolated hairs under Wood light with fluorescent eosin, shellac, alcohol solution Combes and Lehrman (ADS 57 74, 1948) epilating dose 350 accidentally applied twice to one patient without harm F isher (ADS 56 55, 1948), salicylanilide therapy technic cure in average of 6 months Behling and Markel (JID 11 239 1948) Elkhart epidemic 5,400 school children, cured 78% in a year with topical applications; Scully et al. (JID 10 111 1948), inflammatory reactions associated with high cure rate; Rankin et al (SouthMJ 44: 615, 1951) Sporgen effective; Kligman and Anderson (JID 16 155, 1951) M audouini cures good with ointment base as with zinc ethylene bis-dithiocarbamate; La (ADS 64 384 1951), spontaneous cures; Reiss and Doherty (J 147 228, 1951) podophyllum treatment Schwebel et al. (J 149 281 1952) podophyllum worthless in M audouini cases.

THE BLASTOMYCOSES

The blastomycoses are chronic infectious diseases due to budding fungi. These occasionally attack the skin giving rise to purplish, moist, papillomatous lesions, and sometimes invade internal organs and subcutaneous tissues, giving rise to granulomatous tumors. Histologic features of the mycotic granulomas were reviewed by Moore (JID 6 149 1945)

Mycologically Swartz advised me that correctly blastomycetes are yeast like fungi which bud both in lesions and in cultures, including *Cryptococcus neoformans* (*Torula histolytica* producing European blastomycosis), *Candida albicans* and *Pityrosporum ovale* but excluding *Coccidioides immitis Paracoccidioides brasiliensis Blastomyces dermatitidis* and *Histoplasma capsulatum* because, while these produce budding in lesions, they grow moldlike on all media at room temperature.

Criteria were given by Schwarz and Baum (AD 71 143 1955) for distinguishing between true primary infections and the more usual manifestations of deep fungus infections. Primary cutaneous mycoses are characterized by (1) a definite history of the trauma which allowed inoculation to occur and was followed by the development at that site of a solitary chancre within a few days or weeks (2) evidence favoring the probability that the inoculating trauma involved actual contamination with the infecting fungus (3) development of lymphangiitis and regional lymphadenitis, so that the chancre and these phenomena together comprise a primary complex (4) proof of absence of previous pulmonary mycosis by historical clinical serologic and roentgenologic evidence and (5) change of skin reactivity from negative to positive along with, perhaps the finding that the serologic titer rises. Secondary skin lesions, stated Schwarz and Baum often are multiple, are not contemporary and are progressive Regional lymphangiitis and lymphadenitis are not likely unless secondary infection occurs. Pulmonary disease can generally be found if it is carefully sought Skin reactivity that was positive may become negative Serologic response may show increasing titer if the disease is progressive

THE BLASTOMYCOSES AFTER MOORE (ADS 38: 163, 1938)

DISEASE	FUNGI	CLINICAL CHARACTERISTICS	FUNGUS IN TISSUE OR PUS	CULTURE, GROSS	CULTURE, MICROSCOPIC
Coccidioidal granuloma	*Coccidioides immitis*	Infectious granuloma, acute, subacute or chronic. Cutaneous, subcutaneous, or systemic lesions. Lesions may be nodular, ulcerative, papillomatous, verrucoid, gummatous	Cells isolated or in giant cells, spherical, thick walled, diameter 3–80μ, reproduce by endospore formation, budding absent	Colonies flat, somewhat submerged, grayish, becoming white to light cream, with aerial hyphae cottony, at times coremioid, growth rapid	Hyphae septate, branching, 0.5–4μ in diameter; arthrosporous cells 2.5–7μ by 5–12μ; chlamydospores abundant, 6–8μ in diameter; racquet mycelium, terminal hypnospores [illegible] × [illegible]μ; anaerobic endogenous spore formation.
North American blastomycosis	*Blastomyces dermatitidis*, *Zymonema gilchristi*, *Zymonema capsulatum*, *umbellatum*	Infectious condition, often granulomatous. Cutaneous or systemic lesions. Cutaneous lesions primary or secondary, papulo-ulcerative, verrucous or papillomatous, gummatous	Single or budding yeastlike cells, thick walled, 5–20μ in diameter, usually approximately 7μ	Colonies at first yeastlike, then coremioid, finally profuse and cottony, changing from white to cinnamon; radiating ridges and concentric rings of growth. *B. capsulatum* remains white	Hyphae septate, branching, 2–4μ in diameter; conidia pyriform or round, pedicellate or sessile, 5μ in diameter; racquet mycelium, 5–6 × 3.5μ; chlamydospores terminal or lateral, 5.5–7.5 × 13–15μ; ascogenous cells spherical, 5–13μ.
European blastomycosis	*Cryptococcus neoformans*, *Atelosaccharomyces busse-buschkei*, *hominis*	Similar to No. Am. blastomycosis but ulcerative in cutaneous form, with abscesses, little inflammation; in addition cerebrospinal system	Thick walled, heavily encapsulated, simple or budding cells approximately 5–10μ, occasionally larger	Colonies yeasty or pasty, smooth, mucoid to moist, subpultinate; color light cream, becoming light tan to brown with age; growth fair	Spherical to ovoid budding, encapsulated cells approximately 3–8μ in diameter, rarely larger; no mycelium, pseudomycelium or spores.
South American blastomycosis, Paracoccidioidal granuloma: A. Generalized; B. Localized affecting buccal mucosa	(a) *Paracoccidioides brasiliensis*; (b) *Paracoccidioides tenuis*; (c) *P. cerebriformis*	A. Generalized or localized, cutaneous or systemic, granulomatous, papular, verrucous or ulcerative, acute to chronic, usually spreading in lymphatics. B. Lesions localized on buccal mucosa; acute to chronic; verrucous, papillomatous, ulcerative, granulomatous, spreading in lymphatics only in terminal stage	(a) and (b) Cells spherical or ovoid, 1–30μ in diameter, thick walls, simple or multiple budding of minute, spherical, ovoid or bacillary gemmules. (c) Cells spherical or ovoid, 3–30μ in diameter, larger than those of *P. brasiliensis* or *P. tenuis*, thick walled, with simple or multiple budding of small, spherical, ovoid or elongated gemmules	(a) White, adherent to substratum and somewhat hard, well-defined, somewhat cottony. (b) Mycelium mostly submerged; colonies compact, verrucoid or vermiculate at inoculation, showing folds or radiating ridges; white; growth slow. (c) On gl. cerebriform to vermiculate, yeastlike, creamy buff, becoming light cinnamon-buff with age, easily separated from substratum, but filamentous, flat and adherent to dry portions of substratum; growth slow	(a) Hyphae septate, branching, 1.5–3.5μ, hyphal swellings 3–6μ, spherical, terminal chlamydospores to 15μ; conidia lateral, small or pedicellate, 3–7μ. (b) Same as *P. brasiliensis*, corresponding structures smaller. (c) Hyphae irregularly septate, branching, 2–7μ with many swellings; cell arthrosporous, oidioid, dumbbell-shaped; chlamydospores spherical, elongate, pyriform or sclerotia, intercalary, lateral or terminal, up to 15μ.

BLASTOMYCOSIS OF GILCHRIST (NORTH AMERICAN BLASTOMYCOSIS)

Blastomyces dermatitidis is the causative parasite. Infection may begin on some exposed surface, with a small papulopustule which gradually enlarges. Crusting is present almost from the beginning The underlying lesion comes to consist of reddish or purplish, irregular papillomatous tumors bathed in seropurulent fluid. The patches tend to extend peripherally and heal in the center with atrophic scarring

Primary cutaneous blastomycosis, which is rare is exemplified by the patients reported by Wilson et al. (AD 71 39 1955) They developed after infection from a proven source primary chancriform lesions accompanied by lymphangitis and lymphadenitis. They did not develop the cutaneous form of blastomycosis characterized by slowly enlarging plaques of ver

Fig. 689—Blastomycosis. (Dr J. Lamar Calloway)

rucous, pustular dermatitis that is not accompanied by lymphadenopathy They were infected by pathology laboratory work 3 while performing au topsies and 1 while cultivating the organisms.

Cutaneous blastomycosis must be distinguished from tuberculosis verru cosa, sporotrichosis, vegetating syphilids, and bromide eruptions. The demon stration of the organisms, directly in biopsies or by culture is necessary for positive identification of the infection. The pus from microabscesses, transferred to a slide into water not KOH and examined with a narrow pencil of light may be seen to contain the singly budding yeastlike cells which are from 5 to 20 μ in diameter (Nomland ADS 32 924 1935)

Histologically the skin lesion shows remarkable pseudoepitheliomatous hyperplasia. Enlarged and deformed dermal papillae are the seat of chronic, purulent, granulomatous inflammation. *In the plane section of the tissue, this is found within papillomatous* epithelium as microabscesses. The budding *fungi* can be found in the dermal inflammatory tissue fairly easily as a rule. *B dermatitidis* cells are double-contoured and lack the capsule formed by Cryptococcus (Torula)

Fig 690 —Blastomycosis of *Gilchrist.* (*Dr Otto L. Castle.*)
Fig 691 —Blastomycosis histologic structure, showing papillary abscesses and pseudo-epitheliomatous hyperplasia. (*Dr F W Shaw*)

The disease is more often pulmonary in inception than dermal according to Schwartz and Baum (AmJClinPath 1 900 1931) who reviewed 22 Cincinnati cases and 36 from the Armed Forces Institute of Pathology The tendency in the lungs is to heal, but the disease extends via the blood and lymphatic system as well as by peripheral invasion. In active pulmonary disease there is always destruction of the mucosa of the smaller bronchi, while cavities are uncommon and pleuritis is always present usually dry and fibrinous Cutaneous blastomycosis is generally secondary to primary pulmonary infection and the disease appears to be transmitted by way of the respiratory tract Schwartz and Baum believed. That blastomycosis is not a local cutaneous disease but rather a systemic one was indicated by Ormsby and Miller (JCutDis 1 1903) whose photomicrographs showed internal budding only suggestive of (Coccidioides immitis). See Ormsby (ADS 39: 1069 1939)

An epidemic of North American blastomycosis, carefully documented, involved 10 patients in a small southern community studied by Smith et al. (J 159: 641 1955). Erythema nodosum not previously reported as occurring in this disease was observed in 3 cases. Examination of gastric washings was found helpful in diagnosis. Epidemiologic studies by Schwartz and Goldman (AD 1 84, 1956) disclosed 100 cases in 1953, located mainly in the central and southeastern parts of the United States a few in Wisconsin; there were 3 deaths.

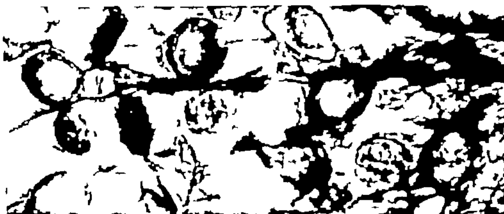

Fig. 694.—*B. dermatitidis* mass from experimental peritonitis of mouse. (Dr. E. Muskatblit.)

Most of the localized infections do not endanger life and respond fairly promptly to appropriate treatment. Scarring usually results. The possibility of systemic dissemination is always present, and systemic infections are serious. A young man with forehead lesions, for example developed meningitis, and autopsy revealed multiple abscesses including several in the central nervous system (Franks and Taylor ADS 48 88 1943) The mortality was 92% in systemic cases followed 2 years or more by Martin and Smith (AmRevTubere 39 275, 488 1939) in their review of 360 cases, with an extensive bibliography This has changed remarkably since the stilbene derivatives were introduced in therapy

Immunologic aspects were studied by Peck et al. (JImmunol 38: 449 1940) who found 2 polysaccharides which fixed complement of immunized rabbits and provoked tuberculin type reactions on intradermal injection in sensitive individuals, who could be hyposensitized. A complement fixation test was positive and appeared to be specific in 8 systemic cases of Martin (JInfectDis 57: 291 1935) Specific allergy was demonstrated in experimental infected guinea pigs by Nelson (JID 5: 257 1943) Skin tests with blastomycin yielded negative results when tried on persons exposed to the infection, reported Schwartz and Baum (JID 18 1, 1952)

Fig. 495.—Blastomycosis tiny abscesses surrounded by epithelium. Several fungus cells can be seen (Dr Fred Weidman)

Fig 496.—Blastomycosis fungus cell within a giant cell. One is budding. (Dr Fred Weidman)

Treatment.—Local, papillomatous lesions can be expected to respond favorably to tincture of iodine solid carbon dioxide or electrosurgical destruction. Roentgen therapy is valuable given in doses of perhaps 200 r weekly sufficient to achieve atrophy of the granulomatous process. Internally iodides in large doses used to be given. Sulfonamides in high concentration inhibited cultures (Noojin and Callaway ADS 47 620 1943) but they did not benefit a patient of Sayer (BullUSAMD 43 333 1942) nor did penicillin although huge doses of iodides did.

Stilbamidine and Related Chemotherapeutic Agents.—Aromatic diamidines were synthesized by Ashley et al (JChemSoc, 1942, p. 103) in their search for trypanocidal drugs.

Propamidine (4 4-diamidinodiph o lo propan hydrochlorid) wa found b Elso (JInfect Dis 76 193, 1945) t be effecti f gist t e *fo B dermat tidis* in a dilution of less than 0.5 mg pe 100 cc aga The drug was tried by Corbert et l (JID 14 71, 1950) whose preliminary report was encouraging The therapeutic potentialities of several

aromatic diamidines were investigated by Schoenbach and Greenspan (Med. 2 : 327 1948) but their work with stilbamidine (4,4-stilbenedicarboxyamidine) did not include its mycologic significance Steroid hormones were investigated with respect to fungistasis by Reiss (ADS 59 403 1949) who found diethylstilbestrol the most effective but *B dermatitidis* was not investigated, and their effect on *C. albicans* and *T histolytica* was nil. Schoenbach et al. (J 146: 1317 1951) used propamidine and stilbamidine in cases of systemic blastomycosis with remarkable results. Curtis and Harrell (ADS 66: 676, 1952) reported experimental studies of the fungistatic action of stilbamidine and several related substances with respect to *B dermatitidis* and they cured cases of blastomycosis with it. Two of their 4 were of the localized type in elderly men who were treated at the University of Virginia Hospital for inoperable cancer of the prostate with diethylstilbestrol. The coincidental response of their fungus infections was noted, and of them they were cured. The other 2 patients had systemic blastomycosis and were treated with stilbamidine which was selected as being the most promising of the group of drugs and without gonadotropic effects. They were cured. Fink et al. (J 151: 1393, 1953) also cured such a patient and . m re critically ill with the systemic disease were cured by Slaughter (ADS 70: 663, 1954) While the noteworthy effectiveness of these drugs is now common knowledge, blastomycosis has by no mean been conquered, as shown by the experience of Sutliff et al. (AnnIntM 41: 89 1954) of whose 15 cases from Memphis, 2 of the 7 treated with stilbamidine proved refractory

The dose of stilbamidine approximates 150 mg dissolved in 250 cc. of saline or 5% glucose and given slowly in from 1 to 3 hours, intravenously daily for 3 weeks, followed by a rest period of 10 days and a repetition of the course The total dose required ranges from 4.5 to 6 0 Gm. or more, and toxic effects from such dosage are not unusual. The drug may produce destructive lesions of the liver or kidneys, fatal 3 or 4 months after the last injection. More likely it may damage the trigeminal nerve producing within from 1 to 5 months after the end of treatment numbness of the central region of the face. The dosage and effects were reviewed by Smith (GP 8 69 1953) who emphasized the fact discovered by Schoenbach *et al.* (AnnIntM 37 31 1952) that the drug *must* be protected from exposure to sunlight in order to prevent its becoming toxic Hepatic or renal toxicity has not resulted from treatment with fresh solutions, according to Miller (J 152 184, 1953)

Stilbamidine is not the preferred agent for treating local skin infections, which can be cured with iodides, x ray therapy and surgery Efforts to find equally effective drugs of less inherent hazard are being energetically pursued, but sensory neuritis must be assessed as a price worth paying fo cure of an otherwise fatal infection. The fungistatic activity of stilbamidine and several related chemicals wa reviewed and investigated by Bocobo et al. (JID 21: 149, 1953) who observed that the pathogenic fungi sensitive to these substances included *B dermatitidis B brasiliensis, H capsulatum S schenkii* and *C. immitis.*

Baxvan and I (unpublished) tried stilbamidine isothionate topically in a vanishing cream base on superficial dermatomycoses, with largely disappointing results. In vitro tests suggested the drug might be effective against *T rubrum M gypseum, E. floccosum, M audouini,* and *T schoenleini,* for these did not grow in mediums to which 1 mg./ml. stilbamidine isothionate had been added. *C. albicans* was insensitive.

See Gilchrist (JohnsHopkHospRpts 1 269, 1896; BMJ 2: 1321, 1902) New and Childrey (AOtol 12: 134, 1930) primary of tongue; Redaelli and Ciferri (JTropM 37: 280, 1934) mycology; DeMonbreun (ADS 31 831, 1935), fatal case; Hamblen et al. (AmJObGyn 30 345, 1935) uterus and tubes involved Hsuh (ADS 43 465, 1941) generalized case helped with iodide; Smith (J 116 200, 1941) diagnosis; Hitch (JID 5: 4) 1942) gentian violet no help although effective in vitro; Feshay and Madden (AmJTropM 22 665, 1942) systemic infection of dog; Jones and Martin (Surg 10 931 1941), unusual osseous case Albert (BJD 56 294 1941) cure with sulfonamide; VanDellen (JInfectDis 76 47 1945) antibiotic from *Chromobacterium violaceum* inhibits *B dermatitidis* Cassady (AOphth 35 84 1946), uveal involvement Levine and Ordal (JBact 52 687, 1946), mycology Brody (ADS 56 529 1947) pulmonary and subcutaneous Starrs and Klotz (AIntM 82 1 29 1948) review; DeLamater (JID 12, 101, 1949) mycologic ariation Manwaring (APath 48: 421, 1949) unusual forms in tissues; Noojin and Praytor (J 147: 740 1951) newborn of infected mother carried complement-fixing antibodies for 3 months although itself uninfected Busehmer (JThoracicSurg 25 468, 1953) pulmonary resection appropriat in 3 cases; Marshak and Rodriguez (ADS 68 94, 95, 1953), 3 stilbamidine cures Parker et l. (J 153 129 1953) stilbamidine cured systemic case, Williams and Klemptner (J 153 840, 1953) patient with tuberculosis and blastomycosis cured of latter with no harm to former by iodides, streptomycin and stilbamidine Edit (J 154 532, 1954) 2 hydroxystilbamidine less toxic than some aromatic diamidines, encouraging in cases of Snapper and McV y (AmJMed 15: 603, 1953) useful in actinomycosis (Miller et l.; J 150 35, 1952) and sporotrichosis (Harrell et al. AI tM 93 162, 1954)

COCCIDIOIDOMYCOSIS

Infection with *Coccidioides immitis* apparently is commonly acquired by way of the respiratory tract through inhalation of spores; this is a hazard to laboratory workers with cultures of the fungus (Looney and Stein: NEngJM

242 77 1950) Endemic foci exist in California (San Joaquin Valley) Arizona, Mexico New Mexico and Western Texas (Burks and Thompson South MJ 39 613 1946) The skin test, negative on arrival, frequently becomes positive in personnel introduced into such regions (Lee CalifWM 61 133

Fig 699—Cutaneous lesions of coccidioidomycosis. (Dr William Allen Pusey)

1944) although such primary infection may be asymptomatic or manifested only by what would pass for influenza (Dickson AIntM 59 1029 1937) Such manifestations are often accompanied by erythema nodosum from which most patients recover without complication (Dickson J 111 1362, 1938 AmRevTubere 38 711 1938) Of 1,351 infections reviewed by Smith et al.

(AmJPubH 38 1394 1946) 60% were without symptoms and only 25% were clinically manifest. Erythema nodosum occurred in 4.6% and dissemination in only 0.25% mostly affecting Negro males. Progressive disease is analogous to the overwhelming tuberculosis of childhood. Features of pulmonary x rays range from a small nodular opacity through exudative but clearing lesions to nodular densities which may eventually calcify according to Winn and Johnson (AnnIntM 17 407 1942)

Primary cutaneous infections occur While most infected perso s recove some suffer progressive disease. Acute dissemi ting primary coccidioidomycosis is almost always fatal in from 1 to 6 months. Chronic disseminating disease coccidioidal granuloma, h a mortality f about 50% Gen rali ation m y follow sk o pulmo ic primary disease presumably via the blood stream.

In miliary coccidioidal granuloma the lesions are found preferentially located on the head neck, shoulders nd upper extremities (Epstein ADS 38: 75_, 1938) They are verrucose and papillomatous. They involve mainly the kin and occasionally the mucosae. Morbilliform ra hes h ve been n ted (Gol lstein an l MoDo 11: J 1 4: 637 1944) Fe er is usual and visceral involveme t follows. The organisms are easily demonstrated.

Fig. 160.—*Coccidioides immitis* in pus. These cells had internally are much larger than those of blastomycosis, and can be seen easily under low magnification. (Dr F D. Weidman.)

Fig. 161.—Endosporulating spherule of *C immitis* in tissue. (Dr Werner Duemling.)

In chronic coccidioidal granuloma, typicall affected re the sternoclavicular joints, the neck, th sides of the feet, and the ingui al regions. The lesions are furunculoid granulomatou becomes. The connective tissues of deep structures re mainly involved a d th mucosae are ffected only rarely The course is low with remissions and relapses. Fever is low or bse t. The viscera are involved to a lesser extent, the organism are more d fficult to demonstrate nd the outlook is better th in the miliary type of case Arthriti involvem t o symptom suggesti g Pott disease, appendic tis or pneumonia may confuse the diagnosis (Rosenberg et al. AInt M 69 238, 1942 Quill and Burch A aRurg 120 670 1944)

Diagnosi depends on demonstration of the organisms, directly in tissues o by culture. A kin test, us ng a vacc nal preparation of *C. immitis* as the antigen, is highly specif (Kessel AmJTropDi 19 199 1939) but reactivity persist long after activity of the disease may ha e faded.

The struct re of cocc dioidal gran loma that of the infectious granulomas, the ca sative organism be g fou d generally w th the gia t cells of the exudat (Wiseri ADS 61: 1010, 1950) They multiply by e dog ous f rmation of spores. In the pus they are doubly contoured sph res 5 to 60 μ in d ameter with granula protoplasm. In iso-

tonic saline, sealed under a coverglass, they quickly germinate a septate mycelium (Wilson: ADS 5 : 561 1948) They grow on dextrose agar The organism has been found in the soil at the place where infection occurred (Davis et al.: J 118 1182, 1942) Dust control by grassing, paving and application of oil has reduced the rate of infection (Smith et al.: J 132 833 1946)

Treatment with potassium iodide has little effect on the course of the disease Antimony and potassium tartrate and roentgen therapy have been used with benefit. Coccidioidin, a vaccinal preparation, has value (Jacobson ADS 40 521, 1939 57 561 1948) Doses must be of proper size and timing to immunize Incision and drainage should not be performed. Thymol in doses as great as 6 Gm. daily may help (Sox and Dickson J 106 777 1936) Penicillin is ineffectual (Arnold and Levy SouthMJ 39 609 1946) The value of stilbamidine and related drugs (see Blastomycosis, treatment) remains to be discovered. Diethylstilbestrol failed in 2 cases of Piper and Goldblum (ADS 70 809 1954)

PARACOCCIDIOIDAL GRANULOMA (SOUTH AMERICAN BLASTOMYCOSIS DE ALMEIDA'S DISEASE)

Paracoccidioidal granuloma is a chronic granulomatous disease caused by *Paracoccidioides brasiliensis P tenuis* or *P cerebriformis* which may affect the skin mucosae lymph nodes and viscera (Moore ADS 38 163 193 see also Conant et al. Manual of Clinical Mycology Saunders, 1944) Localized lymphangiitic disseminated and mixed types of cases are described The generalized disease may be acute or chronic. The fungus may enter the buccal tissues, forming a hard infiltration of the gums, spreading to the lips, nose and margin of the tongue Affecting the skin primarily a lesion may develop upon an abrasion where the fungi have become lodged. *P brasiliensis* was found in a dental granuloma in a woman who also had lymphatic lesions by Bogliolo (ADS 61 470 1950) who thought the infection capable of commencing in periodontal tissues and spreading via the lymphatics so as to simulate Hodgkin s disease Paracoccidioidomycosis shows a marked predilection to involve primarily the gastrointestinal tract including the oral and nasopharyngeal cavities while pulmonary involvement is common, perhaps by extension from the pharynx (Furtado et al. ADS 70 166 1954) Lymphoglandular cutaneous and generalized infections occur frequently but probably only secondarily to other types, stated Furtado et al who preferred *Aleurysma brasiliensis* as the name of the organism

Diagnosis depends on identification of the causative fungus (Jordan and Weidman ADS 33 31 1936) The organism listed as *Paracoccidioides brasiliensis* by Brumpt was first seen by Lutz in 1908

See de Almeida (AnnFacMed Sao Paulo 9 69 1933) Conant and Howell (PSExpBiol 46 426, 1941) Redaelli nd Ciferri (JTropM 37 280 1934) mycology F ri do and Pellegrino (be YBD 1948 p 81), 14 cases treated with sulfonamides, 4 died with disseminated disease, 3 unimproved, 4 helped, 2 much benefited, 1 cured) Perry et al (ADS 70 477 1954) suppressed benefit with sulfdiazine 1 case.

CHROMOBLASTOMYCOSIS

Chromoblastomycosis (Chromomycosis) is a polymorphous parasitic dermatosis, caused by *Hormodendrum pedrosoi*, *H. compactum* or *Phialophora verrucosa* productive of a primarily papular nodular or verrucose painless eruption which may progress with ulceration vegetation and hyperkeratosis. Verrucosities may be isolated or confluent, and may invade the whole foot or leg

Fig. 702.—Chromoblastomycosis of verrucose type, with central scarring. (Drs. V. Pardo-Castello, E. Rio Leon, and F. Trespalacios: ADS 45: 19 1942.)

or other parts of the body Infection seems significantly often to follow injury with some form of wood and usually affects an exposed part unilaterally (Weidman and Rosenthal ADS 43 62, 1941)

Fig. 95.—*Blastomyces brasiliensis* in liver tissue. (Dr Edward A. Gall.)

cauliflower like growths, some being pedunculated. There is usually no pain or lymphangitis. Microscopically the picture resembles closely that of tuberculosis, syphilis blastomycosis, a granuloma or a foreign body reaction. This is particularly evident in the decided hyperkeratosis, the acanthosis and some parakeratosis of the epidermis. In the corium there is marked edema with intense infiltration and fibrosis. This is made apparent by the granulomatous lesions with polymorphonuclear leukocytes, numerous lymphocytes, plasma cells, epithelioid cells, eosinophils, Russell f chsin bodies, macrophages, fibroblastic changes, discrete microabscesses and many giant cells of the Langhans or foreign body type confusing the picture with tuberculosis. Within these giant cells or distributed freely in the tissue may be seen the multilocular thick walled brown cells of the fungus, *P verrucosa*. These cells do not reproduce by budding but by transverse septum production which forms multilocular cells like mulberry clusters. Accordingly with the report f F P de Almeida and me (*Ann. M ssouri Botan Garden* 23: 543 1936) the name was changed from chromoblastomycosis given to the disease by O da Fonseca and A. E. de Arêa Leão (*Rev med cir d. Brasil* 6: 73, 1930), to chromomycosis. A number of fungi may produce the disease. These have different morphologic characteristics which seem to relate them to each other in phylogenetic sequence.

Figs. 708 and 709 —Chromomycosis showing acanthosis, dermal i filtration, and gia t cells. Higher magn fication reveals thick walled, brown cells of *Phialophora verrucosa* in the giant cells. (Moore et al. J 122 1237 1943)

The cases were classified clinically as verrucose, tuberculoid, syphiloid, psoriasiform cicatricial and elephantiasic by Lardo-Castello et al. (ADS 45 19 1942) who made their diagnoses by identifying the yellow brown round cells (sclerotia) in scales, pus and histologic sections where these are found in giant cells or small abscesses. While most cases occur on the extremities, a facial lesion simulating blastomycosis or verrucous tuberculosis was described by Moore and Mapother (ADS 41 42, 1940) who reviewed the literature. Mycetoma like lesions on the hand and wrist were reported by Emmons et al. (J 116 2_ 1941) and by Lewis et al. (JID 10 165 1948) whose patient was cured with x ray therapy and potassium iodide Surgical eradication or partial destruction combined with x ray therapy, is the usual necessity Iontophoresis with CuSo is among the therapeutic measures that have been recommended. Large doses of calciferol appeared beneficial in the 3 cases of Bonilla (ADS 70 665 1954)

MONILIASIS

Candida (Monilia) albicans (Zopf, 1890) identical with *Oidium albicans* (Ch Robin, 1853) is the type species of the genus Mycotorula (Will, 1916) as given by Brumpt. Colonies originate by bipolar sprouting of blastospores and the pseudomycelium is composed of ellipsoidal cells. The organism causes the development of a pellicle in liquid medium liquefies gelatin and ferments sugar The colonies are creamy thick and convex. Pseudomycelium is formed by short cells typically crowned by a verticil of blastospores. The terminal cell bears a bouquet of blastospores. Verticils are numerous, simple regularly spaced and globular at the end

C albicans is a yeastlike' fungus differing from a true yeast in that a pseudomycelium is formed, whereas true yeasts reproduce by budding, and the daughter cells do not adhere to the mother cell. This fungus and others closely related to it cause many different kinds of clinical manifestations, which may be localized, widespread or scattered, acute or chronic inflammatory or indolent They are capable of infecting skin its appendages, mucous membranes, and gastrointestinal tract and other viscera singly or in combination. Some strains in persons are potent sensitizers, capable of provoking eczematous sensitization as well as passively transferable antibodies They are often found behaving as saprophytes, and the factors which influence pathogenicity are ill understood. When one has found monilia, one has not *necessarily elucidated the cause of the disease under investigation.*

Clinical Forms of Moniliasis (Lewis and Hopper NYSJM 38 899 1938; see also Shelmire ADS 12 789 1925 Belisario MJAustral 2 538 1934; Ormsby MichSMSJ 37 135 1938) are as follows

LOCALIZED

Onychia and paronychia
Intertrigo (axillary submammary inguinal)
Erosio interdigitalis blastomycetica (essentially a variety of intertrigo)
Perlèche (essentially a variety of intertrigo)
Superficial glossitis
Stomatitis (thrush)
Localized eczema
Water bed dermatitis
Vulvovaginitis (with or without symptoms)
Gastroenteritis (with or without symptoms)

GENERALIZED

Widespread eruptions usually associated with some of the localized forms. Characteristic flat pustules may usually be observed in some part of the eruption. These pustules become dry and macerated scales form on the surface. With exfoliation, a bright red, moist surface is left with overhanging edges Sparse growth of hair may be an additional finding

Moniliids in which no fungi can be cultured and which are secondary to a focus of infection with C albicans. Pompholyx may be a moniliid

SYSTEMIC

This group includes cases of pulmonary involvement and massive gastrointestinal infection. Such infections are often associated with cutaneous infection and have proved incurable.

Monilial Onychomycosis.—The organisms may inhabit the nail plate, where they produce disease indistinguishable on clinical grounds from other kinds of onychomycosis (q v p 491)

Monilial Paronychia.—See Tinea mycotic paronychia (p 495)

Monilial Intertrigo.—Intertrigo is a clinical name applied to any superficial dermatitis characterized by redness abrasion and maceration, occurring on opposing surfaces. *Hyperhidrosis is followed by fermentation,* and the

skin becomes abraded and raw The gluteal and cruroscrotal folds, the infra mammary region and the folds of the neck are common locations. Hot weather obesity and binding garments are predisposing factors. Monilia are the or ganisms usually to blame although streptococci or staphylococci may be the

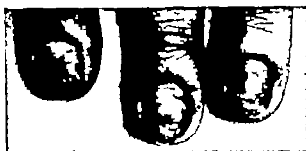

Fig. 710.—Monilial onychomycosis. (Dr W Herbert Brown.)

Fig. 711.—Monilial intertrigo.

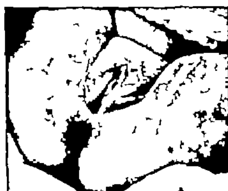

Fig. 712.—Monilial vulvitis in an infant

Fig. 713.—Perlèche. (Dr R. M. Montgomery.)

Fig. 714.—Monilial interdigital dermatitis in a laundress. (Dr James H. Mitchell.)

infecting agents. Monilial intertrigo sometimes represents the result simply of luxuriation of pathogenic flora of the skin the flora including pathogens usually because of the existence of foci of infection. Obese women are the commonest sufferers because of their monilial vaginitis, the presence of yeast like organisms in the vagina being a common circumstance

Monilial folliculitis is not an unusual concomitant of intertrigo especially when this has been treated with an ineffectual ointment (Sylvest ActaD-V 28 201 1948)

In prophylaxis, simple cleanliness and dryness are preventative achieved by loose clothing, good ventilation and the use of bland dusting powder Exertion in hot moist weather almost inevitably leads to trouble particularly in fleshy persons and fat babies. Focal infections and sources of reinfection must be controlled. Wet packs are excellent using cool 1 500 aluminum acetate in water or 1 10 000 bichloride of mercury The parts should be dried, perhaps swabbed with 10% aqueous solution of silver nitrate and dusted generously with borated talc. Often it is desirable to immerse the whole body in medicated baths, and potassium permanganate 50 grains to 15 gallons of cool water is effective Ointment preparations meet with little success although 2% sulfur in Vioform Cream is often helpful. AVC cream or Propiongel may be effectual, along with gentle cleansing with water daily

Monilial Interdigital Dermatitis.— Erosio interdigitalis blastomycetica was one name early given this condition when the organisms seen in smears were misinterpreted as nonmycelial blastomyces. The disorder involves one or both hands and usually appears on the web between the middle and ring fingers. Women, especially laundresses are particularly susceptible (White ADS 16 401 1927) A pudgy configuration of the hand abets the infection by keeping the interdigital web region moist and ill ventilated. The lesions are superficial, inflammatory and sharply defined, and have slightly undermined macerated borders, from beneath which the organism can be obtained and cultivated Extension over the dorsum of the hand and up the forearm is not rare. Diagnosis may be confirmed by KOH preparations and cultures. The disease is resistant to treatment but dryness, débridement and repeated applications of alcoholic solution of gentian violet (Cornbleet ADS 20 184 1929) or 3% chrysarobin in chloroform or Castellani's paint (Seale and Clark SouthMJ 41 627 1948) will usually succeed. Effort must be made to prevent contact with irritating chemical substances, and nutrition should be optimum Vioform Cream with the addition of 3% sulfur is often beneficial

Monilial Stomatitis.—Oral lesions associated with *C albicans* are thrush, glossitis and perlèche

THRUSH is manifest as superficial adherent deposits resembling coagulated milk The lesions bleed if the membrane is forcibly removed The mucosae of the tongue cheeks and pharynx are the sites of predilection. The circumoral skin may be involved *Pityriasis alba* is the name applied to furfuraceous scaling seen about the mouth in children who have oral moniliasis or perhaps perlèche The disease affects infants and sometimes adults particularly pellagrins and other debilitated individuals who cannot keep their mouths clean. Epidemics may occur the organism being transferred by carriers and by unclean utensils. The parasite is readily demonstrated among the epithelial cells scraped from a lesion.

In the newborn the condition appears to result from maternal monilial vulvovaginitis (Carter et al AmJObGyn 39 213 1940 Waters and Cartwright J 113 30 1939) Monilial vaginitis should be looked for during pregnancy and if present treated long before parturition.

Chronic deep infection of the oral mucosa is sometimes seen, producing leukoplakia and ulceration. Ephraim (BJD 61 414 1949) cured such a case with local agents and vitamin A Generous amounts of the B complex should be given, too

GLOSSITIS associated with monilia occurs in sprue pellagra and other avitaminoses. Hyperemia of the fungiform papillae and aphthous ulcers occur along with increased sensitiveness to hot fluids, spices and tobacco smoke In chronic cases there follows atrophy of the papillae so that the tongue is smooth and red, particularly along the sides. An important relationship cer

tainly exists between dietary deficiency and susceptibility to infection. The stomatitis of pellagra responds promptly and satisfactorily to treatment of the pellagra with the B complex. Monilial stomatitis is often seen following the disturbance of equilibrium of the flora when Aureomycin, Terramycin or other antibiotics have been given.

PERLÈCHE is an intertriginous inflammation of the labial commissures. A symptom, not a diagnosis, perlèche is sometimes due to monilia streptococci, contact irritants (toiletries, etc cf Stomatitis venenata) focal infection or avitaminosis and sometimes one fails to find the cause It is usually bilateral The mucosa is thickened and somewhat macerated The lesions extend a short distance onto the skin and onto the mucous membranes. In severe cases there are deep wrinkles and sore transverse fissures which cause considerable discomfort when the mouth is opened widely The lesions must be distinguished from the mucous patches and split papules of syphilis. When secondary syphilis affects the mouth there are always concomitant signs of widespread syphilitic disease Perleche seems to be transferable It has occurred in many individuals in one community such as an orphanage. Since Sebrell and Butler (PHRpts 53 2282 1938 54 2121 1939) showed that ariboflavinosis results in perlèche-like lesions, it is possible that the epidemics have been due rather to food deficiencies affecting a group of individuals than to transference of the disease by contagion. One may define perlèche as a symptom capable of being caused by parasites avitaminoses or contactant irritants. The monilial disease is treated locally by the use of mild astringent mouthwashes, which may advantageously contain myrrh or sodium perborate. In adults the dentures must be kept meticulously clean with nonirritating chemicals. The lesions themselves may be painted with 10% aqueous solution of silver nitrate and a layer of vaseline may be applied at night to protect the fissures from the moisture of drooling while asleep Silicote ointment serves well for this purpose (Reiches ADS 68 336 1953) Attention must be given to nutritional adequacy especially with respect to the B complex.

Monilial disease of mucous membranes in whatever form it appears may respond to the use of 2% aqueous solution of gentian violet a nontoxic but unsightly dye which sometimes irritates mucosae vigorously especially those of the female genitalia. While gentian violet is an effective antifungal agent, adequacy of nutrition in all its aspects must receive attention.

See Manson-Bah and Willoughby (QJM 23 411, 1930), glossitis in sprue, Miller (MJ Austral 2 649 1938) thrush Wright (BMJ 2 707 1940), perlèche in polyavitaminosis, Miller and Dark (AIntM 60 388, 1947) glossitis in sprue Ellenberg and Pollack (J 119 790, 1942) perlèche from malocclusion Nippert and McGilty (JaMAJ 32 298, 1943) perlèche from narrowed bite Finnerud (J 126 737 1944) perlèche Mann et al (JAmDentA 32 1357 1945) perlèche in edentulous mouth, Vamos (ActaD-V 19 241, 1949) perlèche and oral infection Vickers (BMJ 2 1091 1949), angular stomatitis from irritation by denture material, Greenfield (ADS 62 699 1950) perlèche following penicillin powder inhalations Edit (BMJ 2 1430 1950) thrush in infants

Monilial Vulvovaginitis and Pruritus Ani et Vulvae Vulvovaginitis and Infantile Dermatomycosis Vagina as Focus of Mycotic Infection.— Pruritus ani and pruritus vulvae are often due to Candida (or to other fungi such as Epidermophyton) and the infection is likely to be complicated by medicinal and traumatic irritation. Diabetes promotes pruritus because glucose encourages the growth of mycotic organisms. Monilial vaginitis is a common cause of pruritus even in women who do not have diabetes.

Monilial infestation of the vagina is commonplace and frequently asymptomatic It occurs in children virgins and senile women as well as parous ones. The disease may undergo spontaneous cure or it may become chronic with exacerbations at times over a period of months or years. Menstruation has the same temporary beneficial effect on the course of the infection as delivery does in cases associated with pregnancy Infantile oral thrush (q v) may result from infection in the birth canal (Hesseltine AmJObGyn 40 641 1940 Sage and Spaulding AmJDisChild 67 450 1944)

The following types of pudendal moniliasis are seen (Sutton J 110 1733, 1938)

1. Creamy vaginitis resembling oral thrush, with painful and reddened mucosa.
2. Creamy vulvitis, with considerable discharge but much redness or inflammation with or without a small amount of intertrigo which characteristically consists of small, grouped shallow vesicopustules.
3. Ulcerative vulvitis severe superficially ulcerated, with pain, lymphangitis and inguinal adenitis, possibly with mycotic infection of the bladder
4. Pseudoleukoplakic vulvitis in which the mucosa is whitish and opaque and the crusts are hard to remove, but no wrinkling papillomas or hyperkeratosis exists.
5. Eczematoid vulvitis, with a vesicopustular eruption consisting of small punctiform erosions, spreading and resembling intertrigo.
6. Mycotic pruritus of the vulva with few erosions, perhaps, and little discharge diagnosable only by smear and culture.
7. Vesiculopustular cutaneous form, manifesting disseminated involvement principally of external teguments with groups of small vesicopustules the vesicular stage being brief.
8. Cutaneous intertriginous eczematous form, which is intertrigo-like, with or without demonstrable organisms in the genitocrural plica, the inflammation spreading to the pubis, anal region and medial surfaces of the thighs, with but little visible involvement of the vulva.
9. Inconspicuous vaginitis with disseminated cutaneous involvement in the form of patches of intertriginous dermatitis with small vesicopustules not amenable to lasting therapeutic effects until the vaginal infestation has been treated properly
10. Moniliids, often consisting of pompholyx like patches of tiny deep-seated vesicles, which may absorb and result in superficial scaling or which may constitute an inflamed and oozing eczematous dermatitis and which depend primarily on the vulvovaginal focus.

Forms in the male are seen analogous to the types 4 5 6 7 and 8 (except the creamy discharge which is pus plus mucus from the cervical glands) involving the inguinal pudendal and perianal regions. They respond to similar treatment with 1 to 2% aqueous gentian violet and 1 5 000 potassium permanganate compresses, or to 2% sulfur in Vioform Cream Good ventilation, rest and exposure to daylight help Pruritus ani may in some instances be cured by Oidiomycin hyposensitization (Fowle et al JID 3 193 1940)

Diagnostic of monilial vulvovaginitis the exudate is acidic, and smears show budding parasites. Mycelium appears in the smears at times of maximum severity of clinical symptoms. After wiping an applicator over the mucosa one may stir it in 3 cc of isotonic saline solution then examine a drop of this on a slide Streak Sabouraud s medium to confirm

In treatment vaginal douches using 1 5 000 potassium permanganate and vaginal swabbing with 1 or 2% aqueous solution of gentian violet will control the condition Propionate compound jelly containing calcium and sodium propionates and propionic acid in a water-soluble vehicle has real utility as does AVC Cream

INFANTILE DERMATOMYCOSIS is usually monilial In the cases of infantile eczema so-called in which there occur deep red circular and oval circumscribed but coalescing patches of oozing itchy dermatitis the infection is likely to be monilial and it may have originated in the birth canal I have treated infantile mycotic dermatitis with great benefit by the widespread application of 2% aqueous solution of gentian violet for on the skin this drug is efficient nonirritating and nontoxic Asymptomatic monilial vaginitis in pregnant women—and it is far more common in pregnancy than at any other time—certainly ought to be treated before parturition

See LeHaye quoted by Popoff et al (AmJObGyn 18 318, 1929), clinical forms Plass et al (AmJObGyn 21 320, 1931) Hesseltine (J 100 1 7 1933) Bland et al (ADH 36 [illegible], 1937) experimental inoculation of pregnant and nonpregnant women, review, Hesseltine (AmJObGyn 34 855, 1937) iodine in treatment Woodruff and Hesseltine (AmJObGyn 36 467 1938) in pregnancy and newborn Hesseltine and Campbell (AmJObGyn 35 [illegible] 1938), strain of monilia in pregnant and in diabetic Jones and Martin (AmJObGyn 35 98 1938), [illegible] nonpregnant women Winston and Wickerham (YaleJBM 1 [illegible] 663, 1938), [illegible] flora Lyon and Cruickshank ([illegible] 4 [illegible] 194) in pregnancy Munich (CalMJ 39 [illegible], 1941) treatment with [illegible] sodium perborate [illegible] teaspoon to the quart for douches [illegible] SouthMJ 38 [illegible] 1944) [illegible] (ADH 55 113, 1947) undecylenic acid [illegible] ointment cream Council on Pharm (J [illegible] 1949) propionate compound jelly

MONILIASIS OF THE MALE GENITAL ORGANS —Penile infection as [illegible] vaginal are known and are often due to moniliasis of the wife Conjugal disease has been de-

scribed by Engman (ADS 1 370 1920) Dubreuilh and Joulia (AnndeD 3: 145, 1922) Odland and Hoffstadt (ADS 20: 335 1929) and others. These are curable by circumcision, cleanliness and treatment of the spouse unless they are maintained by urethritis or cystitis of mycotic origin, which probably occurs more often than it is diagnosed. Mycotic urethritis was described by Pi cane a d Coppolino (JTropM 41: 333, 1938) who referred to the description by Castellani (Lancet, 1920) of urethritis with white, red or black discharges due to f ngi Moniliasis of the urinary tract may result in blockage of the ureter by masses of mycelium, even fatal anuria (Taylor and Rundle: Lancet 1: 1-36, 1953)

Monilial Systemic and Generalized Cutaneous Infection.—Generalized cases are comparatively rare In these chronic infections the face ears, neck, upper chest and mouth are usually involved and thick, dry brownish crusts occur on the skin The majority of such cases, complicated by monilial pneumonitis and gastrointestinal infection eventuate fatally The lesions are dry with a tendency to crust and scale The patient complains of little itching except when the interdigital spaces are involved. At no time is severe inflammatory reaction present. The condition is afebrile Massive formation of mycelium and spores can be demonstrated in the lesions. Schultz (J 105 650 1935) is aptly quoted as to the formidable nature of the disorder when it becomes generalized and the remarkable ineffectiveness of any form of treatment Sulzberger (ADS 40 804 1939) claimed benefit in 1 patient with sulfapyridine Hazel and Lamb (OklaSMJ 27 395, 1934) reported a woman 23 years old who suffered from generalized moniliasis for 16 years, all treatment proving futile Antibiotic therapy made 3 of 4 patients worse as might be expected (Nikolowski and Miller DWchn 126 969 1952)

MONILIAL GRANULOMA.—Rare, remarkable granulomatous tumors have been described. Organisms are rife within the masses, which resemble those of bromoderma, according to Hauser and Rothman (ADS 61 297 1950) who reported a case and found 13 similar ones in the literature See Thomas (BJD 62 173 1950) Pluss and Kadas (JID 23 317 1954)

See Downing and Hazard (ADS 31 636, 1935) thick, dry brownish, crusted lesions in boy Carol et al. (AfDuS 175 177, 1938) young woman Danbolt (ActaD-V 21 28, 1940), old man with abscesses and bulla Tulipan and Kleinkatblit (ADS 46 642, 1942) case Strand and H bler (ADS 48 119 1943) case Strickler (AmJDisChild 68 382, 1944) child, helped with iodine ointment Ayres (ADS 53 377 1946) boy with nails, face, scalp lesions, also T purpureum

Visceral Moniliasis.—PULMONARY MONILIASIS, simulating tuberculosis, requires here only to be mentioned. Acute and chronic types hav been described (Warr: AnnIntM 5: 307 1931), with cough, mucopurulent sputum catarrh, fever dyspnea, anemia, sometimes fatality The wide variability of the clinical aspects was stressed by Baker et al. (J 102: 1203, 1934) Cavitation is rarely present. The disease often attacks asthmatics with bronchiectasis (Abrams KansMSJ 51: 562, 1950) Potassium iodide in doses of from 1 to 5 Gm. daily may help.

GASTROINTESTINAL MONILIASIS has received much study Presumably infection results from swallowing the organisms (Anderson: JInfectDis 21: 341 1917) Cultures of stools and of gastric contents were made in many diseases by Nye et al. (AmJMedSci 178: 153, 1939) who found C albicans present in higher incidence in pernicious anemia and achylia, yet believed the fungus not important in the etiology of sprue or avitaminosis. Monilial gastritis has been described as having the potentiality for ulceration or even perforation (Bearse AmJDigestDis 5 674 1938) The organisms are present in the gut in generalized cases, and no way for certainly eliminating them is presently known (see Treatment) The administration of antibacterial antibiotics allows monilia to luxuriate in the gut (see Antibiotics and Moniliasis, p. 549) Compare Acrodermatitis enteropathica (p 644)

MONILIAL ENDOCARDITIS was recognized from blood cultures in several cases by Pasternack (AmJClinPath 12 496 1942) Kunstadter et al. (J 149: 829 1952) found 24 cases of mycotic endocarditis in the literature of which 9 were known to have been monilial, and 5 of these occurred in drug addicts. Their patient was an infant, a unique case

MONILIAL MENINGITIS has been known to occur though it is rare Pressure of the spinal fluid is high, giving rise to headache and edema of the optic nerve head. Diagnosis depends on demonstration of the organism in the spinal fluid. The patient of Zimmerman et al. (J 135: 145 1947) who also had oral thrush, recovered probably as the result of the administration of streptomycin. The disease was fatal in the case reported by Halpert and Wilkins (J 130 932, 1946)

SEPTICEMIA was present in the pulmonic and disseminated case of French and Sheard (CanadMAJ 71 238 1954) *Candida albicans* was present in the neutrophil leukocytes. Miliary granulomatous and necrotic lesions were found at autopsy

Fig. 715.—Monilial dermatitis of feet. (Dr. Royal S. Montgomery.)

Figs. 716 and 717.—Monilial granuloma, [illegible] case of Drs. Stephan Rothman and F. V. Hauser (AD&S 61: 297, 1950.)

Immunology Skin Tests and Vaccinal Therapy in Moniliasis.—The humoral and tissue reactions to Oidiomycin are analogous with those to trichophytin. Monilia are potent sensitizers. Treatment by vaccinal hyposensitization has basis in theory but in practice attacks upon the foci of the organisms by means of antiseptics and débridement afford better effect. Trichophyton and Candida are immunologically distinct Skin tests with monilial extracts may be interpreted much as trichophytin tests are (Lewis et al NYSJM 37: 878 1937 38 859 1938) They are of little practical value Patients, for example with monilial pruritus ani, hyposensitized by allergists with Oidiomycin, come to me to be cured by other means.

MONILIDS.—These allergic eruptions occurring specifically in moniliasis are the counterparts of trichophytids. As a rule they consist of tiny closely aggregated, intraepidermal vesicles, and they may be set upon a more or less inflamed base located on the hands, legs or flexures. They may depend on foci in the nails, glabrous skin, tonsils, mouth, vagina, auditory canal or gastrointestinal tract It is commonplace to cure pompholyx of the hands by treating tinea of the feet when pompholyx is a trichophytid I have cured repetitious, pompholyx like eruptions of the hands by means of douches of 1:3 000 potassium permanganate and the application of gentian violet to the genitalia, without treating the hands themselves.

See Hopkins (ADS 25 593 1932) sensitization from gastrointestinal focus; Biberstein and Epstein (ArDuS 165 716, 1932) clinical picture and immunity; Sulzberger (JImmunol 23: 73 1932), immunologic differences between trichophytin and Oidiomycin, preparation of fungus extracts Kerr et al. (JAllergy 5 288, 1934) monilial sensitivity separate from that of trichophyton and epidermophyton.

Etiology—Infection with monilia like all infections, depends upon both the soil and the organism. In food deficiencies, particularly avitaminosis B and in diabetes the individual is more vulnerable Environmental circumstances may favor or inhibit the growth of the organisms, and moisture, warmth and darkness, as in tinea abet pathogenicity *C albicans* is described on p 478

ANTIBIOTICS AND MONILIASIS.—Moniliasis is a recognized complication of antibiotic therapy (*Edit: SouthMJ 44: 231, 1951*) *Stomatitis following therapy for brucellosis* was reported by Harris (J 14 161 1950) and black hairy tongue consequent upon antibiotics was reported by Downing (NEngJM 4 1013 1950) The stools, when bacterial growth is suppressed, become curiously foul, or perhaps odorless, and diarrheic; and pilar or perianal dermatitis, when it appears, shows an abundance of Candida. Many cases of clinical moniliasis following the use of penicillin, Aureomycin and chloramphenicol were reported by Woods et al. (J 145 207 1950) See also Reiches (ADS 64 604 1951); Seligmann (PSExpB 79: 481 1952); Edit (J 149 762, 1952) Candida was found in the peritoneum of a patient of Reynell et al. (BMJ 1: 919 1953) who died following perforation of a peptic ulcer after he had received Aureomycin and ACTH. In an excellent review of the subject Hutchison (JKansMS 54 436 1953) collated 2 fatalities, including 15 from endocarditis and 6 from meningitis. Anorectal complications of antibiotic therapy in 300 patients were reviewed by Manheim and Alexander (NYSJM 54 231 1954) whose cases included pruritus in 207 multiple fissures in 51 ulcerative proctitis in 14 abscesses, fistulae or ulcers necessitating surgery in 14 and ulcerative colitis in 5 Yet most cases in fact recover spontaneously and local therapy is quite effective (Turell and Maynard: J 156 17 1954) Permanganate soak and 2% sulfur in Vioform Cream are useful. Interpreting the perianal dermatitis as representative of pellagra, Morris (GP 9 71 1954) eel traced the value of nicotinic acid. Monilia must be present already if they are to luxuriate under antibiotic therapy *which cannot create the infection according to Robinson (ADS 70: 640 1954)*; in the discussion of this paper hazards of antibiotics in older people who are more likely than young persons to harbor the organisms in the gut, was stressed by Swartz. I have seen significant trouble only in individuals grossly overdosed, whose complication would have been trivial if it had been recognized early and the drug discontinued. Robinson set the figure at 16% as the incidence of *C. albicans* occurring among the normal flora of the gut. He gave about the same figure for its presence in the vaginal tract of normal pregnant women and the oropharynx of normal persons. The growth of *C albicans* on artificial media is neither stimulated or depressed by antibacterial antibiotics he stated, so that the development of monilia is following antibiotic therapy may result from lowered resistance to the fungus perhaps because it overgrows when competing organisms are suppressed. Yet only has vulvovaginal moniliasis increased in incidence since the introduction of broad spectrum antibiotics, but also moniliasis of the male genitalia, evidently as a result of sexual communication of the infection, believed Walsman (ADS 70: 718, 1954)

Cortisone and ACTH therapy was accredited with increasing susceptibility to monilia by Brathund and Holten (abs J 156: 1119 1954) I have not observed this.

Treatment.—To be comprehensive and permanently effective treatment must be directed at the eradication of all *foci* both in the skin and elsewhere. The accessible parasitized tissues should be kept dry and ointments have little to commend them if they allow a film of sweat or ooze to collect, protected from evaporation. Gentian violet has been used for many years and it is one of the most effective parasiticides. Baths in 1 8 000 bichloride of mercury are useful. Douches of 1 5 000 potassium permanganate are fairly satisfactory bichloride of mercury must not be used for this purpose. In pregnancy suppositories of 1 1 000 Merthiolate are of sufficient value to warrant their trial (McIlrath MJAustral 2 54, 1946) Cool, moist packs for 15 to 30 minutes, alternated with drying in a current of air under the influence of radiant heat are effective Roentgen therapy offers temporary alleviation of inflammation, but it must not be repeated beyond the limit of tolerance and of itself it is not curative.

In paronychia, 5% chrysarobin in chloroform is a useful paint.

In onychomycosis, débridement 10% $AgNO_3$ and x ray therapy may be used.

In stomatitis, cleanliness is an important prophylactic measure. Fingers should not be put into babies mouths. Gentian violet has an important place Sodium perborate may be used both for tooth powder and for mouthwash. Vitamin B complex should be given in adequate dosage (Bechet NYSJM 43: 2065 1943)

The generalized cases tax every medical resource and almost all cases on record have turned out badly Hope may be afforded by Mycostatin an antifungal antibiotic. Mycostatin (Nystatin, Squibb) was said to have helped *several cases, according to communications received by Squibb from Holt,* Robinson, and Kunstadter Their literature states that Mycostatin is derived from cultures of *Streptomyces noursei* (Hazen and Brown Sci 112 423 1950) Pale yellow almost colorless, in crystalline form, it is less soluble than when only partially purified is relatively stable when dry but breaks down rapidly in the presence of water It inhibits or kills many fungi but not actinomycetes (Tarbet et al Mycologia 45 627 1953 Raubitschek et al Antibiot&Chemother 2 179 1952) being most effective against yeastlike fungi in their growing stage and less active against spores. Given orally it is poorly absorbed and virtually nontoxic. Large doses have caused nausea and vomiting side effects have been absent or trivial. The drug may be prescribed for the suppression of intestinal fungi, and when given concurrently with tetracycline it apparently protects against the overgrowth of monilia. An old woman with systemic cutaneous and urinary tract infection was reported cured with Mycostatin by Robinson (*JID* 24 375 1955) who prescribed tablets of 500,000 units t i d and an ointment containing the substance for use in the vagina The ointment is effectual but Nystatin irritates some individuals even in a concentration of only 100 000 units per gram Osbourn (AD 72 371 1955) recommended a shake lotion containing 3 tablets in 60 cc of vehicle.

See Widt (ADS 18 479 1928) yeastlike organisms cultivated from 152 of 721 patients with scaling or crusting lesions, some resembling seborrheic dermatitis Stovall and Bubolz (JInfectDis 50 73, 1932 AmJPubH 22 493, 1932 JLCM 18 898, 1933) cultural features, pathogenicity Denham and Hopkins (ADS 28 532, 1933) normal flora does not contain *C albicans* Cornbleet (J 104 1976, 1935) higher concentration of reducing substances in sweat of infected persons than of normal Lamb and Lamb (JInfectDis 56 8, 1935) fermentation and precipitation distinctions, Smith and Lewis (SouthMJ 29 1087 1936) M causing ulcers of ankle responsive to KI Martin et al (JBact 34 99 1937), classification and culture technic Anderson (MJAustral 2 57 1946) cultivation on corn meal extract with ... George and Plunkett (JID 10 337 1948) dissociation of *C albicans* in cultures Riley and Flower (JID 18 285, 1950) inhibition by gentian violet greatly exceeds that by Castellani paint, of which basic fuchsin is the effective ingredient in vitro

TORULOSIS (CRYPTOCOCCOSIS EUROPEAN BLASTOMYCOSIS)

Torulae are yeastlike plants distinguished from higher yeasts in that they form neither endospores nor myceliums, and from Saccharomyces in that

torulae are pathogenic and characteristically do not ferment sugars (Mitchell J 106 450 1936) Rarely *Cryptococcus neoformans* (*Torula histolytica*) produces superficial lesions, but it does not ordinarily invade the skin.

Cutaneous lesions have not been uniform in their clinical manifestations. There have been described (Wile ADS 31 58 1935) acneiform involvement of the forehead furunculoid sores of the thighs associated with broad patches

Fig. 718.—Torulosis. (Dr Udo J Wile.)
Fig. 719.—Torulosis affecting gingivae (Urbach AfDuS 162 401, 1930.)
Fig. 720.—Torula grown from case of Dr Udo Wile.
Fig. 721.—Torula in tissues from case of Dr Udo Wile.

of induration of thigh and popliteal tissues, gummas of the abdomen with hard purplish nodules of the cheeks, swellings on the forehead and neck and over the tibia a granuloma confined to the foot and a mycetoma-like lesion of the foot. Diagnosis depends on identification of the causative fungus. Torulae cause fatal tuberculoid meningitis or encephalitis. They are as often associated with Hodgkin s disease as tuberculosis is (Mallory NEngJM 210 1291 1934)

In their review Cawley et al. (JID 14: 327, 1950) described 13 cases of cutaneous torulosis, 10 of which were associated with central nervous system involvement. The skin lesions in 6 cases were located on the face, scalp and neck; in they were on the trunk. Four were acneiform, 4 pustular or nodular, 3 ulcerative abscesses, and granuloma. 1 showed nodules and plaques resembling ecchymoses and 1 a sinus tract. Mucosal lesions were present in 4 cases, showing violaceous nodules of granulation tissue, tumors and ulcerations. Mucosal lesions occurred on the gums, palate, pharynx, tonsillar pillars, buccal mucosa, nasopharynx and nasal septum. The only lesions clinically diagnostic were the acneiform ones. These authors found 120 human cases in the literature and added their 5 cases to the total.

Fig. 721.—Rhinosporidiosis: mucosal fungations and cutaneous implants in an Indian. (Drs. F. Allen and M. L. Da[illegible] IndMedGaz 77: 376, 1936.)

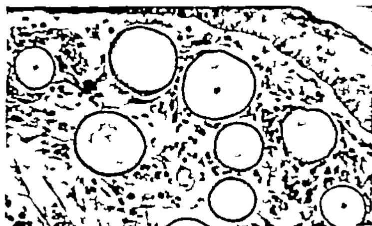

Fig. 722.—Rhinosporidiosis: section showing cystic pattern. (Dr. Ed[illegible] A. Gall.)

Treatment is unsatisfactory, although roentgen therapy, iodides and gentian violet may be tried and excision may be performed if feasible. One may hope that stilbamidine or related compounds (see Blastomycosis, treatment) will prove effectual.

See Stoddard and Cutler (Torula Infections in Man, Rockefeller Inst. N. Y., 1916); Urbach and Zach (ArDerm 162: 401, 1930), oral primary; Weidman (SouthMJ 6: 85, 1933), case in monkey; Benham (ADS 30: 385, 1934; JInfectDis 57: 255, 1935), mycology; Fitchett and Weidman (ArchPath 18: 225, 1934), associated with Hodgkin; Mook and Moore (ADS 33: 951, 1936), fatal, brain and skin; Levin (ArIntM 59: 667, 1937), central nervous; [illegible] (ADS 37: 461, 1938), deep cutaneous lesions; [illegible] Tolhurst (Human Torulosis, [illegible] Univ. Press, 1936), monograph, 12 cases; Daniel et al. (ActaD-V 33: 10., 1953), acneiform exacerbation in chronic pulmonary case.

RHINOSPORIDIOSIS

Rhinosporidium seeberi is a phycomycetic parasite occurring in the form of spherules of various dimensions within the polypoid masses which its presence elicits. Young cysts some 6 μ in diameter have a chitinoid envelope, a vacuolar cytoplasm and vesicular nucleus. Old cysts reach a diameter of 300 μ and have a cellulose-like envelope enclosing numerous singly nucleated spores within a mucinous brown ground substance. The organism has never been cultivated.

Primarily affecting the mucous membranes, usually of the nose and sometimes of the conjunctivae, the lesions due to *R. seeberi* are pedunculated or sessile strawberry-like or raspberry-like tumors consisting of tightly packed tendrils suggestive of filiform verrucae. Cutaneous lesions, solitary or multiple, are usually the result of inoculation from foci located elsewhere according to Allen and Dave (IndMGaz 71: 376, 1936) who described 60 cases and gave a full bibliography. Ocular cases were collated by Kaye (BJOphth 22: 449, 1938); he likened the typical lesion to a cockscomb and described the villous polypi with easily bleeding granulations, the crypts of thickened epithelium, the granulomatous inflammation with plasma cells and lymphocytes, and the rhinosporidium cysts, chiefly subepithelial, their white sporangia macroscopically visible on the surface of the lesion. The infection remains local but is unsightly, uncomfortable and sometimes obstructive to air passages. Most cases have occurred in India and South Africa, but of the 12 reported by 194– in the United States, 4 were Texan (Pasternack: TexasSJM 38: 285, 194–). Cure may be sought with surgical excision or cauterization. Neostibosan seemed adjunctively helpful to Allen and Dave.

See Ashworth (TransRoySocEdi 53: 301, 1923) bibliography; Karunaratne (JPathBact 42: 193, 1936) bibliography after Ashworth's, color plates; Caldwell and Roberts (J 110: 1641, 1938) seventh U. S. A. case, all nasal; Ruchman (AOtol 30: 239, 1939) nasal case helped by antimony, as suggested by Wright (IndMJ 57: 8: 81, 1922); Ormsby and Brown (ADS 54: 231, 1946) conjunctival case.

THE MYCETOMAS

Mycetomas are granulomatous mycotic lesions enclosing fungus grains of various shapes. The grains are formed by felted mycelium and they are discharged through more or less extensive fistulas. In contrast with the tineas, which in general produce only superficial disease, the mycetomas are due to other fungi which produce deeply seated granulomatous inflammation. They gain access into the human body through injuries as a rule, and the foot is particularly vulnerable.

Madura Foot.—This is a clinical entity capable of being caused by various organisms. A typical mycetoma, it is characterized by swelling and gradual disintegration of the subcutaneous structures and the formation of sinuses which open onto the surface of the skin. These mycetomas are characterized by grains formed by voluminous, septate mycelial filaments possessing definite cross walls and forming chlamydospores.

Following an injury, an incised or puncture wound, there develop within a few weeks swelling, edema and indurated nodules. More nodes develop until the affected patch presents a purplish, knobby appearance as in actinomycosis. Some nodules remain firm and solid, but the majority of them undergo necrosis, so as to become perforated by slender, tortuous channels which extend deeply and let escape variable amounts of seropurulent fluid containing variously colored grains. Spontaneous cure is extremely rare. The course may run for many years. Metastasis ordinarily does not occur, but the progress locally is such as to eventuate almost inevitably in amputation.

The disease is seen in tropical climates, where numerous individuals go barefoot, but an occasional case occurs in North America. Barns et al. (AmJClinPath 15: 35, 1945) summarized the 35 cases recorded as occurring in the U. S. A. and Canada by 1945. See Edit (J 141: 1800, 1949) giving description and review as follows: many species of fungi belonging to several genera have been implicated in the various types of maduromycosis, which, nevertheless, may clinically resemble each other closely. Cases may be divided into three groups: (1) those with changes confined to superficial structures in the form of granulomatous lesions of the skin or of the skin and subcutaneous tissues; (2) those with 1 or more fibrous, fatty or occasionally cystic nodules without ulceration of the overlying skin; and (3) the commonest group, wherein lesions are present as multiple subcutaneous nodules which are movable, painless and nontender. Spontaneously or sometimes as a result of injury the nodules rupture and discharge mucopurulent material containing white, yellow or black granules, depending on the particular parasite present, the white or yellow varieties predominating. Maduromycoses have been classed according to the blackish, whitish or reddish color of the fungus grains, but

Fig. 724.—Mycetoma. (Sutton J 60: 1330 1912.)

Fig. 725.—Madura foot, Texas case. (Dr O. Garcia.)

Fig. 726.—Mycetoma.

Fig. 727.—Section of foot amputated because of maduromycosis.

grains of the same color may be produced by more than one parasite. There have been identified as causative organisms species of Nocardia, Allescheria, Aspergillus, Penicillium, Madurella, Indiella, Cephalosporium, Monosporium, and Glenospora (Conant et al.: Manual of Clinical Mycology Saunders, 1945 modifying Gammel: ADS 15: 41 1927)

TREATMENT.—Potassium iodide copper sulfate and various internal remedies, including sulfonamides (Dixon ValMonth 68 281 1941) and penicillin, may be tried. One of 2 patients of Twining et al. (USNMB 46 417 1946) was cured by penicillin the other relapsed and required amputation. Temporary improvement may follow roentgen therapy. Secondary infection may cause death. Treatment is likely to entail eventual amputation.

MADUROMYCOSIS. ETIOLOGIC CLASSIFICATION ACCORDING TO BRUMPT
(Précis de Parasitologie Masson, 1949)

Black Grain Type

ALEUROSPORIA
- *Glenospora semoi* (Chalmers and Archibald, 1917) India.
- *G. khartoumensis* (Chalmers and Archibald, 1916) Africa.
- *G. clapieri* (Catanei, 1917) Africa.
- *G. gammeli* (Pollacci and Nannizzi, 192?) North America.
- *Scedosporium sclerotiale* (Pepere 1914) Europe

White or Yellowish White Grain Type

ALEUROSPORIA
- *Scedosporium apiospermum* (Saccardo 1911) cosmopolite.
- *Indiella mansoni* (Brumpt, 1906) Asia.
- *I. reynieri* (Brumpt, 1906), Paris, Greece
- *I. brumpti* (P. Piraja, 1922) Brazil.

SPOROPHOREA
- *Cephalosporium recifei* (Leao and Lobo, 19?4), Brazil.
- *Cephalosporium granulomatis* (Weidman and Kligman 1945)
- *Acremonium potroni* (Vuillemin, 1911) Algeria.
- *Acremoniella lutzi* (Area Leao and Lobo, 1930)

PLECTASCALES
- *Sterigmatocystis nidulans* (Eidam, 1883) Tunis and Algeria.
- *Allescheria boydii* (Shear 1921) U. S. A.

Greenish Yellow Grain Type

- *Aspergillus amstelodami* (Mangin, 1900) Brazil.

Red Grain Type

- *Aspe gillus* (case of Balfour and Archibald) Africa.
- *Rubromadurella langeroni* (Talice 1935) Uruguay

See Castellani and Chalmers (Tropical Diseases, 1920 p. 2110); Gelman and Gammel (Abury 31: 298, 1932), white grain case, *Monosporium apiospermum*; Shaw and Macgregor (CanadMAJ 33 23, 1935), first Canadian case *M. apiospermum*; Dowding (CanadMAJ 33 28, 1935); Aldridge and Kirk (BJOphth 24 211 1940) yellow; Fienberg (AmJClinPath 14 230 1944) case, *M. apiospermum*; Twining (ADS 50 332, 1944) case, *M. apiospermum*; Symmers (APath 39: 358, 1945) rabbit inoculations with *Phialophora jeanselmei*; Calero (ADS 55 761, 1947) Panama cases; Elliott (J 142 882, 1950); Quinland and Chenault (SouthMJ 43 661 1950) case, *M. apiospermum* contracted in Europe; Carrión (Mycologia 43 522, 1951) case, *Cephalosporium falciforme*

Actinomycosis (Lumpy Jaw) is produced by various microaerophilic fungi which within the tissues form grains composed of fine nonseptate mycelial filaments, in which the partitions are invisible or difficult to demonstrate and in which chlamydospores are not formed. *Actinomyces bovis* is the commonest cause in the United States. It provokes sluggish, nodular infiltrated lesions.

Fig. 728.—Actinomycosis. (Dr Jabez N J ckson.)
Fig 729.—Actinomycosis. (Dr T W Allsworthy.)
Fig. 730.—Actinomycosi of the neck and jaw showing granulomas and sinu tracts draining through the skin. (Dr H. O. Varney.)

Fig. 731.—Actinomycosis. (Dr Sam J Sweitzer.)

which tend to undergo central necrosis and to form chronic subcutaneous abscesses and sinus tracts. The lesions develop slowly Inoculation through the teeth gums or tonsils results in the development of infiltration in the jaw (lumpy jaw) and neck. The nodules may require weeks or months to soften and to become fluctuant Overlying tissue slough, and purulent matter

Fig. 732.—Actinomyces Gram stain showing mycelium of the interior of the fungus mass. (Dr Frederick Wakeman.)

Fig. 733.—Actinomyces ray fungus seen in section Gram stain, showing filaments in interior "Clubs" are seen at the upper margin of the grain. (Dr Frederick Wakeman.)

Fig. 734.—Actinomycetic granule in pus, unstained, X75. (Dr E. Muskatblit.)

mixed with small masses of fungus resembling grains of sulfur discharge from them. The involved region is usually isolated, but generalization may occur The usually yellowish gray granular masses of fungi in the discharge should serve to differentiate actinomycosis from syphilis, tuberculosis, sarcoma or carcinoma. Pus is put in a tube of water and shaken the sulfur granules sink (Colebrook Lancet 1 893 1921)

The organism may be carried nonpathogenic, for it has been found in pus from tonsils and from pyorrhea in, respectively 11 and 18 of 100 examinations performed by Slack (JBact 43 193 1942) Oral trauma appears to be causally related to invasion by Actinomyces (Sullivan and Goldsworthy JPathBact 51 253 1940) *A. israeli* is said to be a normal member of the oral flora (Robinson and Ennever OralSurg 1 850 1948) Aspiration probably accounts for primary pulmonic cases. The disease has followed human bites (Robinson J 124 1049 1944)

Cervicofacial cases are the commonest Pulmonary and deep abdominal cases follow in order of frequency and any part of the body may be infected. In the tongue primary actinomycosis has its onset as a painful swelling which is round, tender and located in the anterior third it becomes softer discolored, purplish and painful, and matter discharges through sinuses (Cameron J 99 1146 1932)

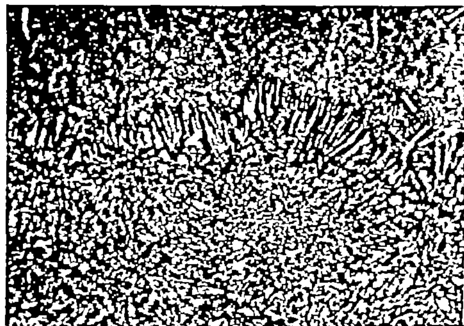

Fig. 31.—Actinomycetic granule in pus X60 (Dr E. Muskatblit.)

Cases primary in the skin, with subsequent fatal hepatic involvement in 1 were reported by Salzmann and Kessler (ADS 36 131 1937) The skin primary which resembled a felon resulted in fatal chronic purulent meningitis reported Morrison et al. (J 110 1552 1938) Infection in the ear not rarely leads to meningitis 76 such cases were collated by Cann and Hollis Lancet 1 130 1931 When the nervous system is involved, the spinal fluid usually is thickly purulent with a high count of polymorphonuclear leukocytes and the patient, appearing not markedly toxic, carries a fever of only 101 F or so and shows paralyses of several cranial nerves Friedman and Levy InternatClin 2 36, 1931 Such a patient may die suddenly

Etiology —Actinomyces may live as saprophytes on some kinds of vegetation and even on human tissues and in tonsillar crypts Their introduction as parasites is usually due to an injury which of itself may be of seeming inconsequence According to Brumpt (1949) the Hyphomycetes are fungi which have a white or dust filamented thallus and which reproduce exclusively by conidia Hyphomycetes with fine nonseptate mycelial filaments 1 μ or smaller in diameter branching laterally having homogeneous content and lacking distinct nuclei, often dissociating into bacteroid particles are Microsiphonales All of the Microsiphonales parasitic on man may be classed in the genera Actinomyces and Nocardia.

Pathology —Actinomycetic parasites develop well in all tissues of the body but clinically they seem to spare the lymph nodes In sections of the granulomas macrophages filled with mycelial filaments are numerous near the vessels Masses of fungi are scattered within the granulation tissue forming the well known clubs The detailed structure of the clubs differs in different kinds of actinomycetic infection and may serve the expert for differentiation, although cultural studies are necessary for exact identification. Problems in diagnosis were elucidated by Weed and Baggenstoss (AmJClinPath 19 201 1949) who observed, in studying

35 fatal cases that one may find structures resembling sulfur granules not yet containing Actinomyces while some cases yield the anaerobic organism on culture but never exhibit sulfur granules.

PROGNOSIS.—Most of the localized cases undergo recovery. Many systemic cases have died. Systemic involvement following upon localized disease is always possible. The disease may heal spontaneously but this is very exceptional. Its progress causes cachexia, suppuration, reduced resistance, and secondary infection. Sulfonamide and antibiotic therapy has in recent years improved the outlook greatly.

ACTINOMYCOSES. ETIOLOGIC CLASSIFICATION ACCORDING TO BRUMPT (1949)

Black Grain Type

Case of Babes (1898) Roumania.
Case of Mironescu (1910), Roumania.
Case of F. de Almeida (1930), hepatic Brazil.
Case of Beron (1931) Bulgaria.
Actinomyces paraguayensis (de Almeida 1940)

Yellow Grain Type

With clubs

BREVIORES (ACTINOMYCES):
- *Actinomyces israeli* (Kruse 1896) cosmopolit [Affects bones anaerobic.]
- *A. thibiergei* (Ravaut and Pinoy 1906) [Does not affect bones.]

MINORES (NOCARDIA):
- *N. mexicanus* (Boyd and Crutchfield, 1921) Mexico and Texas.
- *N. transvalensis*, *N. pretoriana* (Pijper and Pullinger 1927) South Africa.

Without clubs

MAJORES (STREPTOMYCES):
- *S. liquefaciens* (Hesse 1892) Europe
- *S. gartoni* (Brumpt, 1910) Europe

MINORES (NOCARDIA):
- *N. asteroides* (Eppinger 1890) cosmopolite
- *N. brasiliensis* (Lindenberg, 1909) Brazil.
- *N. brumpti* (Bordjoski and Milochevitch, 1915) Jugoslavia.
- *N. madurae* (Vincent 1894) cosmopolite
- *N. nicollei* (Delanoë, 1928) North Africa.
- *N. convoluta* (Chalmers and Christopherson, 1916) Sudan.

INCERTAE SEDIS:
- *A. krausei* (Chester 1901) Europe
- *A. ponceti* (Verdun, 1912) Europe
- *A. gerrai* (Lageron 1930) San Salvador [Affects bones.]

Red or Reddish Grains

Without clubs

MINORES (NOCARDIA):
- *N. somaliensis* (Brumpt, 1906) Africa. [Affects bones.]
- *N. bahiensis* (P. da Silva, 1919) Brazil.
- *N. mycetomae argentinae* (Greco, 1901 Durante, 1911) Argentina.
- *N. pelletieri* (Laveran, 1906), Africa.
- *N. africana* (Pijper and Pullinger 1927) [Affects bones.]
- *N. genesii* (Froes, 1930) Brazil.

TREATMENT.—Iodides have long been standard therapy but sulfonamides and penicillin soon proved their worth as they became available. The patient of McCrea et al. (JLCM 30 509 1945) responded to 120 000 units of penicillin q. 3 h. after failing to respond to 20 000. Of 11 cervicofacial cases 7 were cured and 4 arrested by Dobson and Cutting (J 116 272, 1941; 128 856 1945) using penicillin or a sulfonamide one being sometimes more effective than the other. In a study of 16 cervicofacial cases, Lamb et al. (J 134: 351, 1947) concluded that roentgen therapy and sulfadiazine by mouth suffice in uncomplicated instances, while penicillin must sometimes be given in large doses over a long period of time and is valuable. Penicillin in 45 cases gave best result in pulmonary abdominal and pelvic infections, reported Nichols and Herrell (JLCM 32 1405 1947). A sulfonamide and penicillin cured the patient with central nervous involvement of Jacobson and Cloward (J 137 769 1948). The patient of Arnold and Austin (J 138 955 1948) with lumpy jaw not helped much by penicillin, was cured by Diasone 1 Gm. daily. Of the 6 patients of Chanton et al (SouthMJ 41 1022, 1948) only 2 required surgery when treated with both penicillin and a sulfonamide along with transfusions. Extremely large doses of penicillin may succeed when modest doses have not produced benefit (Sanford and Barnes Surg 711 1949).

Aureomycin cured a mandibular infection that followed extraction of a tooth (McVay et al. J 143 1067 1950 AnnIntM 38 955 1953) and a cervical case of Wright and Lowen (J 144 21, 1950) Terramycin likewise was effectual in doses of from 750 to 2,000 mg daily in 7 cases of cervicofacial infection with *A bovis* (Lane et al. J 151 986 1953) Thymol 10 to 20% in olive oil, has been applied locally and injected into the sinuses, and 1 to 2 Gm of thymol in capsules was given by mouth daily on an empty stomach (Myers J 108 1875 1937 Joyce AnnSurg 108 910 1938 Glemens JPed 16 487 1940) Isoniazid is inhibitory in vitro and, given to 3 patients, yielded results thought encouraging by McVay and Sprunt (J 153 95 1953)

Locally surgical measures are important for incision and drainage débridement and sometimes, plastic repair work contribute to the cure. Osteomyelitis of the jaw is not uncommon and requires the help of the oral or orthopedic surgeon.

Fig 34—Facial mycetoma due to *Nocardia mexicana* (Gradwohl, et al. Clinical Tropical Medicine Mosby 1951)

Fig 35—Nocardiosis of forearm, 5 months duration. (Dr Sam E. Sweitzer)

Roentgen therapy was of greater repute before the modern drugs became available than it is now yet it will, properly used resolve to a significant degree the chronic granulomatous tissue It was at one time adjudged the most important measure available in addition to surgical drainage and the *administration of iodides* (Keijser Strahlenther 56 449 1936)

See Thomassen (L Echo Vet 1885) introduction of iodide in treating tongue cases in cattle popularized by Nocard in 1892 Wolff and Israel (ArPathAnat 126 11 1891) original description of organism most commonly causati of actinomycosis Jacobson (MedJ&Rec 132 342, 3 9 431 1930 5 cases and review Lord and Trevett (JInfectDis 58 115, 1936) organisms in normal mouth Neuber (WienKlinWschr 50 11 6, 193) attempted immunologic treatment Hay and Tribedi BJS rg 26 30, 1938 mammary cases, Cope (Actinomycosis Oxford Univ Press, 1938 p 245) monograph, color plates, quotes Wright who has established cases in 1903 Walker (Lancet 1 1219, 1938), bilomical case following sulfanilamide, cured with sulfanilamide Miller and Fell (J 112 31 1939) case confirming Walker Hall (J 112 219 1939) salpinx ... red with sulfanilamide Tribedi and Mukherjee (IJSurg 2 36, 1939) 35 Calcutta Medical College cases Kolshalk and Wilen (WestJSurg 48 212, 1940), 11 cases due to *A bovis* Franklin (AnnIntM 13 1293 1940 *A muris* Davis (ArchSurg 52 447 1941 46 cases, ... of Michigan, grass-chewing and proximity to animals not the significant in etiology Dobby and Knighton JInfectDis 69 146 1941), oral flora Hamilton and Kirkpatrick BMJ 2 ... 9 194) penicillin cures MacGregor (ProcRoySocM 38 619 1945) differences between human and bovine strains, ... relations to penicillin sensitivity Meckstroth (ADS 66 ... 96 194 penicillin cure review Farris and Douglas (Surg 24 414, 1947), penicillin and sulf both ... cure 5 cases, bilomical, Robinson and Taker (AnnRheum Dis 2 1, 1949) 4 Southern California cases sulf and penicillin not so wonderful Waksman (The Actinomycetes Herbert Hafner N Y 1950), mycology follow Bergey classification Garrod (BMJ 1 1 63, 1952) antibiotic sensitivity in 12 strains of *A israeli* penicillin best

Oosporosea.—Oospora was the genus name now obsolete, but once used to apply to the organisms seen in diseases resembling actinomycosis but in which actinomycotic grains were absent (Brumpt)

Nocardiosis.—Nocardia comprise, according to Brumpt (Précis de Parasitologie Masson, 1949 p. 1 13) a genus of Actinomycetaceae of the following features: easy to cultivate; powdery odorless colonies on solid media resembling those of *Myco tuberculosis* filaments rarely branching almost always acid fast; not liquefying gelatin or producing diastase.

Numerous species are capable of causing the clinical features of actinomycosis (q.v.) In nocardiosis the lesions, according to Weidman (Appleton's System of Med. 10 192, 1937) "usually resemble indolent furuncles of a sort which does not heal either spontaneously or under ordinary surgical treatment; the symptoms, resembling those of a gumma, are not so acute Occurring primarily on the thumb, the affection may extend as a line of gummas along the forearm so as to imitate sporotrichosis [like the case reported by Guy: ADS 2 137 1920]; only laboratory examinations can settle the diagnosis. In one case, there was brawny swelling around the ear; in another [Potron and Thiry: RevmédiEst 45: 159 193, 1913] a lesion on the neck resembled impetigo on the surface but a nodular mass lay underneath. Abscesses have been produced in the inguinal and lumbar regions by *N liquefaciens*, and *N gortezi* caused abscesses in the back and vertebrae. *N pedroensis* and *N fowleri* et al were found secondary to pulmonary disease. *N thibiergei* produced a subcutaneous gumma in addition to widespread lesions in the muscles. *N londinensis*, *N luteolus*, and *N krausei* may extend from the mouth to the subcutaneous tissues of the face. The symptoms may simulate deep ringworm, tuberculosis, actinomycosis or other fungous affections. The prognosis must be guarded, particularly in cases where there is deep extension, for there is the possibility of fatal generalization and death. If diagnosed early and treated with the iodides, there is hope for cure Iodide therapy is successful only when certain species of Nocardia are concerned: *N israeli*, *N liquefaciens*, *N gortezi* and, to a lesser extent, *N pulmonalis*. *N thibiergei* and *N asteroides* infections are resistant to iodide therapy Intensive iodide therapy combined with deep x-ray therapy and surgical evacuation of pus are advisable.

Sulfonamides, penicillin and other antibiotics are sometimes curative A case involving a child's foot consequent to a penetrating injury was identified histologically but not by cultures by Lamb et al. (ADS 67: 141, 1953) Pregnenolone was given orally in a dose of from 200 to 300 mg daily for 8 months, and cure resulted. The drug was chosen because it does inhibit *N asteroides* in vitro

See Davis (AIntM 14: 1, 1914); Pijper (MJSoAfrica 11 141, 1916), Christopherson and Archibald (Lancet 2: 847 1918); Gregor (J 79 812, 1922); Mason and Frost (CalifBJM 21 471, 1923); Foerster (AmJMedSci 167 54 1924) bibliography; Guy and Jacob (J 82 1862, 1924) cases following perforation of ear lobe; Pijper and Pullinger (JTropM, 30 153, 1927) mycetoma due to *N pretoriana* Guy and Helmbold (ADS 27: 224 1933), case, multiple gangrenous granulomas; Cutting and McCabe (AmJPath 25 1, 1949) case, abdominal lymphogranulomatous mass; Hager et al. (NEngJM 241 226 1949) *N asteroides* pneumonitis and empyema, cured with sulfadiazine, penicillin and streptomycin; Bernstein et al. (AnnIntM 36 852, 1952) 42 cases reviewed, resemblance to pulmonary tuberculosis, cerebral lesions, unresponsiveness to antibiotics. Hickey and Berglund (ArchSurg 67 381 1953) 5 cases cured with sulfadiazine, penicillin, Terramycin and appropriate surgery; Moore et al. (ADS 70 307 1954) ulcer near knee due to *N brasiliensis*

SPOROTRICHOSIS

Sporothrices are conidiospore fungi (Hyphomycetes) in which the conidia, simple or septate, hyaline or fuliginous, are discrete and are inserted directly into mycelial filaments. The conidia are mounted on a little pedicle (stipitate) in the genus Rhinocladium, a distinction Brumpt made in dividing Sporothrix into the two genera, Rhinocladium and Sporotrichum. Many of these fungi are of common natural occurrence, living as saprophytes; some of the species are able to parasitize man, animals and plants. There is good reason to believe that *Rhinocladium schenki*, isolated in the United States, is the same as *R. beurmanni*, isolated in France. Other pathogenic species include *R. dori*, *R. gougeroti*, *R. jeanselmei*, *R. indicum* and *R. councilmani*. See Schenck (BullJHH 9: 286, 1898) Cultural characteristics are given on p. 479

Symptoms.—Sporotrichosis is contracted generally by those who come in contact with the soil and shrubs, and infection follows some trifling injury such as the prick of a barberry thorn or the peck of a chicken I like Gastineau et al. (J 117 1074 1941) have seen numerous cases in florists. There was an epidemic involving several children in one part of Kansas City apparently contracted in a particular moldy trash dump

Clinical types of sporotrichotic manifestation have been classified in 5 groups by Lewis and Cudmore (AnnIntM 7 991, 1934) and Collins (ADS 56 523 1947)

Localized.—Most cases in the United States are of this group in which a primary lesion appears on an exposed part. The chancre is indurated, and softening and abscess formation may take place or an indolent ulcer or vegetation may develop. Rarely the disease remains localized but usually after a week or more, painless inflammation ascends the regional lymphatics, along which secondary nodules form. Regional lymph node enlargement is uncommon, a clinical distinction from tularemia. Systemic symptoms or involvement is uncommon. There

is little tendency for spontaneous recovery to occur After healing has been induced by treatment, scarring of some degree usually remains Localized warty cases, without subcutaneous infiltration or spread, are seen like that of Smith and Garrett (ADS 56: 532, 194)

Disseminated Gummatous.—Seen more commonly in France than in the United States, this variety is characterized by the appearance of small, hard, painless, subcutaneous nodules, various in number scattered over the body Within 3 to 6 weeks the overlying skin becomes involved, and the central part of the nodule softens to form an abscess, which may discharge if traumatized, forming a cup-shaped ulcer with an indurated border A lesion may continue indefinitely in the untreated patient.

Fig 38.—Sporotrichosis, showing ulcers which followed incision f lesions.

Fig 39 —Sporotrichosis chancre on fifth finger Lesions ha been incised, ulcers resulted (Dr G M Brown.)

Fig. 40 —Sporotrichosis characteristic lesions. (Drs. Arthur E. Hertzle and J M. Sutton.)

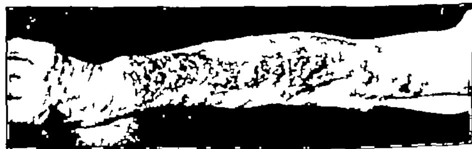

Fig. 741 —Sporotrichosis typical moniliform, noduloulcerati lymphangitis. (Dr T F Turner)

Disseminated Ulcerative.—Like the disseminated subcut neous type this I distinguished by a tendency to undergo early pontaneous ulceration. The ulcers are aried in size and character Large crateriform sores may develop simulating tuberculous lcers or gummatous syphilids. There is little tendency to heal spontaneously I treated, the patient graduall fails.

Epidermic.—While the primary lesion is practically always subcutaneous, rarely the epidermis at near or remote sites becomes secondarily infected, so that papules pustules and

small ulcers develop. In rare cases the disease has been limited to the skin. Tuberculosis is distinguished with difficulty

Systemic and Extracutaneous.—Invasion of deep tissues and organs may occur This happens in disseminated cases when treatment is not instituted promptly The bones & joints may be affected, the tibia being the commonest site. Invasion of muscular and glandular structures may occur and evidence of pulmonary involvement have been reported. Although the epididymis is the common site of involvement in laboratory animals, it is rarely affected in human beings. Gastrointestinal and cerebrospinal infections are extremely uncommon.

Diagnosis.—It is next to impossible to demonstrate the mycelium or conidia in direct smears, but the parasite grows readily on ordinary culture media Tissue diagnosis is not definitive for the lesions simulate those of syphilitic tuberculous or ecthymiform pyogenic infection. Odd clinical examples were described by Smith (SouthMJ 38 505 1945) manifested by pustules, plaques or lesions like bromoderma. Suspicion of the disease should be ever-present and cultural diagnosis is essential (Moore and Manting ADS 48: 525 1943) Asteroid bodies, as are seen in sarcoid are present in some cases (Moore and Ackerman ADS 53 253 1946 Pinkus and Grekin ADS 61 813 1950) The lymphangiitic type in which the row of nodules follows the

Fig. 742—Sporotrichosis, unusual (Dr Leslie M Smith.)

lymph channels draining a traumatic lesion that has proved resistant to ordinary treatment, is almost pathognomonic clinically An agglutination test, using as antigen the spores obtained by filtering the 4- to 12 week-old colonies through cotton, is specific in dilutions as great as 1:4 000 (Weidman Appleton's System of Med., 10 184 1937) and an intracutaneous test with sporotrichin, analagous to the trichophytin test can be performed but these diagnostic methods are not so practical as cultures.

Prognosis and Treatment.—Iodide given internally in the form of sodium or potassium salts, and iodine locally as the tincture or diluted as Lugol's solution, are almost specific. Surgical intervention generally retards cure rather than hastens it Roentgen therapy locally is not successful Potassium iodide should be given by mouth in doses of from 2 to 6 Gm. a day and should be continued for a month after apparent recovery which requires something around 10 weeks. When iodide by mouth does not reach a concentration that is efficacious, concomitant intravenous medication often succeeds. Sodium iodide is given intravenously in doses of from 15 to 30 grains (1 to 2 Gm) dissolved in 20 cc. of water daily if necessary A patient of Dwyer's (pers. comm., 1959) intolerant of iodide was able to take the drug when given cortisone also Sulfonamides penicillin and streptomycin are not effective

HISTOPLASMOSIS

Histoplasmosis, caused by *Histoplasma capsulatum* is an infection characterized by irregular pyrexia hypochromic anemia, emaciation, and enlargement of the liver spleen and lymph nodes (Conant et al. Manual of Clinical Mycology Saunders, 1948) Ulceration of the oral mucosa, especially the tongue and of the pharynx and larynx occurs frequently (Parsons and Zara

fonetis ArchIntM 7o 1 194o) In his original description of the disease Darling (J 4C 1283 1906) noted its resemblance to kala azar Lymph node involvement may simulate Hodgkin s disease Bone marrow involvement accounts for the anemia Diagnosis is accomplished by *identification of the organism* in biopsies but the skin test probably is specific (Pernis et al. J 117 436 1941) The frequency of asymptomatic positive reactors suggests that many an infection like coccidioidomycosis is subclinical.

Of the 12 actual and 3 possible cases of cutaneous histoplasmosis collated by Curtis and Grekin (J 134 1217 1947) 13 had granulomatous or ulcerative lesions, 3 showed nodular lesions 3 had papulonecrotic lesions and 2 had abscesses. In 10 cases the cutaneous lesions were distributed over the face and neck and in C of these they were adjacent to the orifices. Lesions were present on the trunk in 4 cases the extremities in 4 the male genitalia in 2, and generalized in 1 Of 19 cases of histoplasmosis of mucosae adjacent to the skin 7 were granulomatous and 1C were ulcerative usually very painful. Nodules ranging from several millimeters to walnut size were described in 5

Figs 781 783 —Histoplasmosi the man tongue in January, 1944 4 months later and the organisms in a section. (Dr F M Keddie)

cases, hemorrhagic patches or crusts of various sizes were noted in 4 cases, fissures in 2 and perforation of the nasal septum in 3. Lesions were present in the nose in 4 instances, on the tongue in 7 on the buccal and labial mucosae in 5 palatal in 5 gingival in 3 and hypopharyngeal in 7

In a review of 88 cases Miller et al. (ADS 36: 15 194) noted that the lesions f hi toplasmosis may resemble those of tuberculosis syphilis, the deep mycoses, or lymphoblastomas, and that the systemic disease must be distingui hed from kala azar malaria, dysentery and cancer The cyt logically non pecific hronic infect ous granulomas contain macrophages a their la lo reacting cells, and this nflammation may produce ulcers and gummas of the mouth, papules, plaques a l punched-out ulcers, purpuric lesions abscesses a d furunculoid or impetiginoid lesions, localized or general zed.

It is probable that the large majority of infections are a ymptomatic at the onset r are featured by unrecognized upper respiratory illness There are analogies to coccidioidal infection (q.) wherei nly a few i d viduals manifest disease which, more often the affecting the ki ffect the lu gs and mediastinal nodes, giving rise to roe tgenographic abnormal ties difficult to dist gu sh from tuberculosis. The epidemiology of the disease ha for some time been unde the careful scruti y of Furcolow (see ref reare) f the U.S.P.H.S. at the University of Kansas Medic l Center in a region where the infection is endemic and where the organisms have been found in farmyards and chicken houses. Positivity of the

skin test must be interpreted much as tuberculin tests are interpreted, the incidence of positive reactors increasing with the age of the tested subjects and reactivity not being proof of activity of disease.

An "id" eruption occurs in histoplasmosis which simulates the papulonecrotic tuberculid. The lesions are disseminated, occur in crops, affect especially the extremities, and are inflammatory papules which undergo central necrosis and ulceration, healing with atrophic scars.

The similarity to pityriasis lichenoides et varioliformis is so suggestive that careful investigation of cases so titled should be made from this standpoint. I surmise that "parapsoriasis varioliformis" may be a manifestation of histoplasmosis.

Treatment hitherto has been ineffectual with reports indicating that the diagnosis of histoplasmosis meant death within 8 months. Stilbamidine and related chemical substances appear to offer great promise in suppressing or eliminating the disease (Furcolow).

See Hausmann and Schenken (AmJPath 10: 731, 1934), papular lesions with crateriform ulceration, 16-year course leading to death; Shaffer et al. (J 113: 484, 1939) fourth U. S. case, review; Amolsch and Wax (AmJPath 15: 477, 1939), tenth case, infant with cough, leukopenia, fever, weakness; Gunter and Lafferty (AlaMJAJ 9: 337, 1940) headache, fever, necropsy; Brown et al. MISCELLANEOUS AND UNCOMMON MYCOSES

Acladiosis.—Conidiospore fungi of the genus Acladium have been found in cases characterized by scattered ulcers, sharply defined, round or oval, with red and granulating bases, abundant purulent secretion and thick yellow crusts, lesions which were gummalike as well as furuncular located on the palms and soles or elsewhere. The disease is chronic without tendency to heal spontaneously. It is responsive to iodide therapy. It is identified only by cultural study.

Acremoniosis.—*Acremonium potroni* has caused typhoidlike fever and gummalike swellings which underwent ulceration, but without lymph node involvement. Other cases have resembled mycetoma with yellow grains.

Aspergillus and Penicillium.—These genera of Ascomycetes bear conidia in chains arising from specialized cells called phialides. They are moldlike fungi. Several species have been thought to act as parasites and to have caused mycetomas, infections of the lungs and superficial infections of the ear canals, nasopharynx, skin and cornea. They are found commonly enough as saprophytes on crusted, dirty dermatoses, and one must be critical, though not incredulous, of reports of their pathogenicity. Allergists are obliged to take them seriously as sources of inhalant difficulties. See Otomycosis and Onychogryposis.

Cephalosporiosis.—Cephalosporium is a genus of the sporophore division of the hyphomycetic fungi. The organisms, of which there are several species, have produced nodular gummatous lesions and dermatomycoses of varied clinical appearance. Diagnosis depends on the demonstration of the fungus and its identification. These infections in general simulate sporotrichosis and are responsive to potassium iodide and roentgen therapy.

Cladosporiosis.—Cladosporium is a genus of dermatophytes, species of which have produced nodular gummatous inflammations and dermatomycoses unresponsive to iodide. Diagnosis depends on cultural identification.

Geotrichosis, productive of chronic bronchitis with gelatinous sputum or pulmonic disease simulating tuberculosis, may affect the oral mucosa in white patches distinguished from thrush simply by direct examination of scrapings, which reveal characteristic rectangular spores (Brumpt 1949 p. 1742).

Hemisporosis.—Hemispora include hyphomycetic fungi which reproduce by accessory spores or hemispores. Species have been found in cases which resembled sporotrichotic infections and like them were responsive to iodide therapy (Brumpt 1949 p 1801). Osteoperiostitis, generalized nodular eruptions, and gummatous sores with tuberculoid histologic structure have been attributed to Hemispora (Castellani and Chalmers, 1929 p 2106).

Mucormycosis.—Mucormycosis has been diagnosed in paronychia of orange workers by Sutherland-Campbell and Plunkett (ADS 20 651 1934), in otomycosis and in furunculoid lesions of the face by Wade and Matthews (J 114 410 1940 see Mezey J 114 1098, 1940). The 3 cases of Pirila (ActaD-V 28 186 1948) exhibited pustulation with suppurative lymphadenitis and cleared spontaneously in a few weeks uninfluenced by treatment.

Rhizopus, identified by the histologic finding of huge nonseptate mycelium in the central granulomatous masses as well as in the advancing borders of the lesion, apparently caused a curious lesion of a boy's chest (Englander ADS 68 741 1953). The lesion clinically showed a reticulated and atrophic center and a border composed of active lichenoid papules. Therapy was without avail until excision was performed and this cured the patient (Goldman told me (1956)).

Scopulariopsis.—This is a genus of the Ascomycetes related to Penicillium, the conidial apparatus being similar. Species have been isolated in a case resembling sporotrichosis with verrucous chancres and ascending lymphangitis, in onychomycosis and in ulcerative mycetomas and gummatous lesions (Markley ADS 33 627 1936). The curious case presented by Hall (ADS 54 173 1946) had lesions suggestive of hypertrophic lupus vulgaris; this patient improved markedly on potassium iodide by mouth and x ray therapy. See Castellani and Chalmers (1929 p. 2107) Brumpt 1949 p 1978).

Sterigmatocystis.—Superficial eczematous and epidermal disease has been attributed to perhaps purely saprophytic fungi of this genus. *S. cinnamominus* was found in a Peruvian case resembling tinea versicolor. Species have been found in the ear canals. A black grain mycetoma was described by Pinoy as being due to *S. nidulans* (Brumpt 1949 p 1967).

Allescheria.—See Pinoy (JMIJ 2 488, 1919). Castellani and Chalmers (Tropical Medicine ed 3 1929 p [illegible]). Castellani and Jacono (JTropM 3 [illegible] 1934) keratitis case simulating [illegible] paracladiosis described.

DERMATOSES DUE TO ANIMALS

Craig and Faust (Clinical Parasitology Lea & Febiger 1951) and Brumpt (Précis de Parasitologie, Masson, 1949) are the principal authorities used in the preparation of the chapter Valuable also are Riley and Johannsen (Medical Entomology McGraw Hill, 1938) Stitt and Strong (Tropical Diseases, Blakiston 1942) Culbertson (Immunity Against Animal Parasites, Columbia Univ Press, 1941), Ash and Spitz (Pathology of Tropical Diseases, Saunders, 1945) Chatt rjee (Human Parasites and Para itic Diseases, Calcutta, 1953), Brown (Synopsis of Medical Parasitology V E. Brown, Milwaukee, 1953) Piekarski (Lehrbuch der Parasitologie unter besonderer Berücksichtigung der Parasiten des Menschen, Springer 1945) Kudo (Protozoology Thomas, 1954) and Hackett et, al (Manual of Medical Helmi thology Carsell & Co. 1954)

PROTOZOA

AMEBIASIS

Endamoeba histolytica is a rhizopod protozoon manifesting trophozoite precystic, cystic, and metacystic stages in its life cycle. In unstained preparations the trophozoites range from 15 to 60 μ in diameter averaging about 20 μ. The exoplasm is glassy clear the endoplasm finely granular and the nucleus almost invisible. Exoplasmic pseudopodia are rapidly and actively extruded in freshly passed stools, but motility is sluggish in cool preparations. The habitat is the distal gut, and transmission is accomplished by ingestion of substances, usually a polluted water supply contaminated with feces containing cysts of the parasite. Asymptomatic carriers exist.

Symptoms.—Cutaneous involvement may be classified as occurring by ex tension, by inoculation, and from allergy (Touraine and Duperrat PresseMéd. 47: 1086 1939) Extending in the skin following surgical attack upon an amebic visceral abscess, amebic dermatitis is ulcerative starting within 1 to 3 weeks as a rule with a little redness and developing black necrosis or furuncu lar anthraxlike lesions. Perianal extension of colonic and rectal disease oc curs. Inoculation with purely cutaneous amebiasis is rare, the lesions being extensive ulcers or sometimes circumscribed torpid abscesses which crust, ex tend peripherally, and heal with scarring Genitalia of male or female may be inoculated. Allergic dermatoses dependent on amebiasis include anal pru ritus, urticaria, rosacea like disease buccal melanosis and desquamative ery thema from emetine or other medicines. Amebic ulcers in the skin generally are large circular ragged, purulent lesions, with deep red undermined swol len edges. Diagnosis requires positive identification of the organism.

Treatment with emetine a hazardously toxic alkaloid from ipecac, is usu ally successful the hydrochloride being given in 0 065 Gm (gr i) doses sub-cutaneously for 10 (not more than 12) doses in a course (Kreutzer Surg 29: 149 1951) Chiniofon (Yatren) Diodoquin, Vioform and carbarsone are also effective (see Craig and Faust)

Aureomycin was fou d to be effective by McVay et al. (Sci 109: 590, 1949; SouthMJ 43 303, 1950) and of 37 cases treated, 36 were apparently cured with 2 Gm. daily for 7 days. Aureomycin cured cases previously recalcitrant under Diodoquin, carbarsone and even emetine, reported Hughes (J 142 1032, 1950) The recurre ce rate after the anti-biotic compared favorably with that following othe drugs, wrote G tch (NEngJM 243: 165, 1950) while Hall (NEngJM 244 495, 1951) thought it especially effecti e in treating carriers. Gut, liver and belly perforations all respond to Aureomycin, said McVay and Sprunt (SouthMJ 45: 182, 1952), and pparent failures are often attributable to reinfection from a member of the immediate family of the patient.

Emetine, carbarsone and chiniofon combined gave an excellent initial response and a moderate relapse rate; but Terramycin alone and in combination with (1) emetine, (2) carbarsone, (3) chiniofon, (4) chloroquine diphosphate, and (5) bismuth glycolylarsanilate a d chloroquine, and the combination of Aureomycin and chloroquine diphosphate all gave excellent initial responses and the lowest relapse rates observed by Martin et al. (J 151: 1055, 1953) The combination of bismuth glycolylarsanilate and chloroquine in the proportion of 500 mg to 150 mg. was the most effective amebacide disclosed by the compara tive studies of Sanchez (J 151: 1069 1953)

Fumagillin an antibiotic introduced by Hanson and Eble (JBact 58: 527 1949) was shown to be amebicidal by McCowen et al. (Sci 113 202, 1951) Its essential lack of toxicity and its effectiveness against several enteric protozoon parasites, including *E histo-*

lytica were reported by Killough et al. (Sci 115 71 105) Effectively curati e in amebiasis, fumagillin in luced a triking Ile effect of exf llation of palm and soles in of 3 cases of Schindel (J 155: 903, 1054) a well as some sensory an l auditory neuriti

TRICHOMONAS VAGINITIS

The class Mastigophora, flagellate protozoa, includes the Trichomonadidae, of which *T vaginalis* is associated with mucosal disease of dermatologic interest. The organism is pear-shaped, about 10 μ long and possessed of 3 to 5 anterior flagella. The marginal filament along the undulating membrane is not prolonged into a free flagellum and there is a well-defined parabasal body Pathogenicity has not been positively demonstrated.

Symptoms.—While many women harbor the organisms, comparatively few complain. Vulvar pruritus is sometimes attributed to them. Redness, excoriation, edema, pinpoint vesicles and minute caruncle-like lesions were described by Hollander (ADS 36 142, 1937) Kessel and Gafford (AmJOG 30: 1005, 1940) recorded histologic changes, finding trichomonads in acute inflammation with focal necroses; their implants of exudate into normal vaginas produced the disease but implants of cultures did not. Leukorrhea may be profuse and is typically alkaline It is grayish-white seropurulent, and peculiarly foamy when the speculum is introduced. Symptoms tend to be cyclic the exacerbations overlapping the period of menstrual flow Difficulty in eradicating the infection often depends on the presence of rectal, urethral and glandular involvement or on reinfection (Trussell Trichomonas Vaginalis and Trichomoniasis, Thomas, 1947) In the male, preputial and prostatic involvement may be present.

The organisms are readily demonstrated on microscopic examination of a hanging droplet of saline to which exudate has been added. An intradermal test with trichomonas antigen was evaluated by Adler and Sadowsky (Lancet 1: 867 1947) as being of no practical value

Treatment.—Insufflation of the vagina twice a week is effective using a powder containing acetarsone 1 parts, salicylic acid 2, and sodium bicarbonate and kaolin in equal amounts to make 100. The vaginal pH should be kept less than 5 by means of lactic acid douches, a dram to the quart of water which should be used twice a day between periods and three times a day during the menses Hugh Hamilton advises. Acetarsone one grain to 5 cc. of water is an effective and acidic parasiticide for intravaginal treatment (Karnaky: AmJSurg 35: 17 1940) Reich et al. (SGO 84: 891 1947) advised vinegar douches and a gelatin capsule insert containing Argyrol, kaolin and betalactose powder Insufflation of quinacrine powder into the carefully cleansed and dried parts was advocated by Dula (NCarolMJ 9 309 1948) A reomycin by mouth cured the infection in a male reported McV and Sprunt (SouthMJ 44 1122, 1951) Terramycin used in vaginal suppositories seemed effective to Green (aha J 149: 1060 1952)

LEISHMANIASIS

Among the protozoa, those which move by means of flagella comprise the class Mastigophora. *Leishmanias* form a genus of Trypanosomidae the family which includes all flagellates living in the blood and tissues of human beings. Leishmania have vertebrate and invertebrate host and, in their life cycle, a leishmania and a leptomonas stage. In the human host is found the typical leishmania, with ovoid body containing a nucleus and kinetoplast, the latter giving rise to a single flagellum in the invertebrate host. Reproduction occurs by binary fission. The 3 species recognized as infecting man are morphologically identical despite the different clinical pictures produced by them. They can be differentiated on the basis of serologic reactions (Noguchi: JExperM 44: 327 1926) *L. donovani* causes visceral leishmaniasis, or kala-azar *L. tropica* causes cutaneous leishmaniasis, or oriental sore. *L. brasiliensis* causes American leishmaniasis.

Oriental Sore is a specific, ulcerative disorder which usually develops on the leg face or other exposed part of the body A small sore appears at the site of the bite of an infected sand fly *Phlebotomus papatasii* and the reddish papule increases gradually in size. After a number of months it becomes bluish in the center softens and ulcerates. The number of lesions ranges from 1 to 17 most often from 3 to 8 single sores are rare The sore is not accompanied by adenopathy After a duration of several months or even a year an untreated ulcer undergoes cicatrization and leaves a characteristic stellate scar Permanent immunity eventually results (Behdjet abs YBD 1937 p 192) but superinfection with *L tropica* proved possible despite positivity of the leishmanin intradermal reaction, noted Dostrovsky et al. (ADS 66 665 1952) who observed that immunity does not suffice to prevent this, and that circulating antibodies cannot be demonstrated

Three clinical forms were classified by Marchionini (Dermatologica 97: 319, 1947) in a review of some 800 cases from Ankara: the local sore inoculated by the bite of the sand fly the metastatic sores from hematic or lymphatic dissemination resembling lupus erythematosus or lupus vulgaris; and the disseminated nodular variety which showed no tendency to heal spontaneously He recommended Atabrine or locally injected antimony

Fig 757.—Ori[illegible] sore (Dr [illegible] M [illegible]wen.)

preparations in treating local cases, while the metastatic form required, he believed, an antimonyl given for its systemic effect, such as Solustibosan in doses of from 3 to 4 cc. daily for 10 days, accompanied by supportive hygienic measures.

Experimental inoculations reveal an incubation period of from 16 days to many months, depending on quantity and depth of the inoculum and on the degree of individual susceptibility reported Berberian (ADS 49: 433 50: 231, 233 234 1944) A vaccine from the cultures of *L. tropica* may have some preventative value and the intradermal test has some diagnostic value After experimental inoculation the skin test remains negative for about 3 days, then becomes positive (Dostrovsky: JID 10: 435 1948)

Diagnosis by means of positive cultures was recommended by Pachchanian (J 129: 544 1945) using ordinary blood agar slants, and cultural diagnosis seemed easier than the demonstration of parasites in smears, according to Dostrovsky and Sagher (ADS 54: 543, 1946)

Principal pathologic changes are in the dermis. The histologic picture is not distinctive except that it is tuberculoid. The presence of Leishman Donovan bodies, representing the specific parasite readily demonstrable as a rule in a Giemsa stained preparation, is diagnostic.

Fig. 163A —Nodules of leishmaniasis (Dr O. G. Costa.)
Fig. 163B —Spina ventosa of phalanx, due to leishmaniasis. (Dr O. G. Costa.)

The malady is self limited, although its duration can be greatly shortened. Local treatment with wet applications and iodine help and specific treatment with ½ grain potassium antimony tartrate in 5 c.c. water intravenously on 1 day followed 3 days later with 1 grain and continuing with 1.5 grains a week, led to cures (Goodall: IndMGaz 72 2, 1937) Snow et al. (ADS 57: 90 1948) spoke highly of Neostam in treatment but Most and Lavietes (Med. 26 221 1947) preferred ethylstibamine (Neostibosan), giving 0.3 Gm. intravenously daily for 17 days. Treatment failures may be retreated with larger doses, or with stilbamidine.

See Altounyan (JCut&VD 3 161 1885) Wright (JMRes 5 472, 1903) original description of *L. tropica* Andrews (AmJTropM 7 231, 1927) 10 cases in North America; Hasch-khilelsson et al. (AnndeD 6: 210 1935) resemblance to tuberculosis cutis Ray (IndianJPediat 2 149, 1935) acne therapy; Hupoumenakis (ArDerS 178 183, 1938), comparison of oriental sore and kala-azar organism of latter is motile, of former nonmotile Flarer (PresseMed 46 1338, 1938) Atabrine locally and internally to cure; Derim (ADS 41: 874, 1940) recidive and id forms; Templeton (CalifWM 54 76 1941) experimental inoculation; Dostrovsky and Sagher (ADS 48 668, 1943) grenz ray therapy Kozhevnikov (see ADS 48 476, 1943), in U.S.S.R.; Katzenellenbogen (ADS 50: 239 1944) preventative vaccination; Hall and Ryan (BullU.S.ArmyMD Aug. 1944 p. 65) Middle East cases and description Gill (ADS 54: 331, 1946) Palestine cases Conrad et al (ADS 62: 501, 1950) 4 cases, discussion of treatment.

American Leishmaniasis, due to *L braziliensis* differs from oriental sore in its varied and longer course, its failure to produce immunity the involvement of the nasopharynx in from 10 to 20% of the cases, its greater resistance to treatment, and its causation at times of cachexia and death Oriental sore is a milder disease, confined to the skin, responding readily to treatment. See Fox (ADS 30 241 1934 J 123 461 1943) Two clinical forms may be dis-

Fig. 764.—Nasal polyp, leishmaniasis. (Dr. O. G. Cost[illegible].)

tinguished, uta resembling oriental sore and occurring in the arid valleys of the Andes where verruga peruana is endemic, and espundia, a more serious disease involving adult patients rather than younger ones, affecting the mucous membranes, and occurring especially in sylvan regions among persons working in forests and on cacao and tea plantations (Weiss abs YBD 1944, p 305)

Figs. 770-772 —Leishmaniasis, Brazilian cases. (Dr O. G Costa.)

Uta is endemic in limited areas, shows a predilection for children under 4 years of age, runs a benign course, and produces immunity The initial lesions are usually found on uncovered parts of the body never on the scalp or keratotic volar skin. At the beginning they resemble mosquito bites, but become papular and eventually nodular Ulceration may ensue, and impetiginoid, ecthymatous and ulcerous varieties may be distinguished.

Vesicopustules located superficially may become confluent crusted and of a diameter reaching 10 cm., or ulceration ma be less superficial or gummatous sometimes actually phagedenic N nulcerated cases ar also seen sometimes simulating keloid, though without a smooth surface Veg tative form occur too, verrucose or yaw like

Figs. 773 775.—K la-asa nod les nd bpleme tel lesions in nati Indi ns. (S pler 1 Daal pt 1 In IMG n 69 1 1 1924)

Espundia frequently begins around the nasal septum or in othe parts of the upper respiratory mucosae spreading more rapidly than the cutaneous forms, i vasive of the whole extent of the upper passages and even involving, sometimes, the pharynx, larynx and trachea. In the mouth there is predilection for the palate checks d mucosae of the cheeks, but seldom is the tongue involved. Palat l lesions are more often proliferative

than destructive and the resultant granulation tissue may resemble that of blastomycosis. The lesions interfere with respiration and feeding, and marasmus and death eventuate sometimes from edema of the glottis or an acute pulmonary complication.

Regional lymphangitis is common, is often nodular and generally is painful (Kean: ADS 50 237 1944). Ulceration of the pinna is common among workers who collect gum, and bears the name "chicle sappers' ear" (oreja de chicleros). Mutilating and ulcerative lesions of the mouth and nose occur in perhaps 20% of the cases in the moist, tropical regions of Peru (Schmidt: ADS 61: 984 1950).

Treatment with 2 hydroxystilbamidine, 225 mg in 200 cc. 5% glucose given intravenously daily to a total dose of 6.1 Gm. cured a patient without intoxicating her (Snapper AmJMed 13: 6.. 1952).

See McEwen (JCutDis 32, 275, 1914) description and bibliography; Wenyon (JTropM 14 103, 1911) parasitology; Mehrdorf et al (JUD 38 231, 1920) espundia contracted by Briton in Brazil; Fox (ADS 23 480 1931 30 341 1934; J 123: 461 1943); Dostrovsky (AnnTropM 29 123, 1935) intradermal test; Shattuck (AmJTropM 16 187 1936) epidemiology; da Cunha and Dias (abs J 113 1998, 1939) complement fixation test; Humphreys (AnnTropM 36 3 1943) treatment with Pentamidine, diamidine derivative; Costa (ADS 49: 194 1944) Brazilian cases; Stewart and Pilcher (ADS 51 124, 1945), Texas case; Costa (ADS 55 358, 1947), erroneous case; Cornejo and Llanza (quoted J 138 1169 1948), clinical forms, treatment with stibophen, chiniofon, antimony; Hasslins and ll er Cordero (ADS 62: 428 1950) unusual case, Repodral treatment.

Fig. 777.—*Leishmania tropica* in a smear from tropical ulcer. (Army Medical Museum photomicrograph, from Meakins' Practice of Medicine.)

Kala-Azar.—This severe form of visceral leishmaniasis occurs in parts of India, China and the Sudan. It is a localized disease which may attack all the persons in one dwelling or group of dwellings and leave unaffected persons only a short distance away. All races and both sexes are infected. *Phlebotomus argentipes* is a vector, the bite or perhaps the crushed body serving to inoculate. After an incubation period of several weeks, kala-azar is manifested characteristically by an irregular fever lasting for months, uninfluenced by quinine, with hypertrophy of the spleen and liver. In advanced cases, numerous ulcers occur in various places along the digestive tube, such as gangrene of the mouth, or ulcers of the nose or of the large intestine, and on the skin. Wasting becomes advanced, contrasting with the protrusion of the belly which is likely to be distended with ascitic fluid. Cutaneous lesions, leishmanids, contain parasites. On the skin of the body, limbs, or face appear depigmented zones, erythema, nodules, or more rarely verrucous, papillomatous lesions resembling those of xanthoma, with perhaps thickening of the lip, eyelids, and alae nasi. Evolution is insidious and may cover a period of 10 to 30 years. Cutaneous disorders are considered sequels of kala-azar, supervening in some instances in subjects who are ignorant of having had the malady. They may be mistaken for leprosy. Marked leukopenia, even to levels below 1,000 leukocytes per c.mm., is characterized in the blood picture, the reduction

of the polymorphonuclears being especially marked. The main visceral lesions involve the spleen liver and large intestine The tissue of the spleen is firm but friable and macrophages with parasites in them are found here diagnostic on splenic puncture Sternal puncture is a safe way to obtain diagnostic material

TRYPANOSOMIASIS

Trypanosomes are flagellates which have a fusiform fringed body containing two stainable ma ses of chromatin one of which, large a d generally centrally located, is the nucleus a d the oth r small r and caudally located, i the blepharoplast From it arises a whip or flag lla f t ned along the bod so as to produce an u dulati g membrane the a terior en l being generally free *T gambiense* and *T rhodesiense* cause West and East African sleeping sickness respecti ely *T cruzi* causes South American Chagas disease

Symptoms.—African trypa osomes are inoculated by the bites of flies most of which are members of the genus *Glo sina* The site of inoculation the bite i scarcel distinctive prod i g nothing more tha wheal which disappears rath r promptly The region l lymph odes may exceptionally become enlarged prompti after the bite Striki g changes in the kin occur in Europea patients in the form of erythema multiforme-like lesions of polycyclic and annular type Among Negroes itchi g papules are more commonly seen. Area of hyperses itiveness are found in a high proportion of the patient affecting both the skin and deeper part ; the lea t blow or pi ching of deeper masses produces within a second or two such acute pai peculiarly d la ed a to make the subject actually cry out (Kerand l s sign) Generalized edema or true myxedema i a part of the symptom com ple and may be d e particularly in the South American disease to actual damage of the th roid gland These cutaneou phenomena occur in the primary stage of the disease when hyperpyrexia a d acute respiratory and circulatory symptoms are present. They may last for several months or ears with remission Duri g the acute form of Chagas disease t mef ction of the face may be marked, especially of one eyelid and cheek, but the edema loes not pit on pres re See Craig and Faust (Clinical Parasitology Lea & Febiger 1951 p. 182 ff)

METAZOA

Metazoans of many kinds provoke eczematous dermatitis. Among the Coelenterata the Portuguese man-of war provokes coryzal symptoms, pain in toxication and severe urticarial dermatitis by attaching on contact with the skin, its venomous nematocysts (Thomas FlaMAJ 26 83 1939) ACTH, cortisone and Chlor Trimeton promptly relieved a patient of mine

Contact with coral led to urticaria and dermatitis venenata reported Levin and Behrman (ADS 44 600 1941) and a hydroid of the genus Halecium produced similar responses (De Oreo ADS 54 637 1946) Fishermen working the Dogger Bank are subject to coral dermatitis as an occupational disease *Alcyonidium hirsutum* being the irritating animal reported Bonnevie (ActaAllerg 1 40 1948) Ulcers resulting from contact with coral seemed to be associated with malnutrition thought Philps (BMJ 1 846 1950) who recommended first a week of rest and palliation then excision

Jellyfish intoxication and dermatitis were discussed by Stuart and Slagle (USNMBull 41 497 1943) who noted similarity to black widow spider bite They gave calcium gluconate 10 cc. of 10% with prompt benefit Zieman (J 99 1713 1932) advised drying immediately after contact and dry pressure dressings. Contact with jellyfish in tropical waters causes not only redness, urticaria and burning pain at the site of contact, but spasm of respiratory

muscles, difficulty in respiration, pain in the abdominal and back muscles, cough with expectoration, profuse lacrimation, dilation of pupils, nausea dizziness, extreme restlessness and anxiety

The effects of the sting ray are quite similar (Evans BMJ 2 165 1945) Henderson (BMJ 2 300 1945) described his own experience, an unpleasant one indeed, for he almost drowned he obtained considerable relief with brandy Neubert (BMJ 2 839 1948) suffered severely for several days: the area of contact the lip underwent vesiculation and crusting Stung again a few days afterward, his reaction was much less violent suggesting the development of some degree of immunity

Zoacanthoses is a term proposed to cover those dermatoses caused by the introduction and retention of animal structures such as piercing mouth parts and bristles. Some are essentially foreign body irritants many of them are venomous rather than mechanical lesions. Immunity to metazoa may be manifested by encasement in fibrous tissue, inflammatory expulsion from the gut, antibody formation and cellular reaction and more or less specific im munologic diagnostic tests have been devised (Taliaferro AMJTropM 20 169 1940 PhysRev 20 469 1940) See Culbertson (Immunity Against Ani mal Parasites, Columbia U Press, 1942)

Urticaria and eosinophilia accompany many metazoan infections. Hel minthiasis is capable of inducing malnutrition, accompanied by xerosis as of avitaminosis A, pruritus, and pellagra

All metazoa parasitizing man are bilaterally symmetric. They fall into 4 phyla (Brumpt, 1949)

Soft skinned	PLATYHELMINTHES (Flatworms) with body with or without segmentation; celom obliterated. Digestive system if present usually lacks anus.	WORMS
	ANNELIDA (Roundworms) with body segmented celom present.	WORMS
Chitinous integument	NEMATHELMINTHES (Roundworms) with body nonsegmented no articulated limbs.	WORMS
	ARTHROPODA, segmented limbs jointed.	ARACHNIDS MYRIAPODS INSECTS

HELMINTHIC INFESTATIONS

The word helminth, as usually interpreted, now includes both parasitic and free-living species of the roundworms (**Phylum Nematoda**), the hair snakes or gordiid worms (**Phylum Nematomorpha**) the turbellarians, flukes and tapeworms (**Phylum Platyhelminthes**) and the thorny-headed worms (**Phylum Acanthocephala**) By a still more liberal interpretation it may also include the leeches, a Class group of the **Phylum Annelida** (Craig and Faust Clinical Parasitology Lea & Febiger 1951 p 293) See also Faust (Human Helminthology Lea & Febiger 1949)

NEMATHELMINTHES

Nematodes possess an intestinal tract but no proboscis, and the body cavity is not lined with epithelium. They are divided into Aphasmidia and Phasmidia, depending on their lack or possession of phasmids, which are caudal chemoreceptors.

THE PHASMIDIA contain 10 superfamilies, of which the following are of dermatologic interest Rhabditoidea (strongyloidiasis) Strongyloidea (ancylostomiasis) Oxyuroidea (enterobiasis) Ascaridoidea (ascariasis) Spiruroidea (gnathostomiasis) Filarioidea (filariasis, onchocerciasis, loasis) and Dracunculoidea (dracontiasis)

THE APHASMIDIA include the Trichinelloidea, in which the anterior part of the body is filiform, esophagus degenerate 1 testine cellular sexes hologonic, the female with single ovary; polymyarian.

APHASMID NEMATODE INFESTATION

Trichiniasis.—Trichinella contains the single species *T spiralis* of which the adult worm inhabits the small intestine and the larvae emigrate into the muscles where they become encysted They infest the human being cat rat dog pig and other animals. Cutaneous symptoms occur in a small proportion of cases (Spink and Augustine J 104 1801 1935) and include a maculopapular exanthem resembling rose spots scarlatiniform erythema and erythema multiforme Edema of the eyelids photophobia chemosis subconjunctival petechiae rose spots and urticaria are common Urticaria may be the first symptom (Musger DZtschr C8 34 1933) Splinter hemorrhages be-

Fig. 778—Trichiniasis, [illegible] showing edema of face and typical sitting [illegible] palpebral fissures (Dr John W Perkins)
Fig. 779—Splinter hemorrhages under fingernail in trichinosis. (Dr L H Briggs)
Fig. 780—Trichinella larva in sediment of digested human muscle X18. (McNaught AmJTropM 19 181 1939)
Fig. 781—*Encysted trichinella in human muscle cells* (Dr J B McNaught)

neath the nails are petechiae due to larval migrations seen in some 60% of active cases (McNaught AmJTropM 19 181 1939) they were present in 10% of the cases of Semple et al (BMJ 1 1002, 1954) Scarlatiniform eruptions were seen in 2 of 6 cases by Millett (BullUMdMSch 28 163 1944)

The administration of streptomycin in an acute case was followed by immediate fall of the temperature to normal (Tate and Wheeler TransMS 51 11 1950) ACTH effected dramatic relief of fever dyspnea aching and other symptoms in 8 patients of Buylla (abs J 153 690 1953)

The Bachman Skin Test using as antigen a 1 10 000 dilution of saline extract of larvae is of interest. It does not become positive before the second week after onset of symptoms (McCoy et al. JImmun 24 1 1933) and is an

immediate wheal type of reaction when positive (Spink NEngJM 216 5 1937) Perhaps 10% of reactions are false positives, for reactivity once established persists for years (Warren et al. AnnIntM 13 2141 1940)

See Bachman (JPreventM 2 35, 169 513 1928) intradermal test Fritlander (AmJMed Sci 188: 121, 1934) skin test is unreliable in diagnosis Drake et al. (J 105 1340, 1935) Maine epidemic with classic kid symptoms Hall (PublHRpts 52: 539 1937) atypical cases, precipitin test becomes positive later than skin test, organisms found in about 13% of cadavers.

PHASMID NEMATODE INFESTATION

Strongyloidiasis.—Phasmid nematodes of the superfamily Rhabditoidea include the species *Strongyloides stercoralis*. The free-living generation lives in the soil, a roundworm roughly 1 mm. long and 50 μ in diameter The fertilized female discharges embryonated eggs which hatch within a few hours, and rhabditoid larvae emerge feed moult and soon grow into free-living adults. These may metamorphose in unfavorable conditions into filariform larvae resembling those of the hookworm and as such are infective for man, capable of remaining alive in the soil for many weeks On contact with the skin or mucous membranes, they penetrate, producing a petechia and intense pruritus at each site followed by edema and perhaps by secondary infection. Some reach blood vessels and are carried to the lungs, where they perforate the endothelium, enter the alveoli, induce a pneumonitis simulating bronchopneumonia, pass up the respiratory tree, and are swallowed. Reaching the intestine they lodge in the villi and crypts, mature and deposit eggs.

Studying transmission of infection experimentally, Tomita (abs J 117: 11 4, 1941) applied sw be wet with suspensions of *S. papillosus* and *S. fülleborni* to the skin, finding within 4 hours redness, warmth tingling sensations and sometimes vesicular lesions. *S. papillosus* evoked considerably more severe reactions locally but the other parasite induced systemic reactions including urticaria, gastrointestinal upset and sometimes fever

Diagnosis requires the identification of larvae in the feces. A skin test was devised by Fülleborn (ArchSchiffsTropHyg 30: 731, 732, 1926)

Gentian violet enteric-coated tablets of 1 grain size 3 times a day for a fortnight usually succeeds. See Simpson (J 11 828 1939) Craig and Faust (1951)

Ancylostomiasis.—Phasmid nematodes of the superfamily Strongyloidea include the Ancylostomatidae the human hookworms, which are characterized by their possession of oral cutting organs, toothlike processes in the genus Ancylostoma, semilunar plates in Necator Larvae of these worms may penetrate the skin, causing more or less severe irritation and dermatitis.

Ancylostoma duodenale, common in Europe and the Mediterranean region, is a cylindric worm, 10 to 18 mm. long which lives in the small intestine. The eggs, laid in the intestine of man, are passed with the feces, and become larvae. After development, these larvae can penetrate the skin, circulate in the blood and enter the lungs, whence, via trachea and esophagus, they reach the intestine to undergo evolution into adult form. *Necator americanus* is a similar parasite common in America. Penetration of the skin is not done through hair follicles. The lesions in sections show dense eosinophilic infiltration.

Itching, redness, and small pustules result from the percutaneous migration which requires only a few minutes. Bacteria may be introduced into the tissues along with the larvae. Ground itch, miners itch, water itch and mazamorro are lay names applied to the dermatosis. Cutaneous ancylostomiasis usually begins between the toes and extends over the foot. Itchy plaques and erythematous macules may be succeeded by vesicles, pustules and ulceration.

Percutaneous infection with larvae obtained from stools has been used in the treatment of polycythemia (Brumpt and Gajar: IndMGaz 83: 166, 1948)

Catarrhal bronchitis may symptomatically demarcate the passage of the larvae through the lungs. Eosinophilic pneumonopathy Loeffler's syndrome occurring in conjunction with cutaneous helminthiasis, represents an allergic phenomenon. Wright and Gold (J 128 1082, 1945) observed in 9 of 15 cases of creeping ancylostomiasis transient migratory pulmonary infiltration with little or no sign or symptom of systemic disease except eosinophilia of the blood (Wright and Gold: AIntM 78: 303, 1946; Kalmon: Radiol 63: 223 1954) *A. braziliense* was found in the sputum of a patient of Muhleisen (AnnIntM 38 595, 1953)

CREEPING ANCYLOSTOMIASIS.—*Ancylostoma braziliense* of which the dog is the natural host, causes, in its larval state a type of creeping eruption. The disease is common along the coast of the southern part of the United States. Infested cats or dogs inoculate the soil with their feces, and in moist, shady sand or earth mature filiform larvae invade the skin of human beings when opportunity offers. A reddish, itchy papule marks the site of entry and within 2 or 3 days a sinuous tunnel in the epidermis has been produced. The lesion is first erythematous it becomes elevated and vesicular The larva

moves several millimeters or even centimeters per day The portion of the tunnel first made and so first abandoned tends to heal Itching is severe The number of lesions depends on the number of infesting larvae tunnels may be solitary or numerous Exposed portions of the body are the sites of predilection. A larva may persist with its wanderings for several weeks or even months (Dove AmJHyg 15 664 1932)

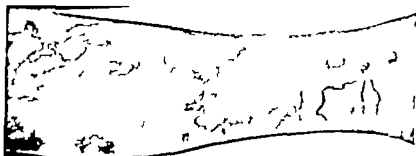

Fig. 782.—Creeping eruption due to Ancylostoma braziliense (Dr O. G Costa.)

Fig. 783—Creeping ancylostomiasis in child's boy back. (Dr Grover Wende)

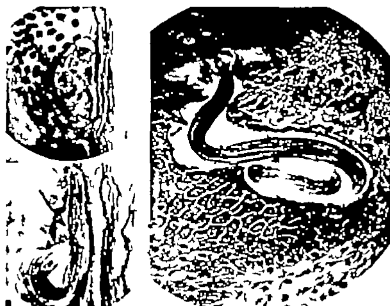

Fig 784—*Ancylostoma braziliense* larvae shown by histologic sections in human epidermis. (Kirby-Smith, White and Dove ADS 13 137 1926)

The larva, located at the terminus of its tunnel may be frozen in situ with the ethyl chloride spray this treatment is usually effectual This is the only treatment which has stood the test of time according to Sompayrac (SouthMJ 47 792, 1954) Halley (SouthMJ 39 371 1946) stated that a grated raw onion poultice applied thick, overnight for 3 to 7 nights, will do the job

In seeking larvae in the skin, where they can be seen with a hand lens, one cleanses the skin at the suspected site with alcohol and applies cedar-wood oil to clear it. The end of the burrow is carefully examined, and the larva appears as a white spheric mass (Bayley: TransRoySocTropM 34: 399 1941) The site may then be anesthetized with procaine and the larva destroyed with the actual cautery or with the electric needle (Farrington: JID 14: 395 1950) Stibanose a pentavalent antimonyl, is said to be less toxic than Fuadin, and by stopping the movement of the larva makes easier its localization and destruction by freezing (Wilson: SouthMJ 45: 177 1952)

Cure might be obtained by intramuscular injections of Fuadin, 6 3% solution 2 cc daily for 5 doses, perhaps repeated after a week's rest according to Smith (J 123 694 1943) Wilson (FlaMAJ 30 425 1944) and Hitch (ADS 55 664, 1947) confirmed this, but Blank (J 123 989 1943) and Dolce and Franklin (ADS 52 174 1945) reported disappointing results. Systemic therapy was judged ineffectual by Loewenthal (AustralJD 2 173 1954)

Hetrazan (diethylcarbamazine) given orally in a dose of 2 mg./kg t.i.d. for 7 days, cured 17 of 19 cases of Van de Frye (JID 12 69 1949) and was almost as effective in the cases of Horton (USAFMJ 1 668 1950) its side effects were few and mild. A dose of some 9 to 10 mg./kg given in syrup t.i.d. for 5 or 6 days was highly recommended by Kelley (FlaMAJ 40 242, 1953)

CREEPING ERUPTION may be due to larvae other than those of *A braziliense* and is representative of frustration of the normal complete penetration and pursuit of its life cycle by a parasite attacking an unsatisfactory host (Caplan: BMJ 1: 433 1950) *Bunostomum phlebotomum* the hookworm of cattle (JParasit 39: 343 1953) can cause creeping eruption on the hands of exposed human beings (Mayhew: ProcSocExpB 66: 12, 1947): small, inflamed papules appear enlarge for 2 or 3 days and are followed by narrow linear slowly extending tortuous, vesicular lesions which itch intensely but clear spontaneously in a fortnight.

Creeping eruption may be due to several kinds of parasites see Gnathostomiasis, Schistosomiasis, Tetranychus infestation and Myiasis.

Ascariasis.—Phasmid nematodes of the superfamily Ascaroidea are fairly large stout forms possessing a mouth with 3 conspicuous lips but without a buccal capsule. *Ascaris lumbricoides* is a round white intestinal parasite ranging up to 10 inches long Infestation is a possible cause of urticaria or prurigo (Stauffer Dermatologica 105 203 1952) and erythema nodosum has appeared in heavily infested children. Cutaneous allergy develops (Borlin Dermatologica 92 187 1946) The life history of the parasite was discussed by Moore (SouthMJ 47 825 1954)

Oxyuriasis.—Phasmid nematodes of the superfamily Oxyuroidea are small forms more or less pin-shaped, with buccal capsule and cuticular esophageal lining well developed.

Enterobius (Oxyuris) vermicularis adults are white worms 2 to 13 mm. in length and 0 1 to 0.5 mm. in diameter the male being about one-third the size of the female. Called pinworms, these inhabit the human ileum, cecum appendix and ascending colon, their heads attached to the mucous membrane of the intestine The female with full uterus migrates toward the anus, and thousands of eggs are laid in the dejecta and rectal mucus. Ova, when swallowed, hatch in the duodenum, and the larvae moult and lodge in the distal gut.

Pruritus ani results from infestation. It is a symptom of remarkable periodicity appearing always in the evening at bed hour probably because of the warmth and quiet which encourage great activity on the part of the worms near the anus. Erythema of the anal margin is seen, with many reddish points from the bites of the worms; there is considerable thick and sometimes blood tinged mucus, in which ova are to be found. Vulvar and vaginal involvement occurs. Otitis externa so caused was observed by Hand and Criswell (ADS 59 249 1949) and was cured by the instillation of benzyl benzoate.

In diagnosis an anal swab is made of Scotch tape wrapped sticky side out about the closed end of a test tube. The sticky surface is rocked against the anus, and the tape is then pasted on a slide and examined for adhering ova (Jacobs JPed 21 497 1942; v.Hofe: J 125 27 1944)

Thymol is a useful vermifuge A dose of 4 grams may be given an adult 1 or 2 to a child dividing the dose into 0.5 Gm parts, giving one part each hour and following the last dose with a saline purge Hexylresorcinol crystoids, 1 Gm. for adults and 0 6 to 0.8 Gm. for children are recommended. The dose is swallowed without chewing in the morning on an empty stomach. Gentian violet also is useful internally 1 grain enteric-coated t.i.d. for 10 days being an adult dose (Wright and Brady AmJMedSci 198 367 1939 J 114 861 1940) Benadryl Emplets, 50 mg daily for 10 days for little children and thrice this dose for patients over 12 years old were reported curative by Siung (BMJ 1 822, 1950) Piperazine hexahydrate is nontoxic safe and effective (Bunibalo et al JPediat 44: 386 1954) Terramycin is the drug of choice among pediatricians currently (Wells et al. Antibiot&Chemother 1 299 1951)

Gnathostomiasis and Related Worm Infestations.—SPIRUROIDEA, a superfamily of phasmid nematodes contains several species of dermatologic interest. *Gongylonema pulchrum* has been reported in the southern ... United States. It eggs are ingested by beetles or cockroaches within which they hatch and burrow and subsequently reach the mucosa of the human mouth throat or esophagus, where they tunnel and migrate Mechanical removal of the threadworms can be accomplished.

Swelling and hyperemia of a girl's lip due to thi parasite was observed by Stiles and Baker (J 91: 1901 1928) and they reviewed 5 other cases. A case occurring in South Carolina was reported on by Young and Hayne (J 151: 140 1953) The parasit ca ing a forearm nodule seen by Forbes (Lancet 1: 651 1919) was not specifically identified. Migrating and itching swellings of the skin associated with high eosinophilia and positive cutaneous reacti ity to an antigen from *Di ofilaria immitis* were seen in Palestin (J 121: ..30 1940) and may have been f this nature for threadworm produce migratory nodules.

Gnathostoma spinigerum para itizes the tiger and other host i the Far East. Eggs in feces hatch out motile larvae which enter a *Cyclops* and later a second intermediary host. In the human being immature worm usually penetrate only superficially prod cing sta t onary or migratory lesion which are abscesses or firm nodules with abscessed centers. G athostomia causing creeping eruption, acute edema, abscesses and nodules can be prevented by cooking fi h sufficiently to kill the vector (Kitamura: ADS 66: ..6, 1952)

Thelazia call pa da i a parasite of the conjunctiva of dog rabbit and man, occurring n China, Burma and India. Other species exist which also evince predilection f r the ocular region. Arthropodan intermediary hosts are involved, and the adult worms, perhaps longe than 1 cm. and creamy white coil in the conjunctival sac and migrate so as to prod ce severe pain lacrimation and irritation, which may provoke scarring of the cornea. They may be removed mechanically *T. cal forniensis* wa the parasite fou d in the conjunct va of the patient of Hosford et al. (AOphth ..: 1165 1942)

Filariasis.—Phasmid nematodes of the superfamily Filarioidea are filiform worms with a simple mouth almost circular surrounded by papillae lacking lips and with buccal cavity at most rudimentary The adult lives in the tissues or body cavity of a vertebrate host

Eggs re partially embryonated before birth, and at about the time of oviposition th embryos uncoil as delicate snakelike microfilariae These circulate in the blood or move in the cutaneous ti sues and are ingested by blood-sucking arthropods. Migrating from the digestive tract of the arthropod vector they undergo m tamorphosis, and mat re larvae migrate into and down th hemocelic cavity in the labium so as to reach the kin of the vertebrate host upon which the vector next feeds.

Wuchereria bancrofti (Filaria sa guinis hominis) is a creamy slender smooth skinned worm th adults of which, several centimeters in length, live in the human lymphatic system. The microfilariae are 100 to 400 times a numerous in the blood at night as during the day although those of the South Pacific lack such periodicity They measure 150 to 320 μ by about 10 μ in diameter Their evolution continues in mosquitoes and they introduce themselves actively through the skin of the human being when the mosquito attacks. Several vectors in add tion to the usual *Culex fatigans* have been determined.

Filariasis occurs in Hungary a d T rkey th Far East Burma, Indi I do China, and vicinity the Dutch East Indies, Philippines, northern Australia and Micronesia, North Africa and northern South America. The hyperendemic areas of yaws and Bancroft's filariasis are notably coextensive (Craig and Faust)

W malayi s a similar worm reported from th Dutch East Indies in association with elephantiasis usually of the uppe extremity It is distinct from *W bancrofti*, which it resembles, but its m rofilariae show two distinct nuclei in the tip of the tail (Craig and F ust 1951)

SYMPTOMS.—Early clinical manifestations of filariasis were clarified by Saphir (J 128 1142. 1945) comprising a well-defined clinical picture Saphir's patients were men exposed in a heavily infected area Within 3 to 6 months

Fig. 785.—Filarial elephantiasis. (Dr Harry M Robinson, Jr.)
Fig. 786.—Hydrocele due to W bancrofti infestation. (Dr Harry M. Robinson, Jr.)

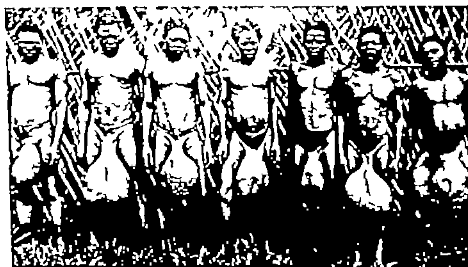

Fig 787 —Filarial elephantiasis, 6 cases. Patient at left has hernia. (Dr L. F J ...gard)

insidiously progressive and intermittent complaints developed with feelings of numbness of an extremity particularly at night followed by aching abetted by exertion and the discovery of axillary or inguinal lymphadenopathy. Periodically recurring pains in axillary, arm, groin, thigh and scrotal regions ensued and nocturnal orchiodynia was commonly experienced. By this time examination would reveal lymphatic and genital findings: multiple slightly tender firm discrete movable lymph nodes of axillary, inguinal and femoral regions regularly and other sites occasionally; funiculitis usually left-sided and occasionally varicocele, hydrocele and epididymitis. Funicular involvement was palpable as a peculiarly nodular tender thickening. Microfilariae could not be demonstrated and diagnostic skin tests were without value. If the patient were removed from the endemic area nothing further developed. Anxiety especially concerned with potential harm to genital function was usual, but such fear was groundless.

Progress of disease beyond the early stages is characterized by lymphangiitis associated with a red streak and perhaps palpable enlargement of the vessel. Dull red, tense, edematous, painful swellings occur in arms or legs. Urticaria and eosinophilia sometimes are met but not always. Swellings develop rapidly, regress and recur. Fever and malaise may accompany these exacerbations. No case of elephantiasis developed in an American soldier and the hazard to the public occasioned by returning military personnel apparently is negligible.

Late stages are characterized by chronic hyperplastic changes in the skin and subcutaneous tissues, which are due to lymph obstruction and inflammation and which may result in enormous increase in size of the affected part known as elephantiasis. Chylous effusions in the chest and abdomen are occasional late manifestations.

DIAGNOSIS is justified in early stages in endemic areas on clinical grounds alone. Exacerbation precipitated by exercise are suggestive. Proof of infection requires demonstration of microfilariae. In the blood they are curiously much more numerous at night than in the daytime (O'Connor: JTropM 40: [illegible], 1937). The mosquito abstracts more of them from a man than can be found in an equal quantity of blood obtained by pin prick (Manson: Filaria Sanguinis Hominis, Lewis 1883; O'Connor and Beatty: JTropM 40: 101, 1937). This periodicity may be concerned with diurnal changes of blood oxygenation (McFadzean: BMJ 1: 1106, [illegible]). Microfilariae may be found in lymph node or hydrocele fluid, or a calcified worm may show up roentgenographically.

The skin test using *Dirofilaria immitis* antigen is of dubious value and the antigenicity of various worms is not greatly different as judged by such test (Lippelt and Mohr: KlWchnschr 17: 1694, 1938).

Histologic changes are those of chronic inflammation, nonspecific unless identifiable worm substance can be found (Michael: USNMBull 45: 225, 1945; Rifkin and Thompson: APath 40: 220, 1945).

TREATMENT during acute attacks should consist of rest and compresses and elevation if swelling and pain indicate their desirability. X-ray therapy and surgery are not advisable then, but elephantiasis may be attacked surgically. Neostibosan in increasing dosage reaching 300 mg., on alternate days, may be given for a month or more; this by influencing adult worms, diminishes the production of embryos (Culbertson et al. AmJTropM [illegible] 130 534 1946). Anthiomaline may be useful (Brown: J 125 952, 1944). Encouraging results with Hetrazan (1-diethylcarbamyl-4-methyl piperazine dihydrogen citrate) were reported by Stevenson et al (J 135 708, 1947) in doses by mouth of 0.5 to 2 mg./kg. t.i.d. for from 3 to 22 days. The drug rapidly eliminates microfilariae from the blood but not from hydroceles and it is not toxic to them in vitro (Hawking and Laurie: Lancet 2: 146, 1949). Its usefulness was first attested by Hewitt (J 136: 708, 1947) but it caused enough side effects in a fourth of the Gambian patients treated by McGregor et al. (BMJ 2: 908, 1952) to earn a bad lay reputation. Avoidance of infected villages, mosquito control, protective clothing and bed nets and insecticidal efforts are indicated when one must stay where the disease occurs (WDTBM no. 142, 1945).

See Kellersberger (J 82: 1197 1924) surgical removal of 85 lb. of scrotal tissue; Earl (Lancet 2 667 1941), suppression with sulfapyridine; Grace (J 123 462, 1943), relatively little benefit from sulfonamide; Wartman (AmJTropM 24 299 1944) in W Pacific cases, diagnosis; Thompson et al. (J 129 1074 1945) early infections, clinical features; Hodge et al (AmJMedSci 210: 207 1945) early filariasis; Coggeshall (J 131, 8, 1946) lymph tissue appears but not seen in soldiers stationed in Samoan Islands; Welch et al (Ibid 105 486 1947) cyanine compounds in treatment; McFadzean and Hawking (BMJ 1 936, 1951) arsenamide 125 mg. I V daily ×10 effective, seldom fatal.

Sporadic Elephantiasis may follow recurrent cellulitis due to bacteria or dermatophytid or it may be due to malformation or to other causes of lymphatic obstruction. Luke (SGO 73: 4 , 1941) listed chronic enlargement of the leg under 6 headings: congenital hypertrophy lymphatic stasis congenital or acquired developmental venous retardation, mixed venous and lymphatic partial obstruction arteriovenous fistulas and miscellaneous. Nonfilarial elephantiasis may be due to recurrent erysipelas (q.v.) carcinomatous obstruction of lymphatics (see cancer metastatic) surgical removal of lymphatics in the treatment of cancer lymphangioma or hemangioma (q.v.) form of von Recklinghausen's disease (q.v.) chromoblastomycosis (q.v.) and other agencies.

See Shattuck (BostonM&SJ 163: 18, 1910) etiology; Stevens (J 100 1754 1933) recurrent erysipelas; New and Kirch (J 100 1230 1933) facial palsy; Homans et al (AnnSurg 100 812, 1934) animal experiments relation to high protein concentration in tissue fluid; Allen and Ghormley (AnnIntM 9 516, 1935) classification of 300 Mayo cases in of lower extremities; Montgomery (ArchIntM 57: 1148, 1936), secondary to cancer of ankle; Hill (BMJ 2 673, 1936) following trauma; Veal (J 108 1236, 1937) vasographic studies of surgical obstruction cases; Cooperstock (AmJDisChild 57 309 1939) congenital; Homans (ArchSurg 40: 732, 1940), varieties of leg cases; Netherton and Curtis (AJDS 41 11 1940) diffuse hypertrophic syphiloma and lymphopathia venerea; Macey (PMSMC 15: 49 1940) nevoid; Allen and Hines (PMSMC 15 164 1940) orthostatic in fat girls; Hovnanian (ConnMJ 13 44, 1949) unusual scrotal case surgically relieved; Blocker (Plast&ReconstrSurg 4 407 1949) treatment; DeTakats and Evoy (Angiol 1 73, 1950) 150 cases of lymphedema treated with elevation, compression, mercurial diuresis heparinization, interruption of sympathetic innervation, x-ray excision; Pratt (J 147 11 1 1951 151: 888 1953) surgical correction.

Pseudoleprosy of Robles was reviewed by Mazzoth (MedMex 21: 103, 1941) who described 6 cases of chronic solid edema of the feet. The disease begins with erythematous macules on the lower third of the leg and persists for several years with non-suppurative inguinal adenitis. Progress takes place with febrile attacks of a few days duration, with enlargement of the affected parts. These attacks diminish in frequency after a few years. The onset is usually at an age between 6 and 20 years. No radiographic alterations are found and no parasites have been discovered although all varieties have been sought. The disease is unresponsive to therapy.

Onchocerciasis.—Filarial worms of the genus Onchocerca inhabit connective tissues and blood vessels of mammals; in man they tend to accumulate beneath the epidermis. Black gnats (Simulium) are the usual vectors.

O volvulus has a transparent opaline body. The mouth is smooth. The male is 30 by 0.13 mm., with rolled up tail; the female reaches a size of 50 by 0.36 mm., and is viviparous. Both sexes are found in the subcutaneous tumors, which range from pea to pigeon egg size and are located in scattered places; the popliteal, lumbar, intercostal, axillary, epitrochlear and nuchal regions. The tumors are nematodic and contain adult and numerous embryo worms in canals in fibrotic tissue. They are generally readily enucleated, and they never occur in deep organs. The evolution is slow, the worm living many years. The tumors never ulcerate. Despite frequent exposure to infected bites, the natives in endemic zones may have only 1 or 2 verminous tumors; some sort of immunity may develop.

The embryos are some 300 by 6 or 8 μ in size; they have no sheath. They migrate in the connective tissue. They are much more numerous in the vicinity of the bite of a vector than elsewhere in the skin.

Symptoms.—In Mexico especially Chiapas and Oaxaca, and Guatemala, infestation is common. In American cases, tumors containing *O volvulus (O caecutiens)* are almost always located on the head. Microfilariae in their migrations are especially liable to enter the cornea iris and conjunctivae so causing scarring and eventually blindness. Cutaneous lesions may resemble erysipelas in the acute phase. Chronic infection results in edema, eczema with hyperpigmentation and especially swelling of the ears. The skin nodules *range from 0.8 to 30 or 40 mm. in diameter* and are hard and red but not painful. In American cases the number is usually less than 8 and they are generally on the head, while in African cases the number ranges from 25 to 100 and the trunk and limbs are the sites of predilection. Ocular lesions were found in about 60% of persons with fewer than 5 nodules but in almost 80% of patients with more than 5 nodules reported Solanes et al. (AmJOphth 32 1207 1949). The nodules contain turbid liquid rife with microfilariae swimming about a core of adult parasites enmeshed in atrophic connective tissue

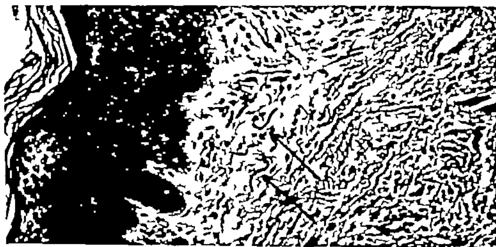

Fig. 795.—Onchocercal dermatitis, erythematous, squamous and papula showing microfilaria in the dermis. (Goldman ADS 49 335, 1944)

PREVENTION consists in staying away from infested regions. If one lives there one must destroy flies, avoid their bites, and excise verminous tumors as promptly as they appear

TREATMENT — A strong solution of Apothesine injected into the verminous tumor kills the parasites renders excision unnecessary, and relieves the symptoms of craw-craw (Stixrud 1938) Roberto (MMéxic 24 265 1944) found wiggling microfilariae in fresh split skin biopsies immersed in saline Hetrazan and Germanin, effective drugs in W bancrofti infection apparently kill the organisms in O volvulus infection but here their administration is followed by intensification of symptoms analogous to the Herxheimer reaction with pruritus, urticaria fever and lymphadenopathy presumably due to rapid killing of the organisms, and the doses must be small and relatively infrequent (Hawking and Laurie Lancet 2 146 1949 Hawking: BMJ 1 992, 1952) Germanin appears to be superior Hetrazan treatment was tried by Ikejiani (W AfricaMJ 3: 135 1954) in whose experience the value of *Dirofilaria immitis* antigen appeared to be doubtful Hetrazan did not visibly influence the worms as observed in nodules excised after it was given It did, however cause itching in all patients during the first day, and occasionally rashes, fever aching leukocytosis and lymphadenopathy Skin lesions began to disappear after the fourth day and were gone within 2 months, only to relapse later The drug evidently affected microfilariae but not adult worms.

FILARIAL ITCH is a manifestation of onchocercal infestation. This is one variety of craw-craw a nonspecific native name The dermatosis is not pathognomonic It occurs in Central Africa Ceylon and China and probably elsewhere Papulopustules and plaques which may crust ulcerate and leave scars are typical The buttocks and flanks the outer side of the thighs, the elbows, forearms and rarely the neck are involved the face genitals and interdigital volar and mucosal surfaces are usually free Repeated attacks occur and the eruption is therefore polymorphous. Urticaria may accompany the attacks. The dermatosis does not of course respond to antiscabietic treatment It resembles dermatitis herpetiformis.

See Strong (NEngJM 204 916, 1931) Strong et al (Onchocerciasis, Harvard Univ Press, 1934, p 234) monograph Bryant (TransRoySocTropM 28 523, 1935) in Anglo Egyptian Sudan Herrejon (quoted J 106 579, 1936) blindness in 30% of population in some places Semadeni (SchweizMW hn 70 75, 1940) slit lamp demonstration in eyes Harris (TransRoySocTropM 34 223 1940) nauk [illegible] Kenya, ichthyosiform and lephantiasic changes Goldman (ADH 50 388, 1944), review and illustration Goldman and Ortiz (ADS 53 9 1946) cutaneous features Ophthalmologic Assn of Guatemala, Unal of S Carlos (Onchocercosis, Enfermedad de Robles 1947 p. 287) Robles disease ; Nwokolo (TransRoySocTropM 43 493, 1950) Nigerian cases, none of [illegible] eyes, Craig and Faust (Clinical Parasitology Lea & Febiger, 1951 p. 4 1) de H [illegible] (BMJ [illegible] 14 1954), solitary worm found in deep groin paratyphoid [illegible] Kershaw et al, (BMJ 2 724 1954) studies of O [illegible] also microfilarial concentration and distribution in the skin, showing patterns related to distribution and severity of skin and eye lesions, with high concentration, unexplained, in lower leg and trunk region of persons infected with moderate intensity

Loasis (Calabar Swellings).—*Loa loa* has a transparent opaline body and a smooth, thick skin dotted with many small bosselation The males are some 30 by 0.33 mm. (3 times the size of *W bancrofti*) and the ovoviviparous females are some 63 by 0.4 mm. They inhabit the subcutaneous tissue and move about constantly so that little tissue reaction is present Embryos are freed into the cellular tissues and enter the lymph and blood They are some 250 to 300 by 6 to 8 μ in size They are typically found in the blood in the morning most numerous there shortly after noon, and they disappear in the evening The mango fly is a vector

In equatorial Africa many natives harbor the parasite in the blood. The adult worm in its migration produces egg-size painless warm swellings resembling angioneurotic edema. Where the skin is thin the outline of the worm itself may be visible They have been known to traverse the conjunctiva Itching eosinophilia and sometimes malaise and urticaria accompany the direct manifestations. Cases have been described by Kimberlin (J 81 1685 1923) Low (JTropM 37 359 1934) Charpy (BullsocfrançD 46: 180, 1939) and others. Adult worms have been surgically removed from the back, axilla, groin, breast penis, scalp eyelids and even the bulbus oculi (Craig and Faust 1951) Cure is effected by such surgical removal which requires both speed and skill and is easiest when the worm is migrating across the bridge of the nose or through the corneal conjunctiva.

Antimony and Mapharsen are not effective but departure from endemic areas is followed by eventual relief (Guy et al.: ADS 47 763, 1943) Hetrazan was used with good results, although it caused temporary malaise (compare Onchocerciasis) in 3 cases affecting missionaries observed by Ten Berg (abs YBD 1952 p. 74)

Dirofilaria conjunctivae and other filarial worms of genera different from *Loa loa* are sometimes found. *D. conjunctivae* measures in its adult form from 5 to 10 cm. in length and 0.5 mm. in diameter; it produces encysted subcutaneous nodules of the eye and other regions, and infestation is cured by its mechanical removal (Craig and Faust 1951)

Dracontiasis.—*Dracunculus medinensis*, the Guinea worm produces a remarkable infestation observed about the west coast of Africa, upper Egypt, Asia Persia and India. The female is from 30 to 100 cm. in length and 1.0 to 1.7 mm. in diameter; the male rarely discovered, is to 4 cm. long The worm lives in the subcutaneous tissues. The female develops, migrates and appears in the skin several months after one ingests with the drinking water certain crustaceans, Cyclops, infested with the larvae.

Adult worms develop within the host, and the viviparous female makes her appearance after several months, laden with larvae at the bottom of a pea-sized, indurated, itchy lesion, the site of which is frequently the foot or leg and through which larvae are extruded; or she may form a soft spongy cordlike mass under the epidermis. The parasites are usually solitary but may be multiple The condition is relatively benign. Urticarial and asthmatic attacks and gastrointestinal upsets may complicate the infestation, often just preceding the development of the local skin lesion (Fairley and Liston: IndJM Res 11: 915; Lc 92, 247 1924; Okojie: BMJ 1: 397 1954)

Fig. 190.—*Dracunculus medinensis* being extracted from foot. Five more worms subsequently issued from this Uganda native. (Dr A. L. Ribeiro BMJ 2 1310 1952.)

Emily injected 1:1,000 bichloride of mercury into the worm or the tumor it produced and after 24 hours the parasite could usually be extracted without trouble. The natives generally pull the worm out of its hole an inch or two and wrap it on a stick of wood. Each day some 3 or 4 centimeters of worm can be rolled up, and with good luck a cure may be attained in a fortnight. Rupture of the worm during its extraction must carefully be avoided. Slaked lime 1 1,000 in the supply of drinking water repeated at intervals of 14 days or so, kills the Cyclops. Boiling and filtering the water before drinking it are effective prophylactic measures.

See Chitwood (J 100 802, 1932) 4 cases in USA Rao (IndianMGaz 24 533, 1930) release of larvae from Cyclops by HCl Moorthy and Sweet (IndMGa 71 565, 1936) biologic control, using fish that eat Cyclops Perry (BMJ 2 1107, 1948) worm found in hernial sac in African youth, Katzenellenbogen (quoted J 144 1391, 1950) 40 cases from Yemen, fever at onset, cellulitis and blisters, worms seen extruding from lesions of feet, legs, buttocks, mammae, palms, penis Katzenellenbogen (Dermatologica 108 129 1954) previously unknown in Israel, 68 cases of *Dracunculus medinensis* infestation found among 48,000 Jews who emigrated from the Bulk area of Yemen.

Platyhelminthes
TREMATODE INFESTATIONS

The phylum Platyhelminthes contains 4 classes, of which the Trematodes and Cestoidea include the human pathogens.

Trematodes are exclusively parasitic organisms, the integument of the definitive stage nonciliated, suckers usually present, circulatory system lacking digestive canal present except in sporocyst generation of the subclass Digenea. This subclass contains the human pathogens. Most of the digenean species are endoparasitic, attaching by suckers, 1 of them perioral; development is complicated, involving 2 or more generations and an alternation of hosts. The host harboring the intermediate stages is a mollusc.

Prosostomata is the order inclusive of all trematodes affecting human beings and contains the flukes and schistosomes. See Craig and Faust (Clinical Parasitology Lea & Febiger 1951 pp. 445 500); Dawes (The Trematoda, Macmillan 1946)

Fluke Infestation.—In *Fasciola hepatica* an illustrative trematode the egg becomes a miracidium a free infusoriumlike embryo. This, in the intermediary host becomes a *sporocyst* which buds internally. Spores are freed and become encysted and in the liver of the definitive host give rise to the adult which produces eggs. Cutaneous nodules generally located on the trunk occur rarely as rice-grain sized sacs containing 1 to 3 worms in a slimy jelly provocative of itching during the first few weeks of subcutaneous existence later becoming firm (Stiles JCutDis 26: 34 1908) Several species of worms cause similar tumors Diagnosis can be made only after removal.

Schistosomiasis.—Schistosomatoidea is a superfamily of the order Prosostomata of the digenetic trematodes. The definitive stage is monecious or diecious, living in the portal blood streams of vertebrates. Cercariae enter the definitive host through the skin. *S haematobium* causes bilharziasis of the bladder *S mansoni* causes intestinal and splenomegalic involvement *S japonicum* causes intestinal and hepatic bilharziasis.

S haematobium cercariae penetrate within 10 minutes when the skin is exposed to polluted water losing their bifid tails at the surface and entering the veins, where in about 2 months they become adults migrate to the bladder and produce disease there During the period of invasion, urticaria may occur along with the usual toxic fever sweats and malaise Fibrous nodules sometimes appear especially in the perineal and bathing trunk areas. Hard at first they gradually enlarge soften, ultimately burst through the skin, discharging thick, dirty caseous material The sores generally persist as fistulas communicating with a deeper organ or mucous surface simulating tuberculosis (Black BMJ 2 4 3 1945) *S mansoni* cercariae penetrate the skin with the provocation of temporary severe pruritus and small papules, which appear within 6 to 8 hours afterward Urticaria and purpura may occur (Hauser NOrlM&J 92 265 1939) Creeping eruption progressing 2 inches per hour along with crusts, urticaria fever painful liver and white cell count of 64 000, 96% eosinophils, was reported by Wright and Roberts (EAfrMJ 21 282, 1944) *S japonicum* infection resembles *S mansoni*. Urticaria accompanied by fever may develop as early as the fifth day after exposure and about the end of the fourth week intense urticaria subcutaneous edema and large wheals affecting both skin and mucosae are usual followed by toxic diarrhea (Craig and Faust 1951 p 464ff Faust et al AmJTropM 26 87 1946) The patient of Fishbon (AmJTropM 26 319 1946) 1 week after exposure had angioneurotic edema of the face chills fever and cough Pruritic papules appeared on the chest and became shotty grouped or coalescent. Some developed pustulation with ova in the pus. The lesions underwent fibrosis when Fuadin was given after ova appeared in the stools.

Skin Test —An antigen may be prepared from infested snail livers, and reactivity to it indicates that the subject harbors living parasites (Fairley in Byam and Archibald Practice of Medicine in the Tropics, Oxford Univ Press, 1922 vol 3 p 1712) The immediate urticarial reaction was described by Hoff (J 107 137 1936) who observed also delayed reactions. No negative reactors were found to be passing eggs reported Alves and Blair (Lancet 2 556 1946) who considered the test more revealing than repeated microscopic examinations in finding cases and assaying results of treatment.

Swimmers Itch —The cercariae of *Trichobilharzia ocellata* and other avian schistosomes cause a characteristic pruritic dermatitis of bathers in the United States. Cort (J 90 1027 1928) recognized the nature of the condition when he experienced it himself as a result of immersing his forearms in water in which were recently collected snails. There occur (1) a prickling sensation which may begin while still in the polluted water (2) erythema, papules and sometimes pustules, (3) intense irritation for the first few days and (4) gradual disappearance of symptoms over a period of some 2 weeks. An exposed bather will suffer less if he wipes dry with a towel immediately after leaving the contaminated water (Brackett J 113 117 1939)

Fig 197 —Schistosome dermatitis After exposure, left foot was promptly wiped dry (Brackett J 113 117 1939)

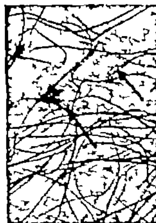

Fig 198.—Schistosome dermatitis Lesions produced by experimental exposure to the cercariae. (Cort 90 1027 1928)

Fig 199 —Penetration of follicles by cercariae causes inflammatory papules. (Dr Laird Lyster Institute of Pathology MacDonald College, Quebec.)

The worms are not parasites of man but rather of birds and mammals; their eggs in the feces of these animals hatch in water into miracidia which develop into cercariae in snails. Control may be accomplished by distributing CuSO on the beach * lb. per 1,000 sq. ft. of lake bottom, adding 70% fresh hydrated lime. The chemicals are disseminated by power pump and long rubber tubes reaching the bottom (the Michigan Plan; see Macy: NoW Med 51: 910 1952)

A Hawaiian marine larval schistosome tentatively identified a *Cercaria littor sal na* (Penner: JParasit 1 36: 466 1950) the adult form of which had not been discovered, is apparently the cause of Pearl Harbor Itch as described by Arnold and Bonnet (Proc HawaiianAcadSci 25: 4 1950) according to Chu (Sci 115: 151 1952) Clam diggers dermatitis seen in the Long Island Sound region seems probably to be due to schistosomes (O ris and Combes: AIDS 66: 367 1952)

Seabathers eruption characterized by erythematous wheals appearing a few *hours after sea bathing and persisting for several days itchy but without complications,* was carefully studied by Sams (AIDS 60: 227 1949) but the cause could not be demonstrated, despite the similarity to schistosome disease

CESTODE INFESTATION

Cestoidea, a class of Platyhelminthes (compare Trematodes) are el el parasitic organisms covered with noncilli ted ntegument; adults hermaphroditic; embryos hatched from eggs; scolex provided with suckers and frequently with hooks for attachment to host no digestive tract; body usually divided into separate, sexually complete units called proglottids All human tapeworms, including *Taenia solium* and *Echinococcus granulosus*, fall within the family Taeniidae of the order Cyclophyllidea in the subclass Cestoda. It is interesting to note that Atabrine is effective against tapeworms (Paeckelmann: DeutschesMedJ 5: 244 1954)

Cysticercosis.—*Cysticercus cellulosae* the larva of the cestode *Taenia solium* causes in man small rounded firm, subcutaneous tumors painful and larger while the parasite is alive and actively irritating but painless, smaller and sometimes calcified after its death. Rarely the lumps become abscesses (Dixon and Hargreaves: QJM 13: 107 1944) The verminous tumor may occur in practically any part of the body 10 cases in the central nervous system were collected by Chung and Lee (ChinMJ 49 429 1935) Atabrine, preceded by a purge with castor oil or magnesium sulfate cured 11 cases of gut infection with the adult worm for Sodeman and Jung (J 148: 285 1952)

Echinococcosis.—*Echinococcus granulosus* (Goeze, 1762) lives in man only in the larval state. The adult worm is only 3 to 6 mm. long and inhabits the gut of dogs particularly The eggs reach the stomach of man by fecal contamination, and the embryos are freed. They generally infest the liver by way of the portal system but may reach any part of the body In subcutaneous tissues, the lesions are walnut to apple-size semitranslucent tumors. The treatment is excision, exerting extreme care to avoid rupture of the parasitic cysts. Some 8% of cases of echinococcosis show subcutaneous lesions. Urticaria, fever pruritus, erythema and hyperhidrosis are among the cutaneous symptoms due to allergy (Godfrey AnnIntM 60 783 1937)

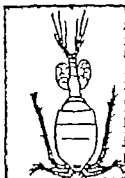

Fig. 601.—*Sparganum* larva of cestode, in eyelid of Annamite girl. (Dr E. Brumpt.)

Fig. 602.—*Cyclops viridi* (×10) intermediate host of Dracunculus (By permission from Medical Entomology by Drs. W A Riley and O. A. Johannsen, McGraw Hill Book Co., Inc.)

The cyst fluid is potently allergenic and may be used for intracutaneous diagnosis. The skin test (Casoni s) sensitizes and should be used but once (Rist PresseMéd 47 201 1939) It failed in the diagnosis of 5 of 27 cases of Kneebone (MJAustral 1 201 1937) See also Fairley (MJAustral 1 472, 1929) and Culbertson and Rose (JClinInv 20: 249 1941) A complement fixation test is also of some value (Rose and Culbertson J 115 594 1940)

Sparganosis.—A sparganum is a larval form, the adult usually being unknown of a pseudophyllodean cestode. Spargana may be found in the subcutaneous tissues and muscles of various vertebrate hosts. Human infection may result from ingestion of larvae and their migration to subcutaneous tissues and further development there or from migration from infected flesh directly into human tissues. The worms are elongated, ivory white ribbons, inducing in infected tissues edema, pain and itching The region of the eye is often involved in French Indo-China Surgical removal of the animal is curative

D mansonoides is perhaps the source of the nonproliferating type of sparganosis found in the United States (Craig and Faust 1951 p. 561) Infestation may be avoided by drinking clean water and not ingesting raw tadpoles or poulticing sores with polluted raw meat, unhygienic habits which can be eliminated from natives by education. See Castellani and Chalmers (Tropical Medicine 1929 p 606) Feng and Hoeppli (ChinMJ 50 1457 1936) Feng et al. (ChinMJ 54 530 1940)

ANNELIDA

Leeches.—Roundworms of the phylum Annelida include the class Hirudinea, the leeches, the bites of which are of dermatologic interest. The leech maintains the flow of the blood it sucks by introducing an anticoagulant albuminose hirudin into the skin (Q.M.N. J 172 184 1946). The leech is likely to be discovered by the dripping of blood from the bite, which is painless, but the wound is slow to heal after the animal is removed. A leech may attach itself to the skin or to the mucous membrane of the upper respiratory tract, pharynx, esophagus or conjunctiva. When it is fully gorged it drops off, but it should not be pulled off lest the jaws remaining in the wound incite severe inflammation or secondary infection. To hasten its release one may apply strong brine, alcohol or vinegar to the site of attachment, or apply a lighted match to its body, or cocainize the head and remove the slippery body gently and carefully from a nasal passage. There is the hazard of its falling into the trachea, and the patient should be placed head down when a leech is removed from the nose or throat.

Attack can be avoided by wearing suitable protective clothing, by impregnating the clothing with dimethyl phthalate, and by boiling the drinking water. *See Craig and Faust (Clinical Parasitology, Lea & Febiger 1951, p. 606).*

Fig. 501.—Leech bite on forearm. (Dr. Clyde Cummer.)

ARTHROPODA

The phylum Arthropoda consists of invertebrate, segmented, bilaterally symmetric animals. Their bodies are composed of more or less well-differentiated parts enclosed in a chitinous frame, and the paired extremities are articulated. They possess a complete digestive tract with mouth and anus, a blood system, a central nervous system with brain and with paired nerve trunk and ganglia for each segment, and separate sexes. The classes **Arachnida** and **Insecta** include all parasites of man. The class **Diplopoda**, millepedes, consist of fangless nonvenomous animals with pairs of legs for most segments. The class **Chilopoda**, centipedes, possesses a single pair of legs per segment, the first pair modified to form poison claws. A Texas representative *Scolopendra morsitans*, can kill mice and *S. cingulata* venom produces painful edema and papules in human beings. Urticarion and purpura constitute the maximum of their maleficence, and they cannot bite through thick epidermis. Now and then one wanders into the nasal passages and sinuses. The class **Crustacea** contains a few eucopepods, such as Cyclops, which serve as intermediary hosts of worms of consequence to human beings. An outline of arthropodan dermatoses was given by Canizares and Shatin (ADS 68 157 1953). See general references on diseases due to animals.

Arachnida are terrestrial arthropods with tracheal or cutaneous respiration, the body being formed, in general, of 2 parts: the anterior (cephalothorax) bears the mouth and 4 pairs of legs, and the posterior part (abdomen) includes the anus. Some members of the class bite or sting. This class includes the **Arthrogastra**, the orders of which have distinctly segmented abdomen (scorpions, pedipalpida, solpugids or pseudoscorpions, and harvestmen) and the **Sphaerogastra**, spiders proper which lack distinct segmentation. **Araneida** (spiders) and **Acarina** (mites and ticks) are orders of sphaerogastran arachnids.

Pedipalpida, whip scorpions, are more feared than the facts justify. Vesiculation has resulted from crushing a specimen upon the skin.

Solpugida are spiderlike forms lacking a true cephalothorax. The fangs can produce wounds, but venomousness is wanting.

SCORPION STINGS

Scorpionida, true scorpions are mainly tropical. They may reach a length of 8 inches and are pre-eminently predaceous creatures which lie hidden by day and hunt by night. Most true scorpions of the United States are of little significance, the sting of *Centruroides vittatus* the common one, for example being no more severe than that of a bee. Some species found in the southern part of the United States and throughout Mexico are decidedly dangerous. The clear colorless toxalbumin introduced perhaps into a bare foot, produces intense pain numbness, sweating salivation, rapid pulse shallow respiration, fever convulsions and even respiratory paralysis and death especially if the victim is a little child.

C suffusus is the common Mexican species. Deadly species in the Southwestern U.S.A. are *Centruroides sculpturatus* and *C gertschi* which reach an adult length of about 3 inches and are to be described as long and slender with delicate-appearing pinchers and a small thornlike structure at the base of the stinger.

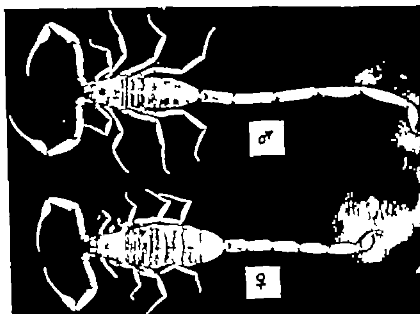

Fig. [illegible].—*Centruroides sculpturatus*. (Courtesy of Herbert L. Stahnke, Ph.D., Arizona State College, with permission not to be copied.)

Effects of the sting were graphically described by Stahuke (Scorpions, Arizona State College Tempe 1949)

> Immediately after being stung, one experiences a prickly pin sensation which may become quite painful. The spot becomes hypersensitive so that bumping it causes additional tingling sensations. A sort of prickly pin sensation and numbness travel up the extremity leaving the part or the pathway with a woody feeling. Severe tingling and electric sensations may be experienced throughout the whole body. This venom does not produce a swelling or discoloration at the site of the sting. A feeling of tightness develops in the throat, and the tongue may develop a feeling of thickness so that tiny children will try to reach into the mouth to remove an imaginary obstruction. There may be a difficulty in speaking, and a restless or [ ]itt ry feeling develops. In adults this may or may not lead to slight, involuntary twitchings of the muscles; small children in this stage will not be still, and often attempt to climb up whatever conf[ ]es them. The restless condition may lead to a series of sneezing spasms accompanied by copious salivation and nasal fluid discharge. The restlessness may develop into a severe convulsive state sometimes with curious activity of aimless crawling while bent forward, followed by backward bending of the trunk, that is usually rhythmic. The arms may be flailed about, and breathing is labored, with pronounced wheezing. This activity may last for from 45 minutes even to 12 hours, leading to acral cyanosis and death. When recovery

takes place the last part of the body to become free of the effects of the sting will be the part actually stung and this may be hypersensitive for several days so that jarring it evokes tingling or painful sensations.

Treatment advocated by Stahnke requires the prompt application of a tourniquet proximal but close to the sting Ice the site then pack the entire part in crushed ice and water The tourniquet is removed after the tissues have been refrigerated and within 5 minutes. Immersion in ice water is kept up for 2 hours. Definite swelling then present indicates that neither the deadly scorpion nor black widow caused it and, if so immersion in ice water is no longer needed Antivenin or other medication is not necessary unless definite symptoms of poisoning are present When possible the offending animal which produced the sting should be saved for identification. Incision of the site of the sting is erroneous. Supportive measures of all kinds may be appropriate including oxygen inhalation, artificial respiration and anticonvulsant therapy *Do not* give Demerol (Stahnke ArizMed 11 51 1952)

ACTH has been tried. I have seen notable relief in acarine intoxication with the adrenocortical drugs. Cortisone was successful in a case of Maretic (J 152 609 1953)

Antiscorpion serums have been developed but are often species-specific and so therapeutically helpful only in limited regions where particular species are prevalent (Craig and Faust 1951 p 642) No immunity develops following repeated stings. The only prevention lies in avoiding the animals.

See Hoffman (AnInstBiolMex 2 291 1931 3 42, 1932) scorpions of Mexico de Magalhaes (JTropM 41 393, 1938) Brazilian Kent and Stahnk (SouthwestM 23 1?, 1939) southwestern U S A. ARANEIDISM SPIDER BITES

All true spiders produce venom but few have fangs able to pierce the skin or venom potent enough to produce more than transitory irritation (Craig and Faust) The tarantulas despite their dreadful appearance are essentially innocuous. The genus Latrodectus, relatively small spiders of the family Theridiidae are the ones to be feared. Species occur in almost every country and *L. mactans* the black widow is the member of consequence in the United States southern Canada, Cuba Mexico and elsewhere in the Western Hemisphere

L mactans is coal black, with orange or scarlet markings. The male is about 6 mm long the female about 12 mm The abdomen is globose and has an hourglass-shaped reddish spot on its mid venter These spiders spin coarse tough webs about old lumber under outdoor privy seats in garages and basements and in trash piles, where they should be carefully avoided in order to prevent bites.

The bite is painful and the site becomes swollen and perhaps purpuric, soon there occur general symptoms of intoxication including twitching and tremor numbness vomiting sweating aching abdominal cramps that may falsely suggest the urgent need for surgery (Wilson Surg 13 924 1943) and even shock or delirium While the symptoms are sometimes exceedingly violent, actual fatalities have been few

In treatment repeated intravenous injections of 10% magnesium sulfate are advised (Davis J 130 783 1946) Atropine morphine, pituitary extract or epinephrine may be indicated. Calcium gluconate 1 to 2 Gm. intravenously given at once will usually relax muscle spasm (Miller J 139 1238 1949) and provide better relief than morphine The antivenin should then be given after testing the patient for allergy to horse serum from which it is prepared (NNR J 129 1017 1945) and desensitizing him if necessary This Sharp and Dohme preparation has value if given early enough (Kirby-Smith

SouthMJ 38: 696 1945) Prior to its introduction convalescent serum was found to contain antibodies and possess therapeutic effects (Gray CalifWMed 43 328 1935) The intramuscular injection of 2 cc. 1:2000 neostigmine methyl sulfate accompanied by 1/150th grain of atropine will relieve promptly according to Bell and Boone (J 129 1016 1945) confirmed by Holloway (ArkansMSJ 47: 75, 1950) Immediate incision and suction may be tried One may flame the site of the bite at once with a burning match head and so prevent aftereffects (J 122 208 1943) Spraying the web with 10% DDT in kerosene results in death of the spider (Van Riper Sci 104 111 1946)

Fig. [illegible]—Black widow spiders (females) *Latrodectus mactans*. From the collection of V Lewhim, (Merck Report, July 1946, from article by Herbert L. Stahnk : Some Poisonous Animals of the United States; by permission of the author and publisher)

Fig. [illegible].—Spider bite on leg, species not identified; not unusual in Missouri.

Necrotic Arachnidism was described by Witkind of Montevideo (abs J 153 1552, 1953) as consisting of cutaneous necrosis, progressing to dry gangrene at the site of the bite, fever jaundice, hemoglobinuria, cutaneous and intestinal hemorrhages, exanthema and hemolysis. It is a serious condition and is fatal in a high percentage of children. A spontaneous regression of the acute symptoms occurs between the fifth and seventh days; local necrosis follows a slowly regressive course. In 2 cases which proved fatal, the spiders were captured in the act of biting and were identified as females of the *Loxosceles laeta* species. *Loxosceles laeta* spiders are common in certain cities of Uruguay and other countries of South America, and it is their bite which produces the necrotic, eruptive and icterohemolytic forms of arachnidism.

Spiders of undetermined species produce painful bites which are followed by central necrosis and an erythematous sometimes vesicular areola measuring a few inches across. I see such cases once or twice a year and may prescribe the topical application of tetracycline ointment. On the legs such lesions have been followed by the development of chronic lichenoid dermatitis. Compare gangrenous spot of Chili, described by Macchiavello (PuertoRicoJPubHealth 22: 425 1947)

ACARINE PARASITISM

Mites have globoid bodies formed by the fusion of the cephalothorax and abdomen. They have 4 pairs of extremities in the adult state; the larvae are hexapod. The terminal segment of the legs possesses organs of fixation: hooks, claws, or pediculated suckers. Many are parasites. Of the order Acarina, superfamilies containing members of dermatologic interest are **Ixodoidea** (ticks), **Sarcoptoidea** (itch mites), **Tyroglyphoidea** (food mites), **Demodicoidea** (follicle mites), **Parasitoidea** (parasitoid mites), **Tarsonemoidea** (mites of grain itch) and **Trombidoidea** (chigger or red mites).

TICKS

Ixodoidea are large mites covered with a leathery integument and adapted exclusively to blood-sucking from mammals, birds and reptiles. The family Argasidae are soft bodied and the Ixodidae are hard bodied.

Argasidae.—Ticks of the genus *Ornithodoros*, some 30 species of which parasitize a variety of birds, mammals and even reptiles, infest nests and beds of their hosts, commonly dirt-floored thatched huts of man. They feed intermittently. Most of them bite painfully and provoke persistent, firm, itchy papules. *O. moubata* inoculates African tick fever with its bite. *O. hermsi* transmits relapsing fever in California. *O. turicata* is the vector of sporadic recurrent fever in America.

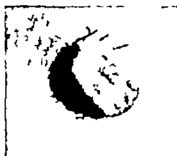
Ixodidae are vectors of great medical interest because in numerous localities they transmit to man various spirochetoses, rickettsioses and tularemia; and they may cause tick paralysis, sometimes fatal, as well as local inflammatory accidents.

Ixodidae are hematophagic in all stages of their evolution. They feed throughout the year or only at some seasons according to climatic condition and their host peculiarities. Each species seeks certain hosts by preference but when these are not available they content themselves with accidental hosts. *Dermacentor andersoni* and *D. variabilis* are vectors of Rocky Mountain spotted fever and tularemia. *D. occidentalis* the Pacific coast tick has transmitted tularemia.

Tick Bites.—The biology of ticks and the tissue reactions to them were discussed by Winer and Strackosch (JID 4 249 1941). The site of the bite is marked early by edema and eosinophilic infiltrations, later by mast cells. A dermal nodule may remain unresolving and have to be cut out.

Tick bite granulomas resemble the nodular dermal fibrosis histologically showing an eosinophilic granuloma, appearing sometimes as late as 10 weeks after the bite and persisting as an itchy eczematoid lesion or a pink, painless nodule 1 cm. or so in diameter (Allen AmJPath 24 367 1948 Tobias JID 12 255 1949). Similar nodules may occur in scabies (p. 606).

D. variabilis evidently by envenoming the skin of the occipital region, produced alopecia of motheaten appearance in 2 children observed by Ross and Friede (AD 71 524 1955).



To remove a tick, one may touch it with tobacco juice, kerosene, a hot nail or one of the essential oils, thus inducing it to remove itself. The cutaneous lesions are urticarial and itchy but themselves usually inconsequential.

Avoidance of tick infested regions is important in avoiding tick transmitted disease (see Rocky Mountain Spotted Fever) Repellents are useful (see Chigger mites, treatment)

Tick-Bite Paralysis.—Motor paralysis due to the bite of a tick and relieved by the removal of the tick has been observed in man and animals. The condition affects children as a rule There are observed weakness of sudden onset ataxia, motor palsy clear conscious mental activity afebrile intoxication, and paralysis progressive even to a fatal termination unless the tick is removed. Its removal is followed within 48 hours by recovery *Dermacentor andersoni* and *D variabilis* are the usual offenders reported the venom rather than the function as a vector is responsible.

TICKS.—Davis (PHRpts 54: 1345, 1939), *Ornithodoros parkeri* transmission of relapsing fever; Brunet (BJVD 15 63, 1939) *D andersoni* embedded in penis, requiring dissection Pasternack (J 112 1814, 1939) tularemia following tick bit Cooley and Kohl (PHRpts 54 44 1939), key to Amblyomma in U S A.; Woodland et al (J 122 1156, 1943), tick bite fever in Texas (see endemic typhus) Cooley nd Kohls (The Argasidae of N Amer Central Amer nd Cuba, Uni Press, Notre Dame Indiana, 1944) Feder (J 126 292, 1944), fever and secondary infection complic ting tick bites Cooley (The Genera Dermacentor and Otocentor [Ixodidae] in the U S. ITCH MITES
SCABIES ANIMAL AND HUMAN

Sarcoptidosis.—In scabies resulting from infestation with mites whose natural habitat is other than human the peculiar restriction and specificity of the relationship of parasite with host is such that the acari do not thrive and multiply Thus the harboring by man of an animal mite may be unpleasant, but it is not serious (Toomey UCutDis 25 705 26 473 1922) See Stigter (abs J 154 722, 1954); Booth and Jones (ADS 69 531 1954) mites in industry

Some occasionally involve human beings and live on them for a time provoking the itch temporarily The absence of burrows is noteworthy in all of these types. They produce diffuse and pruritic miliary or polymorphous eruptions and either heal spontaneously or are easy to cure See Brumpt (1949 p 1215)

S minor (Fürstenberg 1861) ar cati	from arious rodents and carnivora. Mild in man taken from cat, it persisted a fortnight
S. scabiei var aucheniae	from llama
S scabiei var cameli	from camels or dromedaries (may be severe)
S scabiei var canis	from dogs; disappe rs spontaneously (dog scabies may be indistinguishabl from human [Toomey])
S. scabiei var caprae	from goats may be severe
S scabiei ar lupi	from wolf
S. scabiei var equi	from horse, ass and mule. Slightly larger than that of human being Burrow re not present, but the cari bound in scales and crusts.
S scabiei var leonis	from lion
S. scabiei va ovis	from sheep
S scabiei va suis	from pig; mild, nd heals easily
S scabiei va vulpis	from fox. Infestation from skinning animal

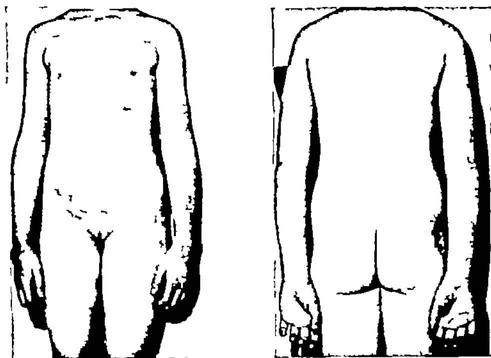
Sarcoptosis of Animal Origin, contracted from horse mule or ass is acquired by direct contact with sarcoptic mange in these animals and is manifested with prompt itching soon followed by papules and urticaria, with worse symptom at night than in the day. *The face scalp, external genital axillae breast and interdigital areas almost invariably* remain free. The forearm suffer most and the arms, neck and ones of restriction by clothing are involved. The burrows are very short the vesicles are comparatively large and erythema, with or without urticaria, is widespread and severe. Crusting may occur and pigmentation may result. Th disease resembles that produced by harvest mites. It requires treatment a for ordinary scabies.

Cat scabies causes serious, ven fatal disease in the cat affecting particularly th head and external ear. In man there may occur limited patches of papules on the neck, circumscribed, or gradually extending in bizarre fashion so a t incl d the sides of the trunk and thighs, but avoiding hairy areas. Erythema, tiny papules and tough little apical vesicles are seen. Itching is continuous and worse at night. The hands, buttock and external genitals are not affected (Davies: BJD 53: 18 1941). Infestation of man may result also from the handling of mangy rabbits (Kaufmann: AmJCli Path 1 601 194).

Chorioptosis, fetlock scabies du to *C communis* (Gerlach 185) occurs in horses, oxen sheep and goats. The parasite lives in colonies in long hair. The disease it produce begins generally above the hoof in the horse and spread upward rarely so far as to the belly. It develops slowly is worse in winter and causes abundant epidermic desquamation. Tuft of hair pull out and leave the skin bare and smooth; later it becomes crusted, fissured and bleeding. In man there is provoked severe erythematopapular dermatitis of short *duration, involving the hand wrists area of contact rarely generalized. Thi acute form* i sual a rare chronic generalized papulocrustaceous form ha been described (Menger 1896)

Chorioptes symbiote a *bovis* (Verheyen, 1862) ha been found on the head of human beings ca si g f w s mptoms.

Psoroptosis, cattle scabies, due t *P communis* in oxen sheep horses and cattle producing thick scales and severe pruritus but no burrow. It does not propagate on man, where the first instance w recorded *by* L. Wilson in 1843 th mite i barely visible wh ti h spot on hair or epidermal surface



See Warburton (Parasit 12 265, 1920) rieties of sarcoptic parasites in ma and nimal Buxton (Parasitol 13 146 1921) taxonomy, Widman (ADS 5 675, 1922) *S scabiei ar hemi* is from orangouta g Goldman nd F klman (ADS 59 1 3, 1949) Siamese gibbons with disease resembling Norw gian scabies i fected human being. Fisher et al (ADS 63 328, 1951) *Dermatoph goides scheremetewskyi* found on boy with *T purpureum* infection, also on scalp of a zoology professor and members of his family pathogenicity l bious, ha been found i urine

Scabies (**The Itch**) the infectious disease due to *Sarcoptes scabiei* var *hominis* is characterized objectively by intraepithelial burrows made by the female for depositing ova. This results in intense itching and in multiform lesions due to scratching. Secondary coccic infection is common

S scabiei var *h m n s* (Linné 1758) Female pearl gray o pinkish about 330 μ long, 300 μ across oviparous. Male pinkish, about 225 μ by 175 μ. Venomous salivary gl d open i the buccal cavity. Ovum bearing female inhabit th end of the burrow wh h he has made in the epidermal laye. Mal also ma li e in the burrow o more often, outside the burrow u der the epidermis. Egg laid by the f male measure 150 by 100 μ. Those farthest volved are those farthest from the female located of course neare the orifice of th burrow. De elopment takes place in 4 stages: (1) day after be g laid, the o um becomes a hexapod larva. It h tches i the burrow which it promptl lea es t live on the surface of the health skin. It enlarges and undergoes several moults. ( ) D th xteenth da th nimal mo lts agai and gives rise to an octopod n mph which li es n the cust on the kin. (3) Another moult, which occurs about the twenty eighth day set free pubescent mal and female animals. (4) Following the final moult wh ch occurs about the sixth week the pubescent a d fecund female develops a ew orifice which serves f r the laying of eggs. She the forces herself into the skin producing a characteristic burrow in which she lays eggs.

See Munro (JRoyAMC 32 1 1919) W burton (Parasit 12 265, 1920) Sarcoptes arieties i man nd nimals Buxton (Parasit 13 146, 1921 BMJ 2 39 1941), Friedman (Biology of *Acarus* cabiei, Froben, 1942) Heilesen (ActaDV 26 I Suppl. 14, 1946) Baker and Wharton (An Introduction t Acarology M cmillan, 1952)

Symptoms.—Itching worse at night is the main complaint. The areas *of predilection are the dorsal aspects of the interdigital webs, flexures* of the wrists, axillary folds, lower abdomen, buttocks, genitalia and ankles. In infants the palms and soles frequently are involved. Other parts of the body also are occasionally attacked but the face and scalp escape except in infants.

Figs. 309 and 310.—Scabies.

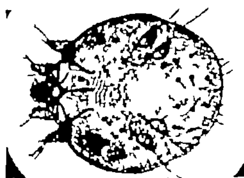

Fig. 814.—*Sarcoptes scabiei*, female. (Dr. Fred Weidman.)

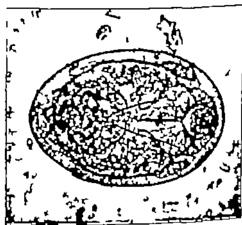

Fig. 815.—Ovum containing larva of *Sarcoptes scabiei*. (Dr. Fred Weidman.)

Fig. 813.—Scabies. (Dr. George M. MacKee.)

Figs 616-618.—Scabies (Dr Robert N Andrade)

Fig. 619.—Scabies, typical penil lesions. (Dr Sam [illegible] [illegible]altzer)
Fig 620.—Norwegian scabies (Beatty BJD 25 [illegible], 1912.)

The lesions, consisting mainly of small excoriated papules and vesicles, are seen on close examination. Tiny cuniculi or burrows can usually be found. These appear as whitish tortuous or zigzag superficial, threadlike channels. The closed end is marked by a tiny grayish speck the resting place of the female parasite The burrows are a few millimeters long and are most numerous on the interdigital webs mammary region in women and shaft of the penis in men. The disease is slowly but steadily progressive as a rule and, if neglected involvement soon becomes more or less general In cleanly individuals the eruption usually is scanty and impetiginous or urticarial manifestations may overshadow those of scabies.

Experimental Inoculation of Scabies.—Observing the course of self inoculation with a single female acarus Clayton (BMJ 1 752 1944) noted that she crawled about 1 cm then burrowed in, rapidly at first and was entirely within the epidermis at the end of an hour She thereafter traveled 1 mm in 2 days. *Itching began after 3 more days and became intense within* another 2 weeks. By the fourth week scattered lesions began to appear Since the life cycle is accomplished in from 7 to 13 days propagation to the stage of clinical disease takes at least 3 weeks. The symptoms and gross signs appear only after the patient has become sensitized to the mite but following a second infection the patient responds with inflammation and itching immediately (Mellanby Scabies, Oxford Univ Press 1943 MacKenna BMJ 2 287 1950)

Norwegian Scabies. —In neglected cases of long duration the number of acari may become enormous with extensive crusting and the disease may involve not only the trunk limbs, palms and soles but also the face and scalp. Itching is not necessarily present and such a case pruritus absent was described in an uncomplaining moron by Sweitzer and Winer (ADS 43 678 1941) The assertion that scabietic infection occurs by predilection among the mentally deficient (Hodgson BMJ 1 316 1941) led to lively disputation and psychometric testing with the view becoming widely accepted that the parasite is unconcerned with the intellectual capacity of the host (Mellanby et al. Lancet 2 596 1942) Crusted scabies, the name Colnan (BJD 62 71 1950) prefers to Norwegian does not generally itch much really is associated with mental deficiency and is productive of hyperkeratotic lesions of hands and feet and involvement of the face and scalp which escape infection in ordinary cases. There is some question as to whether the mite in crusted scabies is identical with the ordinary one (Anderson BMJ 2 25 1952) Swarming with parasites estimated at 10 000 per cc. of crust (Grutz Dermatologica 97 279 1948) the disease is highly infectious and requires isolation. In fact, cross-infections often lead to the correct diagnosis in cases originally not recognized (Wells BMJ 2 18 1952)

Complications of scabies include secondary infection (impetigo ecthyma furunculosis cellulitis erysipelas, infectious eczematoid dermatitis) medicinal *dermatitis venenata, urticaria and dermographia insomnia and psychosomatic* reactions such as delusion of parasitism and neurodermatitis (Allison NoWMed 38 23 1939 Goldman WarM 5 294 1944) Secondary infection will not clear until the animal parasites have been eliminated after this has been done antibacterial medication is likely to prove unnecessary I have wasted some penicillin as well as antihistamine drugs on some cases of scabies, a disease not always textbook Albuminuria observed during scabies was thought to be coincidental by Niles (ADS 38 19 1938) but it might be incited by secondary streptococcic infection, as seen by McIntosh (JIowaMS 33 181 1943) while Wang et al. (ChinMJ 66 277 1948) reported a number of cases of acute glomerulonephritis (p 282) in secondarily infected patients.

There occasionally occur large papules, oval elevated and hard, of a reddish or bluish red hue early later losing the bright color and often presenting central bluish black hemorrhagic crusting (Cremer abs YBD 1948, p 357) These lesions, few in number appear where the epidermis is thin,

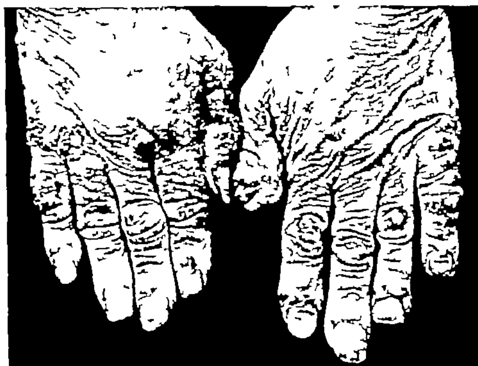

Fig. 821.—Norwegian scabies. (Dr. O. G. Costa.)

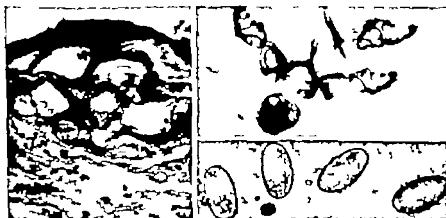

Fig. 822.—Norwegian scabies section shows numerous burrows in superficial epidermis and empty shells of ova scybala are seen as solid black lumps. (Dr. Fred Weidman.)

Figs. 823 and 824.—Above are recognizable parts of exoskeleton of *Acarus scabiei* such as may be identified in a scraping. Below are ova. (Hand, USNMB 46: 834, 1946.)

especially in genital mammary and axillary regions, and they harbor the mites and persist for months, perhaps promoting recurrences despite treatment They are seldom seen in untreated cases. They may become pyodermic and may require excision for cure Compare Tick bite granuloma

Diagnosis.—The distribution of the lesions is suggestive The head is not involved in adults a distinction from dermatitis herpetiformis. The hands may escape but the anterior axillary folds in both sexes, the waist the nipple region in the female and the shaft of the penis in the male should be scrutinized. The interscapular region is free In babies the soles, palms, scalp and flexures of the wrists usually are involved Nocturnal itching is typical when asked if he itches more in the daytime the patient is likely to answer in the negative with vehemence he itches at night Persons in close association with him are likely also to be infected. The discovery of burrows is seldom impossible although it may be somewhat difficult (Stokes J 106 674 1936) The unclad patient under examination is likely to manifest goose flesh (Semon and Barger BJD 29 173 1917) An infant lying in its crib rubbing its soles together probably has scabies (Dennie's sign) Lesions may be limited to the penis (Gilman ADS 52 83 1945) Exudative *erosion of the scrotum is perhaps scabietic Impetigo of the buttocks is almost* pathognomonic of scabies (MacCormac BJD 29 141 1917) A scabietic individual may complain of and manifest only urticaria until meticulously searched for evidence of parasitism

The mite or its products are usually easy to demonstrate

A dissecting microscope is a great aid to one who is not nearsighted. One searches the likely areas of interdigital web or flexure of wrist for a burrow At the end of it is the tiny whitish globule of the mite beneath the epidermis, or at least the pit where this should be With a needle point inserted along the burrow one dissects the epidermis and the mite adheres to the tip of the instrument Transferred to a slide it may be seen crawling vigorously and may be exhibited to the patient in order to secure his cooperation with the treatment to be prescribed if one is sure that the patient will be edified by the marvel rather than sickened.

Scrapings examined in 10% NaOH may enable one to identify parts of mites, eggs, moults or scybala (Friedman PaMJ 47 39 1943) This technic is illustrated in the articles of Hand (USNMBull 46 834 1946; JMichSMS 47 519 1948) KOH solution applied to the site selected for scraping prior to obtaining material enables one to obtain material containing microscopically identifiable debris (Hellier BMJ 1309 1945) If one paints likely places for burrows with a solution of fluorescein in glycerol and alcohol, burrows if present are penetrated by the fluorescent fluid and show as luminous streaks under Wood's light (Hirschfeld ActaD-V 26 4 1946)

In pediculosis corporis, the parasite or its ova can be found in the seams of the underclothing the hands and feet are unaffected, and the interscapular area is usually the site of numerous long excoriations. Nonscabietic dermatitis frequently involves the palms and soles and the face there is no history of familial infestation, cuniculi are absent the distribution of the eruption seldom simulates that of scabies and nocturnal aggravation of itching are absent

Errors in diagnosis arise from failure to suspect the infestation, or to recognize its complications, or to recognize it itself; interdigital and penile burrows, nocturnal itching distribution of the eruption and identification of the source are features one may depend on.

Epidemiology.—Close personal association and lack of cleansing facilities enhance the liability to infection. War conditions increase its incidence School children pass the parasites to one another and bring them to their families. Mediate transmission probably does not occur and disinfection of clothing is unnecessary (Shand BMJ 1 98 1944) Clothing impregnated with DDT does not prevent one's acquiring the infection (Hellier BMJ 2 555 1945)

Why the disease is now actually rare in North America is unknown (Epstein AD 71 193, 1955) I have not picked an acarus from a patient of mine for several years.

Treatment.—The cure of a case of scabies depends on the external use of parasiticides. Impetigo due to scabies does not contraindicate such therapy Sulfur is a reliable agent, and hexachlorocyclohexane benzyl benzoate beta naphthol, pyrethrum derris derivatives and other chemicals can be used successfully

The parasite is not hard to kill, success depending largely on the universality of application of parasiticide to the host overlooking no solitary

acarus. *S scabiei* is an obligate parasite on the human being It does not live longer than a few hours on intermediary objects. Overtreatment is to be avoided. A method I use may be outlined as follows

℞	Phenol	1.0
	Salicylic acid	6.0
	Sulfur precipitated	10.0
	Petrolatum, to	120.0

Do not refill.
Sig: Salicylic acid-sulfur ointment for scabies.

1. Begin treatment with a hot bath, using nonmedicated soap generously *Dry* skin. Then rub in ointment gently from neck down covering the *whole* body palms and soles, fingers and toes.

_ Rub in ointment morning and night for * days On the final morning take a soap bath and change all clothing and sheets.

2. Use the same sheet and the same underwear until the third sulfur ointment application is finished and you have cleaned off the ointment. Launder everything and start fresh. Ordinary lau dering suffices. *Do not* use more sulfur ointment unless so directed.

Lesions may persist and itching continue, despite successful attack on the mites themselves. This persistence of irritability must not of itself be considered justification for a repeated course of the parasiticide for contact dermatitis would result. It is to be allayed patiently with aluminum acetate baths, phenolated calamine lotion and barbiturates until 2 weeks have elapsed, by which time cure has generally proved subjectively satisfactory However if recognizable scabies still persists the patient is retreated.

Benzyl Benzoate (Nielsen s method: Kissmeyer: Lancet 1: 21 1937; Currey: CanadPHJ 30: 294, 1939): (1) Use equal parts of soft soap isopropyl alcohol and benzyl benzoate. (2) Warm bath rub with soft soap rinse. (3) While wet, brush over whole body benzyl benzoate mixture fo 5 min tes. (4) Let thi dry then paint it on again for 5 minutes. (5) Let this dry then put on same old clothes. (6) After 24 hours take cleansing bath and don fresh clothing Like myself Mallen (BMJ 2: 452, 1942) prefers the aqueous emulsion. Graham (BMJ 1: 412, 1943) obtained 99% cures in 1,000 cases treated with a single application without disinfecting clothing. Geffen (BMJ 2: 825, 1944) dispensed with both preliminary bath and scrubbing and attributed recurrences mainly to reinfection. Aq a bentonite was the vehicle and 2% Duponol C the emulsifier for the 25% benzyl benzoate preparation highly recommended by Slepyan (J 124: 1127 1944) Dermatitis venenata may follow benzyl benzoate and is sometimes severe (Daughtry: J 127: 88, 1945)

NBIN is applied as a spray benzyl benzoate 10 DDT 1, benzocaine 2, Tween 80 (wetting agent) 2, water to 100. Topicide is Lilly s proprietary of approximately this excellent formula. See Carpenter (JID 7: 93, 1946)

See Goldman (ADS 33 878, 1920) King (BMJ 2 416, 1940) I gram (BJD 54: 228, 1942) Robinson and Robinson (SouthMJ 40 1010, 1947) Tyrocaine, benzyl benzoate, benzocaine and tyrothrycin; Appel (NEngJM 242 74, 1950) benzyl benzoate especially effective if applied by medical personnel.

Derris (Rotenone) Treatment (Saunders: BMJ 1 624 1941; 1: 127 1942): (1) Use 4 ounces of powdered derris root in 1 gallon of water (2) To cupful of (1) add a dram of soap flakes; apply ove whole body 6 times in 2 days. One may dilute this to half strength to avoid rritation. Good when water is scarce, nonodorous nongreasy no sterilization of clothing no supervision needed, cheap, requires no skill to dispense. Epstein (ADS 45: 950 1942) reported 15% failures.

Eurax (containing 10% of crotonyl N-ethyl-O-toluidine) is reported as satisfactory (Couperus JID 13: 35, 1949; Tronstein OhioSMJ 45: 859 1949; Patterson: SouthMJ 43: 449 1950) Colorless, odorless and onstaini g it is a good ant pruritic according t reports.

Hexachlorocyclohexane, the gamma isomer 1% in cold cream, wa successful in 95% of the cases of Woolridge (JID 10: 363, 1948) The course of treatment consisted in a bath, inunction, 12-hour int rval, inunction, 12-hour interval, final bath. This is available as Kwell (Commercial Solvents Corp.) Cannon and McRae (J 138: 557 1948) cured 100 cases without irritation. Absorption of large amounts of the drug causes convulsive death (Mebbs J 138: 1.53, 1948) Experience has indicated that, as used in human scabies, it i effectual and harmless (Kornblee a d Combes: ADS 61: 407 1950; H lpern et al. ADS 62 648, 1950) Gamergent contained this along with other pesticidal chemicals effecti e against lice and other arthropods (Cornbleet et al.: ADS 66: 103, 1952) See Council on Pharmacy (J 144: 543, 1950)

Tetra Ethyl Thiuram Monosulfide (Tetmosol)—In 25% concentration in an alcoholic vehicle, then diluted 1 4 in water immediat ly prior to use, this drug seemed nonirritating cheap and effective on being rubbed over the body ccording to Percival (BMJ 2: 451, 194_, see Bradshaw Lancet : 273, 1944) Gordon et l. (BMJ 1: 803, 1944) recommended a soap containing Tetmosol, and an epidemic was controlled with a 10% soap preparation by Mell shy (BMJ 1: 38, 1945)

Pyrethrum.—An ointment containing 0.75% pyrethrins seldom irritates, has a pleasant odor and is generally curative when used daily for from 5 to 7 days, being applied each time after a hot bath (Sw itz r and Tedder: MinnMed 18: 793, 1935)

Thiosulfate—Hydrochloric Acid (Demyanovich's method: J 11 ; 2375, 1930; 1 31: 879 1944): (1) Shower bath with green soap and brush, during which clothing is disinfected. ( ) Rub onto skin for 15 minutes a 40% solution of thiosulfate. Dry with crystals of the salt. Rub on 5% solution of hydrochloric acid. (3) Repeat ( ). Cures 80% in 1 treatment of less than * hours. See Ravaut and Mahleu (BullsocfrancD 41: 135 1934); Kulchar and Meininger (ADS 34: 18 1936)

Scabicide was a propri tary supplying the Danl h treatment. It contained sulfur 10% balsam of Peru % and phenol 1% in a cold cream vehicle (Norris: OhioMJ 39: 551 194). Using the Danish method, Greenwood and Reilly (ADS 35: 602, 1937) reported over 5% of the patients were irritated although some 94% of over 4,500 patients were cured by a single application

See Oppenheim and Fantl (Kli Wchn 49: 187 1936) dermatitis from scabicidal medication, including death from ulfur past ; Montgomery (AnnMilitet 9: 219 1937) history description, bibliography Mellanby et al. (BMJ 2: 1 1943) treatment with various medicines Oppenheim and Smith (AIDS 46, 370, 1913) self 25 potassium carbonat 19 petrolatum 125 MacCormac (Practitioner 152 91 1944) enereal origin in Army; Dujardin (be IJD 68 73 1948) monographic Friedman (The Story of Scabies, Froben Press, 1919); Daly (JID 12 11 1949) new synthetic chemicals promising; Frakken and Van Vloten (be NTID 1949 p 311) pa i e tra fer of reactivity t parasite Grummitt (Sci 111: 361, 1950) di (p-halophenyl) alkyl carbi is highly toxic t mites, highly specific.

TYROGLYPHID MITES

Tyroglyphid mites, world wide in distribution are sometimes present in flour sugar ham meats, grain in mills, cereal foods, hair upholstery mattresses, etc., according to Anderson and Fishman (ADS 57 227 1948). *Aleurobius farinae* (Linn) has caused severe itching in handlers of wheat *Carpoglyphus passularum* (Hering) spoiled dates and prunes; *Glyciphagus domesticus* (deGeer) has been identified attacking grocers *Rhizoglyphus parasiticus* (Dalgetty) was found causing dermatitis about the toes and ankles of Indian tea plantation workers.

Tyroglyphus longior has caused in handlers of copra and cheeses an irritation which resembled scabies or dermatitis venenata (Cleveland ADS 41 831 1940 Thomas BJD 54 313 1942 Castellani BJD 25 19 1913 Saunders ADS 50 245 1944). Diffuse erythema without the suggestion of individual bites was observed by Nixon (BJD 56: 235 1944) whose patients, handling cheese cargoes at Glasgow were irritated by dead mites as well as by live ones. The cheese dust produced by their activity proved to be a sensitizer on patch testing. Dowling and Thomas (BMJ 2 543 1949) considered the powdery dust a primary irritant among the girls handling cheeses whom they studied. The hands arms, legs and sometimes the trunk may be involved but the face is seldom if ever affected. The lesions may be pruriginous papules which subsequently become papulopustules and pustules. The eruption seldom disappears spontaneously while the patient continues handling infested materials. Castellani found 5 to 10% betanaphthol ointment a useful remedy

T siro (Linn. 1758) in ha dlers of infested or m ty shells of vanilla, caused acarian cutaneous anillism to be di ti guished from chemical vanillism or intoxication.

De m toph goide scheremetewsi has been foun l in the urine but it pathogenicity is dubious (G rges UCutRe 4 820 1938). See Fisher et al. (ADS 63: 336, 1951) cutaneous infestation

Rhyzoglyphus hyacinth caused dermatitis from the handli g of decaying onions. Pruriginou inflammat on w th p h ad-sized papules, excoriat on and secondary infection, resulted from the act vity of the acari, which were present in large numbers on the plants. Pawlo ky an l Ste (ArDuS 158 443 1929) described their investigations of this onion mite dermat ti

Histiogaster entomophagus (Laboulbene 1852) swarmed in a tumor of a finger. It may also cause d sease imilar to cutaneou va illism due to *Tyroglyphus siro*.

Carpoglyphus passula um ha bee observed by Oliver and later by O Donovan (BJD 52: 297 1940) in et ologic relation hip with papular dermatitis of the forearms in laborers working with plums and figs.

FOLLICLE MITES

Demodicidosis.—*Demodex folliculorum* var *hominis* is a minute parasite occurring in the hair follicles and sebaceous secretion in a considerable proportion of adults. The animal is cigar-shaped, measuring about 0.3 by 0.04 mm. Some believe it causative of some cases of rosacea, for in cases in which the

Fig 325.—*Demodex folliculorum* in sebum. (Dr Eugene A. Hand.)

Fig. 326.—*Demodex folliculorum*. (Drs. Ayres, Anderson and Foster.)

Fig. 327.—Canine demodicidosis (sarcoptic mange). Inflammatory and foreign body reaction to acarines in canine skin. (Maier JLabClinM 24 594, 1939.)

organisms are numerous, clinical improvement along with their disappearance is obtained with sulfur ointment (Ayres: ADS 21 19 1930). Others have accredited it with the causation of tinea versicolor like discoloration of the skin and tinea-like impetiginoid, and rosacea like lesions (Miskjian ADS 43 745 1941 Nicholas ADS 47 793 1943)

See Whitfield (ProcRoySocM 13: 102, 1920) organisms found in resistant case of scabby dermatitis of face thought contracted from mangy dog, cured with sulfur ointment, Lawrence and Brodie (MJAustral 1: 520 1931) in blotchy dermatosis of face, "pityriasis folliculorum" Fuss (AnnderD 4 1083, 1933; 6: 326, 1933) action perhaps foreign body in sebum, photomicrographs; Lawrence (ADS 32: 633, 1935) in impetiginous lesions of face absent elsewhere; Henry and Hory (Ibid 193, p. 198) pathogenicity dubious, histology of canine disease Batunin and Iolkin (DWchn 101: 1355 1935) frequent in rosacea, infrequent in normal Maier (JLCM 21 594 1939) in dog Miskjian (ADS 63: 28, 1951) tiny red papules in scalp perhaps caused by Demodex.

RAT AND BIRD MITES

Parasitoidea is the superfamily containing *Liponyssus bacoti* the common rat mite and *Dermanyssus gallinae* a common parasite of fowls which may temporarily infest human beings.

Rat mites transmit rickettsialpox (q v) When efforts are made to exterminate rats, *L bacoti* seek other blood producing in human beings itchy wheals and papules with central puncta especially on the extremities. Insecticidal spray or fumigation with HCN will exterminate them The rash may be

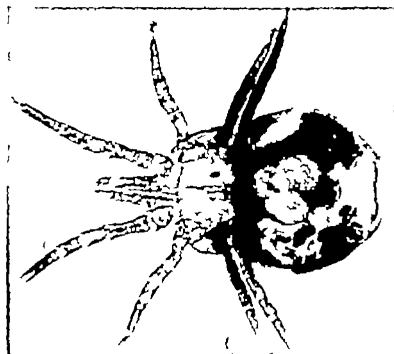

Fig 416.—*Dermanyssus gallinae* (Dr Joseph W. Shaw and M H A Pommerening ADS 61 466, 1950.)

mistaken for scabies. Department store employees were the sufferers observed by Weber (J 114 1442, 1940) and relief followed the extermination of rats, during which procedure an insecticidal spray should also be used to prevent human invasion when the rats are killed (Lowell ADS 54 278 1946) The organisms are tiny red mites about 0 5 mm across and 0 75 mm. long

Fowl mite infestation results from the nocturnal activity of the animals, which migrate from abandoned nests of pigeon, starling or sparrow as a rule *D gallinae* is pear-shaped about 1 0 mm over-all grayish yellow and eyeless, able to run swiftly over the skin into which it does not burrow Infestation may be mistaken for delusion of parasitism It is a cause of lichen urticatus (Rockwell ADS 68 82 1953) The mites may reach a sleeping patient by way of an open window seeking blood on which to feed when the avian hosts *have departed from their infested nests. They may reach the* patient directly too in the course of handling chickens or pigeons or cleaning the coops. A pet canary was the source in the case of Cole and Driver (ADS 37 322, 1938)

The bites in man occur especially on the upper trunk, pubes, breasts, umbilicus, face and scalp and are urticarial and itchy The disease once

recognized, is easy to manage by destroying the source and by using repellents, such as Kwell on the patient and a suitable spray along the path of the migration.

See Rickettsialpox; also Toomey (UCutRev 25: 705, 1931) gamasoidosis Lawrence (MJAustral 2 410 1931 2 16, 1935 BMJ 2 572, 1935), D. [illegible] Sulzberger and Kaminstein (ADS 33 60, 1936) D. [illegible] Pirila and Kilpio (ActaD-V 29: 70, 1949) rat mite dermatitis.

CHIGGER MITES AND GRAIN ITCH

Tarsonemoidea (Grain Mites) —These mites are predaceous on insects which attack grain crops. *Pediculoides ventricosus* lives as a parasite especially on the larvae and nymphs of the corn moth. When it is unable to attack these insects, it passes onto the body of man and produces a polymorphous, papular or papulovesicular erythema, accompanied by severe itching and sometimes by fever

In Indiana the principal insect hosts of *Pyemotes (Pediculoides) ventricosus* are the Angoumois grain moth and the wheat jointworm, the latter being the larva of a small fly that lays eggs in the wheat stalks, which are not destroyed by the high-cutting combine harvester machines; the storage of surplus corn has encouraged the luxuriation of the grain moth (Booth and Jones J 150: 1575, 1932) Male and female mites are sexually mature at birth. The males, relatively few and usually among the first born, remain on the mother's abdomen and fertilize females as they are born, soon after which the females scatter in search of food. They can travel only short distances and cannot long survive especially in warm weather without food. Under favorable conditions new litters appear at intervals of about 1 week and as many as 300 young are produced each time.

The parasites attack people working with grain, particularly those who unload it (Rogers: J 123: 887 1943) Synonymy of such names as prairie itch and Ohio scratches was reviewed by Kittredge (VaMMonth 60: 357 1933; J 107: 2109 1936) The first American description of the cases was that of Rawles (IndianaMJ [illegible]: 837 1909) Occurrence in Italy was noted by Ancona (Policlinico 30 45 1923) who observed that exposed mill workers after a time developed asthma as a result of infestation. Australian incidence was described by Swan (MJAustral 2: 573, 1934)

Leptus autumnalis was identified attacking persons engaged in picking bush beans in the vicinity of Basel, Switzerland, by Schuppli (SchweizMWchr [illegible] 368, 194[illegible]) They have been found in Great Britain France, Holland, Germany and Denmark (v Mallinckrodt Haupt: UCutRev 34 744, 1930) Palestine cases were reported by Katzenellenbogen (ADS 55: 631 1947)

Trombidoidea (Chigger Mites and Harvest Mites) contains the family Trombidiidae which are of medical interest These are acari of silky hairiness, reddish in color free and predatory as adults, as larvae parasitic on vertebrates and arthropods. The larvae known as *Leptus*, or harvest mites, are fixed for various periods of time on animals whose blood or lymph they suck. All larval trombidiidae attacking man produce local phenomena and sometimes general intoxication, with erythema of severity which varies with the species and number of parasites. These tiny animals are common in the temperate zones, and their attacks usually are credited to the much rarer chigoe, a flea. Only the larvae are parasitic. On contact with the vegetation on which these are located the skin is invaded. They run at the rate of 10 cm. per minute and tend to attach themselves on thin epidermis where they happen to meet an obstruction such as a garter belt or brassière. They do not burrow Within a few hours they are engorged with blood and drop off (J 117 406 1941) See Wharton and Fuller (Manual of the Chiggers U.S. Nat'l Museum, Washington 1952)

Trombicula irritans (Riley 1873) is the chigger common in America. It is brick red in color and oval in shape and it measures from 0.3 to 0.5 mm. by 0.25 to 0.3 mm. It lives in nature on woody decaying substances and the fecal matter of arthropods and occurs during July and August in enormous numbers in grass and bushes, fields, and moist, swampy places.

Trombicula species transmit Japanese river fever (scrub typhus; see p. 257)

Neoschoengastia nuneri infestation, observed by Andrade (BolMédHospInf, 1944; GacMédMéx 77 221 1947) in the vicinity of Mexico City, resulted in disease resembling grain itch with pruritic lesions, insomnia, fever leukocytosis and eosinophilia.

See Whitfield (ProcRoySocM 13: 102, 1920) orga lem found in resistant case of scabby *dermatitis of 1 ce thought contracted from mangy dog, cured with sulfur ointment.* Lawrence and Brodie (MJAustral 1 529 1931) blot by dermatosis of face, "pityriasis folliculorum" Fuss (Annidel) 4 1082, 1933 6: 3 6, 1935), ction perhaps as foreign body in sebum, photomicrographs; Lawrence (ADS 32: 632, 1935), in impetiginoid lesions of face absent elsewhere Henry and Hory (abs YBD, 1937, p 198) pathogenicity d blous, histology of ca line disease Batuni and Iolhi (DWch 101: 1288, 1935) frequent in rosacea, infrequent in normal; Maier (JLCM 21 891 1939) 1 dog Miskjian (ADS 63: 8.. 1951) tl y red papules in scalp perhaps caused by Demod

RAT AND BIRD MITES

Parasitoidea is the superfamily containing *Liponyssus bacoti* the common rat mite and *Dermanyssus gallinae* a common parasite of fowls which may temporarily infest human beings.

Rat mites transmit rickettsialpox (q v) When efforts are made to exterminate rats *L. bacoti* seek other blood producing in human beings itchy wheals and papules with central puncta especially on the extremities. Insecticidal spray or fumigation with HCN will exterminate them. The rash may be

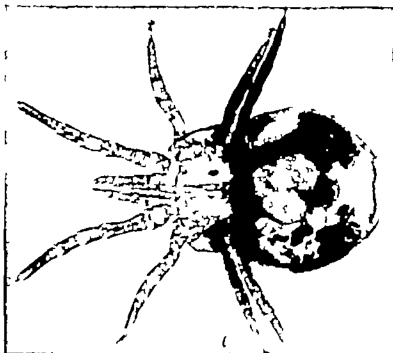

Fig. 836.—*Dermanyssus gallinae* (Dr Joseph W. Shaw and M R. A. Pommerening ADS 61 466, 1950.)

mistaken for scabies. Department store employees were the sufferers observed by Weber (J 114 1442 1940) and relief followed the extermination of rats, during which procedure an insecticidal spray should also be used to prevent human invasion when the rats are killed (Lowell: ADS 54 278 1946) The organisms are tiny red mites about 0 5 mm across and 0 75 mm. long

Fowl mite infestation results from the nocturnal activity of the animals, which migrate from abandoned nests of pigeon, starling or sparrow as a rule. *D gallinae* is pear-shaped, about 1 0 mm over-all, grayish yellow and eyeless, able to run swiftly over the skin into which it does not burrow Infestation may be mistaken for delusion of parasitism. It is a cause of lichen urticatus (Rockwell ADS 68 82, 1953) The mites may reach a sleeping patient by way of an open window seeking blood on which to feed when the avian hosts have departed from their infested nests. They may reach the patient directly too in the course of handling chickens or pigeons or cleaning the coops. A pet canary was the source in the case of Cole and Driver (ADS 37 322, 1938)

The bites in man occur especially on the upper trunk, pubes, breasts, umbilicus, face and scalp and are urticarial and itchy The disease once

recognized, is easy to manage by destroying the source and by using repellents, such as Kwell on the patient and a suitable spray along the path of the migration.

CHIGGER MITES AND GRAIN ITCH

Tarsonemoidea (Grain Mites)—These mites are predaceous on insects which attack grain crops. *Pediculoides ventricosus* lives as a parasite especially on the larvae and nymphs of the corn moth. When it is unable to attack these insects, it passes onto the body of man and produces a polymorphous papular or papulovesicular erythema, accompanied by severe itching and sometimes by fever.

In Indiana the principal insect hosts of *Pyemotes (Pediculoides) ventricosus* are the Angoumois grain moth and the wheat jointworm, the latter being the larva of a small fly that lays eggs i the wheat stalks, which are not destroyed by the high-cutting combine harvester machines; the storage of surplus corn has encouraged the luxuriation of the grain moth (Booth and Jones: J 150: 1376, 193.) *Male* and female mites are sexually mature at birth. The males, relatively few and usually among the first born remain on the mother's abdomen and fertilize females as they are born, soon after which the females scatte in search of food. They can travel only short distances and cannot long survive, especially in warm weather without food. Under favorable conditions new litters appear at intervals of about 1 week, and as many as 300 young re produced each time.

The parasites attack people working with grain particularly those who unload it (Rogers: J 123: 887 1943). Synon my of such names as prairie itch and Ohio scratches was reviewed by Kittredge (VaMMonth 60: 357 1933; J 107: .109, 1936). The first American description of the cause was that of Rawles (IndianaMJ 2: 237 1909). Occurrence in Italy was noted by Ancona (Policlinico 30: 45, 1923) who observed that exposed mill workers aft r a time developed asthma as a result of infestation. Australia incidence was described by Swan (MJAustral 2: 572, 1934).

Leptus autumnalis was identified attacking persons engaged in picking bush beans in the vicinity of Basel, Switzerland, by Schoppli (SchweizMWchr 7 569, 1949). They have been found in Great Britain, France, Holla d, Germany a d Denmark (v Mallinckrodt Haupt: UCutRev 34 744, 1930). Palestine cases were reported by K tzenellenbogen (ADS 55: 621 1947).

Trombidoidea (Chigger Mites and Harvest Mites) contains the family Trombidiidae which are of medical interest. These are acari of silky hairiness, reddish in color free and predatory as adults, as larvae parasitic on vertebrates and arthropods. The larvae known as *Leptus* or harvest mites, are fixed for various periods of time on animals whose blood or lymph they suck. All larval trombidiidae attacking man produce local phenomena and sometimes general intoxication with erythema of severity which varies with the species and number of parasites. These tiny animals are common in the temperate zones, and their attacks usually are credited to the much rarer chigoe, a flea. Only the larvae are parasitic. On contact with the vegetation on which these are located, the skin is invaded. They run at the rate of 10 cm. per minute and tend to attach themselves on thin epidermis where they happen to meet an obstruction such as a garter belt or brassière. They do not burrow. Within a few hours they are engorged with blood and drop off (J 117 406 1941). See Wharton and Fuller (Manual of the Chiggers, U.S. Nat'l Museum Washington, 1952).

Trombicula irritans (Riley 1873) is the chigger commo in America. It is brick red in color and oval in shape and it measures from 0.3 to 0.5 mm. by 0.25 to 0.3 mm. It lives in nature on woody decaying substances and the fecal matter of arthropods, and occurs during July and August in enormous numbers in grass and bushes, fields, and moist, swampy places.

Trombicula species transmit Japanese river feve (scrub typhus; see p. .37).

Neoschongastia nunezi infestation, observed by Andrade (BolMédHospInf, 1944; GacMédMéx 77 221 1947) in the vicinity f Mexico City, resulted in disease resembling grain itch, with pruritic lesio s, insomnia, f e leukocytosis and eosi ophilia.

Harvest mites are abundant during the summer and autumn in some countries. The larvae attack the legs and accumulate in the regions of bands which bar their movement such as belts and girdles. They force their rostrum into the skin provoking severe itching and papules surrounded by red or violaceous areolae. These are soon excoriated. Intoxication and fever may result. The acari live only a few days on man. The eruption produced by *P. ventricosus* is fairly well generalized and rapid in development. Schamberg (JCutDis 28 67 1910) described 3 clinical types: urticarial vesicular pustular, the most common, varicelloid and erythema multiforme like. Itching has its onset after perhaps 24 hours. It is almost intolerable and is worse at night. Secondary infection is quite common as a result of abrasion. There may be malaise, some fever and moderate lymphadenitis. Urticaria is differentiated by the presence in grain itch of central vesicopustules. Varicella is less pruriginous, and the course of its eruption is more rapid. The lesions of scabies are different in character and distribution.

Treatment.—One should avoid exposure to the animals. Weak parasiticidal ointments to which an antipruritic such as 0.5 to 1.0% phenol has been added, prove comforting. Some harvest workers claim that they avoid infestation by taking sulfur by mouth. Immunity occurs in some persons and mites are partial to others. Bathing with soap, applying to the skin a weak dilution of phenol in boric acid ointment and dusting the clothing with sulfur are procedures which yield some protection (Parkhurst ADS 35 1011, 1937). Carbon tetrachloride, collodion or nail polish, applied to the bites, is comforting. Careful but firm wiping of lesions with gasoline gives relief for a few hours (Fasting J 119 536 1942). Collodion with Metaphen relieves the itching of a lesion to which it is applied (PHRpts 55: 1312, 1940). Ethyl aminobenzoate, 15% in flexible collodion is likewise comforting but occasionally imprisons pathogenic cocci, which then produce an impetiginous bleb at the site (Sutton J 120 26 1942). During the period of illness and intoxication, cortisone in full dosage by mouth gives immediate and great relief. The antihistamine compounds are less effective.

Various repellents successfully prevent infestation, among the best of which are 6-12 and Kwell the active ingredient of which is hexachlorocyclohexane. A lotion containing 2% rotenone is helpful (Williams et al. SM&SJ 103 199 1941). A solution of 5% dimethylphthalate and 2% soap is useful for dipping clothing so as to render it repellent (J 144 1324 1950). Disinfestation of terrain may be achieved by spraying on the ground the insecticide Dieldrin at the rate of 2¼ lb. to the acre and this is also apparently useful against ticks (Traub et al. JEconEntomol 47 429 1954 quoted by QMN J 157 1172, 1955). The Army clothing impregnant M 1960 protects against chiggers and ticks. It contains equal parts of N butylacetanilide, 2 butyl-2-ethyl-1 3-propanediol and benzyl benzoate with 10% of an emulsifying agent.

Tetranychinae, spider mites, spinning mites, or red spiders, are tiny acarine animals which feed on the tender tissues of plants. *Tetranychus molestissimus* is found in Argentina and Uruguay where it is known as the Bicho colorado, and where it attacks mammals and man, causing severe itching and in the latter fever as well.

Tetranychus telarius is a species parasitizing vineyards, causing the red disease. The bite in man provokes a tiny blanched papule that lasts a few minutes (Brumpt, 1940).

CREEPING ERUPTION due to a similar mite was reported by Murray (BMJ 1: 1076 1930) the disease being common in Natal and Zululand. The lesions are characteristically thin, inflammatory tracts, which lengthen. The feet, genitalia and buttocks, of natives and Europeans of any age, are attacked by predilection especially in the hot wet months. The superficial burrow is actually about 0.33 mm. wide, seemingly wide because it is surrounded by inflammation, and it is commonly secondarily infected. See p. 633.

HEXAPODA

In true insects, the adult possesses a single pair of antennae and 3 pairs of legs. The body is segmented and divided into head, thorax and abdomen. Typically the thorax consists of 3 segments and supports 3 pairs of legs and

2 pairs of wings and the abdomen is composed of 10 segments, the terminal one modified for sexual purposes. Some insects develop without metamorphosis, the adult developing from the nymph which hatches from the egg. Others undergo gradual, others, partial and still others complete metamorphosis in which the adult evolves from the pupa which has developed through several larval stages from the egg.

Insects perform their pathogenic services to mankind by mechanical and chemical external irritation, by insertion of venom, by provocation of eczematous and systemic allergy, by evolution and migration on, in or under the skin, and by transmitting, inoculating and disseminating viruses, bacteria, fungi, protozoa, filariae and other parasites (Jarcho, WarM 3: 447, 596, 1943).

See Fox (Insects and Diseases of Man, Blakiston, 1925); Hull (Diseases Transmitted from Animal to Man, Thomas, 1930); Huff (Sci 74, 456, 1931) types of transmission of disease from arthropod to man: biologic cyclopropagati e cyclodevelopmental and propagati e, mechanical; Riley and Johannsen (Medical Entomology, McGraw Hill, 1932); Neveu-Lemaire (Traité d'entomologie médicale et vétérinaire, Vigot, 1938); Sutton and Sutton (Diseases of the Skin, Mosby, 1939, p. 1331 ff.); Belding (Textbook of Clinical Parasitology, Appleton-Century, 194_, p. 589 ff.); Smart (Handbook for the Identification of Insects of Medical Importance, British Museum, 1943, 269 pp.) including fleas and arachnids, practical and authoritati with key; Obermayer (J I I 3: 454, 1942) tropical dermatoses and entomology; Brumpt (Précis de Parasitologie, Masson, 1949, p. 1667); Herms (Medical Entomology, Macmillan, 1950) authoritati guide in human and veterinary science; Craig and Faust (Clinical Parasitology, Lea & Febiger, 1951, p. 628, classification, p. 633, medical importance); Roy and Brown (Entomology, Medical and Veterinary Including Insecticides and Insect and Rat Control, Calcutta, 1954).

Hexapodan Dermatoses include those due to the following orders

Orthoptera	grasshoppers, crickets, cockroaches
Ephemerida	may flies, lake flies
Trichoptera	caddis flies
Mallophaga	biting lice of birds and mammals
Anoplura	sucking lice, pediculi
Heteroptera	bedbugs, assassin bugs, kissing bugs
Siphonaptera	fleas
Coleoptera	beetles
Lepidoptera	moths and butterflies
Diptera	two-winged flies, mosquitoes, botflies, houseflies
Hymenoptera	bees, hornets, wasps, ants, ichneumon flies

Orthoptera.—These are of little dermatologic significance. The order includes grasshoppers, crickets, cockroaches and the like; they have chewing mouth parts and two pairs of wings, of which the outer is more or less parchmentlike and the inner membranous and folded when at rest. Roaches and crickets are dermatologically insignificant, although they are capable of serving as mechanical vectors of pathogenic bacteria.

Zonocerus elegans(?) — *Eupelopus dure di*, an African wingless locust, discharges a yellowish fluid from the pores at the side of the body which may produce dermatitis venenata with swelling, redness and vesiculation (Stannus, quoted by Riley and Johannsen, 1932, p. 118). Hjalmar Carlson described to me his experience during plagues in Kansas; mechanical damage resulted from the forceful removal of grasshoppers which were clinging to the skin and the lesions burned and stung and required several days to heal.

Ephemerida.—The order includes May flies, which may appear seasonally, particularly in the Great Lakes region, in pestilential myriads, so that a lake shore may be heaped inches deep with the putrescent remains. Inhalation of their fragments may cause asthma, sometimes urticaria. Rarely the insect crushed on the skin provokes eczematous dermatitis (Figley, JAllergy 11: 376, 1940).

Trichoptera.—The caddis flies appear in enormous numbers about lakes and streams. They occasionally cause asthma and urticaria (Parlato, JAllergy 3: 1?0, 459, 1932).

Mallophaga.—The biting bird lice are wingless forms which attack birds and animals. Members of the genera *Goniocotes*, *Lipeurus*, *Goniodes* and *Menopon*, according to Toomey (UCutRev 25: 705, 1921), particularly attack cleaners of fowl coops and handlers of chickens and pigeons. Biting lice are vectors of *Dipylidium caninum*, the dog tapeworm, which infests dogs, cats, and rarely human beings.

PEDICULOSIS

Anoplura.—These wingless sucking lice parasitize warm-blooded animals. Only the family Pediculidae are hominixenous. Pediculi of man, exclusively hematophagic insects, are specific parasites. Their voracity is considerable, and they eat 2 or 3 times a day. They have little resistance to inanition and die in discarded clothing in a few days (Davidson, MJAustral 1: 533, 1943), more quickly when humidity is low. The bite is

disagreeable and itchy in persons who are not accustomed to it or who possess special sensitivity Lice are permanent parasites. Seasons have no influence on their generations, which succeed one another without interruption. The life span of adults is perhaps 6 or 8 weeks. The resistance of the lice and their eggs to heat is relatively slight. In delousing, the procedure must be conducted with care so that all parts of the clothing and coverings are exposed to adequate heat and drying

Pediculus humanus capitis and *P humanus corporis* interbreed without reduction of fertility their biologic characters are intergradient (Nuttall: Parasit 11 329 1919 Keilin and Nuttall: Parasit 22 1 1930)

The head louse is grayish in color The male is some 1 6 mm. long and 0 7 mm wide, the female is 2.7 mm by 1 mm. It lives in the hair of the scalp occasionally in the beard. Rarely it is found in the pubic region. The female fixes her eggs or nits to the base of the hair The young hatch on the sixth day and become adults on the eighteenth, after having undergone 3 moults. Eggs may then be laid within a day or two

The body louse is larger than the head louse and is dirty white in color The male measures 3 mm. in length and 1 mm. in width the female is 3.3 mm by 1.15 mm. This louse is found on the skin only at the time of feeding Ordinarily it hides in clothing or ornaments. It is cosmopolitan. It is a dangerous vector of typhus fever While the exact method of transmission of this disease is not known the excreta of the infected louse may be infectious. The spirochete, *Borrelia recurrentis* of relapsing fever is transmitted from man to man by the body louse. See Buxton (BMJ 2 1245 1939 1 341, 1940 The Louse Arnold, 1947) Bacot (BMJ 1 788 1916) entomology

Phthirus inguinalis (Phthirus pubis) Forelegs delicate, with long slender claws other legs stout, with short, stout claws thumblike process of tibia short and stout abdomen short and broad. Nits are fixed at the base of hairs. Young hatch on seventh day and are able to reproduce 15 days after their appearance. The pubic louse is not known to transmit infection.

Pediculosis Corporis.—As a rule the animal resides in, and lays eggs near the seams of the clothing. It comes upon the body only to feed, commonly in the interscapular shoulder and waist regions. Early lesions are minute, red noninflammatory points, elevated but little Usually the lesions quickly become papular and wheuled. Excoriation leads to the appearance of bloody crusts. Itching is a prominent symptom Secondary infectious manifestations frequently develop Acquired hypersensitivity to lice may result in urticaria (Peacock Nature 118 696 1926) In long-standing cases there may be more or less brownish pigmentation. Parallel linear excoriations in the interscapular region are almost pathognomonic. Among British troops in 1916 95% of the men were infested and they supported from 10 to 20 and even up to 1 000 cooties (Peacock BMJ 1 745 784, 1916)

EXPERIMENTALLY lice caused at first only pin-point, flat, red, noninflammatory lesions but, after a week and as a result of developing sensitivity reaction became papular with surrounding erythema, and even vesicular reported Peck et al. (J 123: 821 1943) Intradermal tests with louse antigen, that from feces being especially active caused transient wheals in nonsensitive but tuberculoid reactions in sensitized individuals. The distress, widespread dermatitis, and psychic disturbance of the host were described by Rosebase (NEngJM 234: 665, 1946) Morris (NEngJM 233: 180 1945) attributed leg ulcers, in some instances, to infestation. The rearing of a colony of lice was described by Culpepper (AmJTropM 24: 327 1944) Lice nurtured upon a laboratory worker depleted the blood at the rate of from 10 to 25 cc. daily causing anemia (Finkel: Arch f rI ereM 1934, p. 34)

MORBUS ERRONUM (VAGABOND'S DISEASE)—Persons long infested develop pigmentation from chronic dermatitis, excoriation and perhaps malnutrition. The pigmentary chronic dermatitis occurs in grossly neglected and subnormal, vagrant individuals. Animals on deficient diets become susceptible to pediculosis (Y dkin: J 101: 921, 1933) and the lack of the B complex is significant perhaps, in human infestation (György: ProcSoc ExpBiol 33: 383 1935)

TREATMENT.—The clothing must be sterilized. It may be autoclaved, ironed with a hot iron dipped in naphtha or gasoline, or boiled. It may be fumigated with hydrocyanic acid, carbon tetrachloride or 10% creolin solution. To discard and dry the clothing for several days suffices by starving the

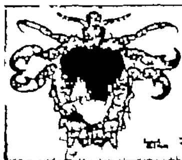

Fig. 343.—*Pediculi humanus orporis* (Dr. Fred Weidman.)
Fig. 344.—*Phth p bis.* (Dr. Fred Weidman.)
Fig. 345.—N t of louse ttached t hai

lice and desiccating the nits. Fumigation with methyl allyl chloride is effective (David BMJ 2 108 1943) Resistance to DDT develops, and lice have been reared through their complete life cycle on cloth impregnated with 0.1% DDT in acetone (Hurlbut et al Sci 115 11 1952)

Skin irritation and secondary infection may necessitate astringent baths, such as weak potassium permanganate In cases complicated with ecthyma and furunculosis nits are usually present in the pubic, axillary or perineal hair crop the hair change the kit and remove nits with the application of paraffin, and relief may be obtained (Semon and Barber BJD 29 173 1917)

Pediculosis Capitis.—Children are more susceptible than adults. Itching is usually the predominant symptom The presence of parasites and their ova is discoverable on close examination. Usually one finds exudative coccic dermatitis of variable severity matting of the hair especially in the occiput, and lymphadenitis, especially of the posterior cervical nodes. Conjunctivitis was often present, and corneal ulcer was not rare in the cases of Hirtenstein (BMJ 2: 75 1943)

DIAGNOSIS is simple if the disease is suspected. The animals are active and visible, and nits are readily found if sought. They show white fluorescence under Wood's light, which aids in rapid diagnosis (Spiller ADS 63: 499 1951)

TREATMENT.—Clipping the hair is seldom necessary, although it facilitates the work One application of Topicide will probably cure A simple method of therapy uses the petroleum cap the scalp is soaked with a mixture of equal parts of coal oil and olive oil (inflammable) then loosely bandaged After 12 to 24 hours, the dressing is removed, and the head scrubbed with soap and water Larkspur is satisfactorily employed in the same way Way used 20 cc. of xylol in 30 Gm. of petrolatum. Tincture of cocculus indicus, 33% in water may be applied freely 2 or 3 times daily for several days, its use supplemented by frequent shampoos. Persistent nits may be loosened with weak washes of acetic acid (vinegar) or lemon juice and removed with a fine-toothed comb DDT 2% emulsion, 1 application without previous washing is fairly reliable (Frazer BMJ 2: 263 1946) but the animals die slowly are irritated and wander from the scalp disgustingly when attacked with DDT alone A dust containing 10% DDT and 90% pyrophyllite was effective (Cowan et al. AmJTropM 27 67 1947) who applied about a teaspoonful to the scalp and left it without washing for one week the course might require repetition. Rotenone powder alone does the job (Murphy SouthMJ 36 53 1943) Davis (J 123: 825 1943) reported single application cures with phenyl or benzyl cellosolve 40% ethanol 30 methyl salicylate 5 and water to 100 NBIN containing benzyl benzoate 68 Tween 80 14 parts, ethyl aminobenzoate 12, and DDT 6 to be diluted with water to 1/6 this strength is efficient for both lice and scabies (Eddy: JID 7 85 1946, Am JHyg 47 29 1948) Delousing of 1,500 000 persons in 45 days was achieved by dusting their underclothing with DDT 10% in pyrophyllite with Flit guns (Ahnfeldt JTennMA 37 263 1944) A second powdering a week after the first kills what hatches later Kwell containing hexachlorocyclohexane may be recommended highly Lethane (n butyl-carbitol thiocyanate) 15% in purified kerosene a single application left in the uncovered scalp for 2 or 3 days, kills the lice effectually (MacHaffie CanadPubHealthJ 32: 606 1941) A benzyl benzoate preparation was approved by Blackstock (BMJ 1 114 1944) A thiocyanoacetate and sulfosuccinate preparation was effectual and rarely irritating according to Shelanski et al. (ADS 51 170 1945) The agents recommended by Busvine and Buxton (BMJ 1 464 1942) were (1) 25% technical lauryl thiocyanate in white oil (2) 50% lethane 384 in white oil and (3) derris cream.

Sources of reinfection should be controlled for a high proportion of the patient's contacts also harbor lice Superstitious Polish refugees in England during World War II would reinoculate their children with lice as fast as they were deloused on the hypothesis that it was unhealthy not to be infected.

Fig. 846.—Pediculosis capitis, showing ova on hairs. (Dr J. L. Lak)

Fig. 847.—Pediculosis capitis with secondary infectious eczematoid dermatitis. (Dr O O Costa)

Phthiriasis.—Ordinarily the crab louse confines its activities to genital, abdominal and anterior thoracic regions, but it may involve the axillae, eyebrows, lashes and body hair of hirsute persons. Recognition depends on discovery of the active, tiny reddish brown animals, or their ova attached to hairs, or the iron rust like spots of excrement. Cutaneous lesions and symptoms are like those occurring in pediculosis corporis. Infection can readily occur through contact with contaminated bedding and clothing as well as by intimate contact. The animal lives on the skin, not in the clothing.

It is not especially unusual to find the lice and nits on the eyelashes, and this region alone may be involved (Wright and Friedman AOphth 11 995 1934 Fleming BMJ 2 87 1943; Goldman ADS 57 274, 1948) I saw a case of heavy infestation of the scalp with *P pubis* in a child, asymptomatic and sought because the taches bleuâtres were recognized on the extremities.

A remarkable case of bullous allergic reaction to the presence of the animals was reported by Kern et al. (ADS 65 334, 1952) which actually resembled pemphigus.

Maculae Caeruleae (taches bleuâtres) are rounded slaty gray or bluish macules, sharply discrete and of pea to fingernail size occasionally seen on the thighs, abdomen and thorax of heavily infested persons. They are due to introduction into the skin of salivary gland material of the lice and disappear after disinfection (Dugué and Mallet abs JCutVD 1: 319 1883) Fever and malaise as well as this curious vasomotor phenomenon are sometimes observed (Saidi and Farrington AmJMedSci 214: 308, 1947)

Treatment —DDT 0.5% in cold cream, a single application to hairy parts below the neck is simple and effective (Sutton, Jr BullUSAMD 4 45 1945) Kwell, containing hexachlorocyclohexane, may be recommended. Using these agents, it is unnecessary to clip the hair or to shave the parts. Insecticidal treatment must be coextensive with the parasitism. Tincture of cocculus indicus, diluted with 3 parts of alcohol or water may be applied several times daily Camphor 1% in mineral oil, is excellent. Mercury ointment is less satisfactory When the eyelashes are involved, the patient is usually a child, but a general anesthetic is seldom needed to permit manual removal of the insects and their ova (Ronchese NEngJM 249 897 1953)

BUG BITES

Hemiptera.—Members of the order have sucking mouth parts enclosed in a segmented beak, which arises from the front of the head; they are generally provided with 2 pairs of wings; they undergo incomplete metamorphosis. In the suborder, *Heteroptera* the anterior wings are partly formed into elytrons, while the posterior are membranous; only these are medically important. Bedbugs, squash bugs stink bugs and assassin bugs are familiar names of representatives. While many entomologic subdivisions of the order exist, the families Cimicidae (Bedbugs) and Triatomidae (Assassin Bugs) are of interest. Reduviid bugs, including the Triatomidae are blood suckers, capable of inflicting painful bites with local swelling or even generalized urticaria from the potent salivary toxin. The so called "kissing bug" accomplishes its bites without producing pain at the time (Arnold and Bell: HawaiiMJ 3: 121, 1944)

Assassin Bugs have a short, trisegmented beak attached to the tip of the elongated head, and a distinct neck; the antennae have 4 segments, the tarsi 3. Several thousand species are known. They are predaceous, living on the blood of insects. In man, their bites are decidedly painful, and productive of swelling and soreness which may last for a week. The bites of hematophagic species are much less consequential than those of the hunting types. Members of the genus *Triatoma*, in particular *T megista* (Burmeister, 1835) are vectors of *Trypanosoma cruzi* (American trypanosomiasis) Also are several species of other genera. Several species, including *Triatoma (P mstrongylus) megista*, can puncture the skin painlessly withdrawing blood from exposed tissues, such as the lips. Other families of Hemiptera contain members which can inflict injuries.

Notonectidae, or back swimmers, small aquatic bugs that swim on their backs, are able to inflict painful bites.

Belostomatidae contain various species of *Lethocerus* that bite painfully

A few of the plant feeding Hemiptera Heteroptera may suck the blood of man on occasion (Riley and Johannsen, 193_)

Bedbugs.—Cimicidae have vestigial hemelytra and no posterior wings antennae in 4 segments, lower lip in 3 segments, tarsus of 3 segments, no ocelli.

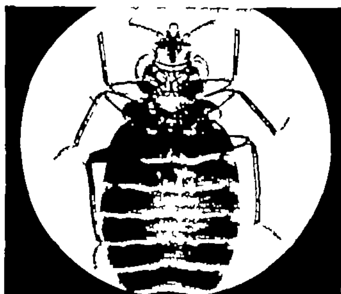

Fig. 848.—*Cimex lectularius*, the bedbug (×20). (From Gradwohl: Clinical Laboratory Methods and Diagnosis, Mosby.)

Fig. 849.—Bites on thigh and ankles produced by *Haematosiphon inodora* (Dugès, 1892). (Dr. Robert N. Andrade.)

Fig. 850.—*Haematosiphon inodora*. (Dr. Robert N. Andrade.)

The genus *Cimex* includes *C lectularius* (Merrett 1667) the common bedbug and other species which may attack man.

Cimex lectularius the bedbug is cosmopolitan. The adult is 4 to 5 mm. long by 3 mm. broad. The body is covered with short bristles and hairs Its stink glands lie on the inner surface of the mesosternum. Its eggs are pearly white oval, and about 1 mm. long and are laid intermittently over a long period in crevices of bed and furniture and under seams and loose wallpaper glued to the spot by a sort of mucilage. Adults have been kept in a closed vial for a year without food and have survived. They feed on other creatures if man is not available Three or 4 generations a year, in combination with their natural hardihood and inappetibility to birds and other predatory creatures, make them a pest hard to conquer

The bedbug makes cutaneous punctures in efforts to reach the capillaries, but it approaches the body only to feed, residing in crevices of mattresses and elsewhere A transitory wheal develops, and this may be succeeded by a circumscribed purpuric lesion which persists for several days. Erythematous wheals of uniform size about that of the fingernail three in a row with central red puncta are typical The lesions are usually multiple and give rise to more or less itching and burning The condition is to be differentiated from urticaria, in which the eruption is generalized and more or less symmetric and the lesions do not present central puncta. Itching and burning can be relieved by carbolized calamine lotion. The history is strongly suggestive when the patient retires without lesions and awakes with new ones.

The crevices of the seat covers of a particular trolley car harbored bedbugs which caused a puzzling epidemic of bullous erythema of the calves of the women who rode the vehicle (Kinnear Lancet 2 65 1948)

Bedbugs may be got rid of by (1) fumigation with HCN burning sulfur formaldehyde or other toxic vapors (2) heating the house to some 130 F by shutting the windows and turning up the furnace or (3) hanging coal tar naphtha on cotton diffusion screens near the walls for 24 hours at 60° C. Mercuric chloride solution may be poured in cracks where the eggs are (Cragg IndJMRes 11 449 1923) Beds and springs may be torch flamed Repapering, repairs of cracks, painting and DDT spraying are effective.

Hematosiphon inodora (Duges) a poultry bug prevalent in Mexico, spread from chicken houses to attack human beings, reported Andrade (MedMexico 31: 143, 1951) The bites appeared in small zigzag groups, evoking wheals, papules, vesicles, excoriation, insomnia and secondary infection. They were generally located on the legs, occasionally on the scalp. The bat bug has been known to bite human beings in Japan (Brumpt, 1949)

See Cummings and Austen (The Bedbug, Its Habits and Life History and How To Deal With It, British Museum, 1932); Ashmore and Hughes (BMJ 1 160 1938) coal tar naphtha technic Slack (Nature 143 78, 1939) 13 autosome pairs in *C lectularius* Windsor McLean (MJAustral 2 211 1939) *C hemiptera* among Chinese laborers in Nauru; Yasui (abs ADerm 46: 745, 1942) antigen and complement fixation tests Med. Research Council (BMJ 1 198, 1942) insecticides useful in bomb shelters pyrethrins, thiocyanate, and coal tar naphtha, with proper maintenance.

FLEA BITES AND CHIGOE INFESTATION

Siphonaptera (Fleas) are insects which parasitize mammals and birds. They are wingless, with highly chitinized and laterally compressed bodies. The legs are fitted for jumping. Mouth parts are formed for piercing and sucking Their parasitism is not closely limited the hungry flea is a desperate creature, and its willingness to exchange hosts is the basis of its danger as a carrier Their transmission of bubonic plague is notorious. *Xenopsylla cheopis* is the rat flea especially important as the vector of plague and endemic typhus. The flea infected with *P pestis* is not infectious until bacterial masses obstruct its esophagus, and the flea so infected excretes organisms in its feces and dies within 48 hours (Eskey: AmJPubH 28: 1305, 1938) Many other species bite man and may transmit disease.

The flea exposed to strong light seeks to hide and if kept for several days in a narrow glass vial gives up his proclivity for jumping these facts form the basis of his training for participation in a flea circus.

Siphonaptera comprise families **Pulicidae**, having well-developed thorax small head quadripartite labial palpes and an abdomen which even in the gravid female never becomes deformed; and **Sarcopsyllidae**, having short thorax, undivided labial palpes, and an abdomen which in the gravid female bulges considerably

Pulex irritans the common flea, is of practically universal distribution. Some individuals are apparently more susceptible than others to its attacks, and the severity of ensuing irritation is likewise variable depending apparently on acquired hypersensitivity (Boycott Nature 118 591 1926) Immunity eventually develops (Lunsford ADS 60 1184 1949) Desensitization with flea antigen may perhaps be successfully accomplished (Cheney et al. AmJ

Fig 551 —*Pulex irrit* , the flea commonly affecting human beings. (Gradwohl: Clinical Laboratory Methods and Diagnosis, Mosby)

Fig. 552.—Flea bites on ankles.

TropM 19 327 1939, Hatoff J 130 8[illegible]0 1946) Large doses of thiamin may prevent bites or diminish reaction to them (Eder APed 62 300 1945) Ordinarily the cutaneous lesion is a pale or erythematous, evanescent, itchy wheal, with a minute reddish, hemorrhagic point at the site of puncture. Occasionally the manifestations may simulate purpura. To diagnose one may don white hose, sit in the dark put on light suddenly and find the fleas on the socks (Baskin ADS 39 1075 1939) Camphor and essential oils gen-

erally exert a prophylactic effect in keeping the body free from the pests. Derris derivatives are valuable (One Spot Flea Powder) For the relief of the itching which in some instances is intense resort may be had to carbolized calamine lotion. Shaking out the bedding prevents the hatching of eggs. Where fleas are troublesome floors should be as bare as possible. Cedar oil and other oils used in floor cleaning will drive away fleas. DDT dusting and rodent extermination are control measures. Various repellents, such as Kwell are effective.

Syndrome of de Amicis.—In Naples was reported a mysterious form of prurigo affecting Americans visiting Italy It was manifested by the simultaneous occurrence in several members of the same family beginning at the time of the patients arrival, of an eruption made up of rose-colored papules covered by bloody crusts located on the trunk and the extremities. DeBlasio (BullsocfrançD 44: 446 1937) concl ded that this prurigo-like cutaneous response develops in certain patients when they cross the ocean, as a result of meterologic and climatic variations—and entomologic.

Chigoe—*Tunga penetrans* is the important species of burrowing fleas (Sarcopsyllidae) with short thorax. The abdomen of the gravid female bulges considerably The fecund female fixes herself in the skin, forcing herself into it little by little. After sucking blood for several days, she reaches the size of the fruit of a mistletoe and her body encloses multitudes of eggs. These hatch in 8 days and become adult in 3 weeks of further development. The chigoe almost completely parasitic, is indigenous to tropical America, and is occasionally encountered in the temperate zones. The primary cutaneous lesion is a shallow burrow of which the opening is blocked by the last 2 segments of the body of the parasite which swells with blood. It usually attacks the feet, particularly the toes beneath the free margin of the nail. Secondary infection extensive ulceration and even gangrene may supervene. The animal may be touched with turpentine and so induced to retreat (Stixrud) or it may be removed from the skin with the aid of a blunt needle. This should be done promptly before it burrows deeply and swells. Larvae may be found in the skin scraped from the vicinity of the burrow (Faust and Maxwell ADS 22 94 1930) Rupture of the creature while it is in the skin, or during the effort to remove it is to be avoided with care Wearing good shoes prevents infestation as a rule.

BLISTER BEETLES

Coleoptera.—In this order no member is a true parasite None inflicts a poisonous bite or sting but several species have an epidermonecrotizing principle in their chemical composition, so that they provoke blistering

Blister Beetles are of the family Meloidae. The thorax is narrower than the head or elytra, and the body is soft, slender, loose-jointed and sprawly i appearance. Many species exist. The adult feed on flowers and foliage Cantharidin is the volatile, crystalline substance to which the beetle owes its vesiculating property It ra ges from 0.4 to some 2.5% of the dry weight of the beetle and is sol ble in ether chloroform, be zene ad olive oil, but only slightly soluble in alcohol.

Cantharis (Meloe) vesicatoria is the so called Spanish fly abunda t in southern E rope and parts of Russia, where collectors, their faces and hands protected, shak the insect in the morning from the poplars ashes and lilacs where they feed in the early summertim onto sheets, whence they are collected, killed and dried. *Epicauta*, a potato beetle (not the Colorado potato beetle) is of this group. *Pomphopoea sayi*, sometimes a pest on peach trees in this country may cause serious poisoning of man. Among the rove beetles members of the genus *Paederus* contain a blistering principle not cantharidin.

The lif cycle of the Meloidae is not completely known; the insects appear and disappear suddenly and are present in numbers with seasonal periodicity Seasonal bullous dermatitis is a title und r which this beetle disease has been described.

The lesion which results from crushing a blister beetle on the skin is a large tense bleb which itches and burns. While lesions occur on exposed skin, they also occur beneath the clothing where the insect may be blown by a gust of wind. Microscopically one finds in the lesion intracellular and intercellular edema of the epithelial cells, extreme in degree. Absorption

through the skin may result in irritation of the kidneys. Stupid poisoning of 2 young women was reported by Nickolls and Teare (BMJ 2 1384 1954) who estimated that 0.5 mg of crystalline cantharidin might produce fatal blistering of the esophagus.

Benzene followed by soap and water will remove most of the vesicant, if used promptly. After the blister has developed it may be cut into from the side and 1% gentian violet in water may then be introduced into the cavity to prevent infection while the epidermis renews itself (Swartz and Wanamaker J 131 594 1946 Huse abs ADS 42 349 1940)

Tribolium destructor infesting a residence caused an urticarial eruption in an old lady whose skin reacted positively to a patch test of crushed beetle antigen (Bonar DWchr 1?? 837 103?)

See Castellani and Chalmers (Manual of Tropical Medicine, Wood, 1919 pp 326 2794) Baccaredda (Giornale ... 6 1422, 19 ?) *Paederus fuscipes* causing summer epidemics; Riley and Johannsen (Medical Entomology McGraw Hill, 1938 p 168); Huse (abs ADS 42 349 1940), *Paederus* ... causing dermatitis in July in Japan QMN (J 128 1131, 1948); Craig and Faust (Clinical Parasitology Lea & Febiger, 1951 p 826) Lehmann et al (AD 71 34, 1955) review and biology of *Epicauta* ... the commonest cause in southwestern U. S. A.

Fig 332.—Blister beetle bulla (Swartz and Wanamaker J 131: 594 1946.)

CATERPILLAR DERMATITIS

Lepidoptera the order which contains the moths and butterflies. They are characterized by the presence of scales on the body and wings and by the fact that the mouth parts are usually in the form of a coiled sucking tube. Metamorphosis is complete the larval stages being typically wormlike or hairy as caterpillars.

Nettling hairs of the larvae of some lepidopterid provoke dermatitis, perhaps in part by functioning as foreign bodies, probably as allergens, and certainly by virtue of poisons in them. Their properties of irritating may be destroyed by heat or alkali without altering their structure (Tyzzer JMedRes 11: 43 1907) No caterpillar bites or stings, despite the wicked appearance of some of them; but some innocent looking or even attractive have hairs which are highly irritating while others have spines that present at their tips spinules connected with underlying poison glands, the content of which may occasion caterpillar rashes.

Hylesian moths irritated the crew of a ship, reported Hill et al (J 138: 737 1948)

Caterpillar dermatitis occurring in Massachusetts and other parts of New England usually results from the nettling hairs of the caterpillars of the Brown tail moth *Euproctis crysorrhoea* and of *Megalopyge opercularis* many other species are also homininoxious. The first manifestation is pruritus, which develops 20 to 30 minutes after contact. Erythematous macules soon appear

usually followed by wheals. Cutaneous lesions are limited to the area of inoculation. Hairs lodged in the clothing may provoke generalized dermatitis. The disorder usually develops during the months of May and June at a time when the caterpillars are maturing. Numbness, nausea and vomiting may accompany severe percutaneous intoxication. Conjunctivae may

Fig. [illegible].—The brown-tail moth. (Dr Herman Pinkus.)

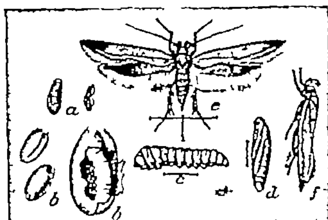

Fig. [illegible].—Brown-tail moth. (Webster.)

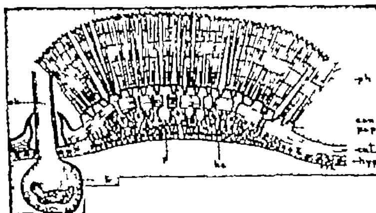

Fig. [illegible].—Brown-tail moth caterpillar section showing epithelium underlying nettling hairs. (Miss Kephart's drawing, courtesy of Drs. Riley and Johannsen, Medical Entomology McGraw-Hill Book Co Inc.)

be affected as the skin is. Blond, thin, sun-sensitive skin and also heat and humidity favor the development of dermatitis susceptibility to which is variable while some subjects undergo hardening (Touraine et al. Presse Méd 55 654 1947).

Contaminated clothing should be destroyed. The hairs are generally imbedded so deeply in the skin that considerable time must necessarily elapse

before the irritant is disposed of The application of 1:2,000 mercuric chloride lotion followed by painting each spot with flexible collodion, is a useful measure.

Moths and butterflies are of the same immunologic group for skin testing purposes (Parlato J Allergy 3 459 1932)

Lepidopterid larvae with poisonous spines that incite urtication include those of *Lagoa crispila L. pyxidifera Sibine stimulea Automerino* the larva of the Io moth, several Eucleidae and numerous members of the genera *Hemileuca* and *Hemerocampa* and of the families Liparidae and Arctiidae (Riley and Johannsen 1938)

Megalopyge opercularis the puss caterpillar is well known in the Rio Grande Valley Children call them asps and are respectful of their sting The envenomed patient suffers with aching pain of the affected extremity sweating nausea and distress comparable with that of a black widow spider bite McKinsey told me that a gram of calcium gluconate intravenously given prompt relief The caterpillars defoliate shade trees being fond of hackberry elm and plum and it requires spraying with 7 pounds of lead arsenate to 150 gallons of water a heavy dose to kill them (Hungerford) They are the most potent of North American caterpillars.

MYIASIS

Diptera (Flies) are insects with 1 pair of membranous wings attached to the second thoracic segment the second pair of wings being replaced by minute, club-shaped halteres mouth parts adapted for sucking metamorphosis typically complete Either they are acephalic as larvae or maggots, such as one finds on decomposing substances, or they are provided with a head with buccal pieces, eyes and antennae as are the larvae of mosquitoes and gadflies.

Two suborders are recognized ORTHORRHAPHA and CYCLORRHAPHA. The former includes species whose pupae escape from the last larval skin through a T-shaped opening Cyclorrhapha on the other hand escape from the pupal case through a round opening made by pushing off its anterior end. BRACHYCERA are those with short antennae composed of 3 segments. NEMATOCERA are those with filiform antennae composed of more than 3 segments.

There are many kinds of flies including *Musca domestica* the common housefly. Some of them bite painfully others transmit disease either as vectors or as mechanical conveyors, and the larvae of yet others can burrow in the skin.

Taxonomy is complicated; the following merely lists some families

CULICIDAE	mosquitoes
PSYCHODIDAE	sand flies, including the genus *Phlebotomus*, members of which transmit pappataci fever Carrion's disease and, perhaps, leishmaniasis
CHIRONOMIDAE	biting midges, gnats and punkies
SIMULIIDAE	black flies
TABANIDAE	horseflies and gadflies
MUSCIDAE	including biting stable flies
GLOSSINIDAE	tsetse flies
SARCOPHAGIDAE	flesh flies
OESTRIDAE	warble flies
OSCINIDAE	eye gnats which mechanically convey infectious agents of lacrymal secretions, sweat and exudates

BRACHYCERA Families of Parasitologic Interest after Brumpt

TABANIDAE	Squamae well developed		third longitudinal wing vein forked	ORTHORRHAPHA
ASILIDAE	Vertex almost convex	rudimentary squamae	anal wing cell ends in a point on the posterior edge	
LEPTIDAE	Vertex elevated			

SYRPHIDAE	Wings with a vena spuria and transverse veins	rudimentary frontal ampulla; body lacks macrochaetae (bristles); frontal suture absent: ASCHIZA	CYCLORRHAPHA
PHORIDAE	Wings lack vena spuria and lack transverse veins		
PUPIPARA	Abdomen nonsegmented Wings present or absent Head adherent to thorax	frontal ampulla well developed; body has macrochaetae; frontal suture present: SCHIZOPHORA	
MUSCOIDEA	Abdomen segmented Proboscis well developed Alar lobule generally rudimentary		
OESTROIDEA	Abdomen segmented Highly developed alar lobule		

TABANIDAE, including horseflies, gadflies and deer flies, are common pests of cattle horses and other animals, and often of man. They are big sturdy flies with broad abdomen, large hemispheric head, large eyes and short antennae. Only the females are blood suckers; males feed on flowers or plant juices. The family is of world wide distribution and contains some *,500 or more species. Their larvae are generally aquatic. Eggs are typically deposited in masses on water plants growing in marshy or moist ground. They are commonly laid in masses of several hundred, perhaps covered by a varnish or secretion, often light in color at first, becoming dark. In a week or so, cylindric larvae tapering at the ends, escape into water or damp earth and lead an active carnivorous life feeding on worms, snails and insect larvae until mature. The larval form may last for months; the pupal period is 1 to 3 weeks.

Many Tabanidae, particularly the Pangoninae inflict painful bites on man, actually drawing blood. Animals may be severely damaged by them. Secondary infection of the bites may occur. Tabanids are able mechanically to transmit tularemia, trypanosomes and other pathogenic agents, including *B anthracis*. *Chrysops dimidiata* and *C silacea* are known to inoculate *Loa loa*. Hypersensitivity to deer fly bites was cured by desensitization with an antigen of macerated and Seitz filtered flies by Mease (J 1[?]: 237 1943)

ASILIDAE, the hawk flies include a few insects known to be homininoxious.

LEPTIDAE, the snipe flies are of moderate size with conic bodies. *Symphoromyia pachyceras*, a California species, and *Atherix longipes* from the region of Oaxaca, Mexico, inflict painful bites.

SYRPHIDAE are dermatologically of no importance. The larvae of some of them devour plant lice.

PHORIDAE are of little dermatologic interest. *Aplochaeta scalaris* has produced cutaneous myiasis of animals and man in India. Asthma, associated with a positive skin test and proving capable of hyposensitization by immunologic methods, was reported due to the mushroom fly *Aphiochaeta agarici*, by Kern (J Allergy 9: 604, 1938)

PUPIPARA is the suborder comprising animals having leathery skins and laying completely formed pupae. Of its 4 families, the Hippoboscidae are the parasitic forms. They are all bloodsuckers, and the bites of those which attack man are almost imperceptible. Their importance as vectors of human diseases is doubtful, probably not great. *Hippobosca equina* is a species found in numbers about the tail ends of horses and cattle; wanting domestic animals to feed upon they utilize man. *H camelina*, common in Africa, inflicts painless bites which become slightly pruriginous papules.

MUSCOIDEA contains the houseflies and their allies. This large suborder includes many biting flies, among which the paraglossae are chitinous and sometimes bristly with tiny teeth that serve to perforate the skin, in contrast with tabanid and nematoceran bites in which the soft lower lips serve only as a sheath for the perforating buccal pieces.

The larvae of Muscoidea are of especial interest. The insects live generally in dependence upon vegetable or animal juices. Many lay their eggs or larvae on cadavers or animal substances where they hasten the putrefactive processes. Adult larvae dry up and are transformed into pupae, within which evolve the nymphs which mature into the imagines, perfect adult forms.

Muscoidea are divided somewhat artificially into 2 groups: Acalyptera, lacking winglets; and Calyptera, which have winglets. Among the acalypterous Muscoidea, there is little of dermatologic interest.

Sarcophagidae are calyptrates with smooth eyes; plumate antennal bristle either downy at the base or entirely smooth; abdomen uniform in color rarely has metallic luster usually is gray silky and of quite regular pattern. Of especial medical interest, sarcophagid flies include the genera *Sarcophaga*, *Sarcophila* and *Wohlfahrtia*:

Sarcophaga lambiens in cutaneous myiasis in Brazil.
S ruficornis in cutaneous myiasis in India.
S. t[?]bereae in cutaneous myiasis in Morocco.

Sarcophila meigeni l r in cutaneous ulcers in Europe
S rurails, infestation f wounds in E rope
Wohlfahrtia magnifica wound yiasl in Guinea.
W sha a and myiasl l Sudan has been used for rgical myiasis.
W v gil f runcul myia is. Larv burrow int the skin especially t the folds, provoking l flammation nd f runcular l ions they ca be removed from these by forceps (Hill rlborne and Brown: AJDisChild 91 339 1934)

Muscidae are calypterid flies with antennae in the form of a style plumed to its tip, the abdomen is short and lacks large bristles, macrochaetae at the margins of its segments. Many species para itize man in both their adult and larv l states.

In those which lay eggs the eggs hat h out primary larvae which enlarge rapidly under favorable circumstances, undergo a first moult, and become secondary larvae. They feed moult and become third larvae, the final stage When fully developed they empty their intestine take the form of a bulging sack and are then called pupae. From the pupa comes the nymph which develops into the imago, 4 moults having been required in the entire process.

The larvae are hard to classify in detail; in general, they are conic in front, cylindric in the midportion, thicker behin l. They have both anterior and posterior stigmata in the second and third larval states. The antennae are of 2 segments, small and conic Two boreal hooks are visible.

Muscidae may be divided into those which bite and those which do not.

Bit ng Fl s.—Interesting biting muscidae include *Glossina* tsetse flies, with the species *fusca palpal s* a l *morsitans* being exceedingly important as vectors f the trypanosomes whi h cause leeping sickness; and *St morys* including species which carry eggs and larvae of *Dermatobia*

Nonbiting Fl es.—These include the following:

Auchmeromyia l teola of Afric li in bout the h bitations of man. Its larvae li e in the soil and are blood suckers at night They probably lo not act as vectors.
Call phora eryth oceph la causes myia l of wounds. Larvae ha e been used in treating osteomy el ti Other species of *Call ph ra* also cause myiasis.
Chrysomyia bez ia a larv may in est wou ds of animals nd man the larvae may cause furuncular myiasis and may l ale nasal sinuses ven eroding the nasal bones.
Cochliomyia hom nivorax often infests wounds in America. The larv e, called screw worms, are whit and are formed of 12 segments of which the upper edges bea circles of ery small pi es The rrangement of these gi es some justification for the ulga name Infesting hogs in particula they lso ttack man The screw worm is the larv of *C americana*, not of *C macellaria*, according t Cushing nd Patton (AnnTropM 7 339 1933)
C rdylobia anthropophaga adults li on decaying substances. Their larvae invade the skin of man and various animals l Africa Cayor worms, as they are called, hatch from eggs l id on the ground They acti ely force thei way int the kin, where they develop for fortnight or so, then crawl out through a f runcular lesion which they provok transforming themsel es into pupa withi 24 hours nd hatching withi 3 weeks. The N tal larv is simula
Lucilia are call phorine muscids of medium size and lustrous metallic green color the green bottle flies *L caesar* nd *L sericata* often found in wounds. The latter recog ized beneficial by Larry (1842) was purposefully utilized by Baer (JB&JSurg 13 438, 1931) in the treatment of wou ls.
Musca is the genus of the domestic fly d ngerous because of its mechanical transference of pathogenic organisms, such as *B typh sus* ont food in its feet or dejecta. A useful control gent i tangl foot, a mixture of 5 parts of resin in 1 of castor oil. The filthiness of flies l undeniable, and they ought t be combatted energetically *M d mestica* caused nasal llergy and positi skin tests (Jameson JAllergy 9 272, 1938)
Phormia regina produces severe cutaneous myiasis of sheep in Texas. It has been found in man, particul rly in the intestine

OESTROIDEA co tains the Oestrinae (botflies, heel flies) which are of especial signifi cance in connection with creeping eruption and other forms of myiasis of man and animals.

Adult hav a l rge hemispheric head with a pair of faceted eyes separated by a brow bearing 3 ocelli. Antennae are sh rt third segment bears bare or plumed style Proboscis sometimes well developed somet mes hidden in a buccal fossa (CUTEREBRINAE) but generally small en rud ment ry (OESTRINAE) Wi g veis almost a in Muscidae; winglet al wa s present. Imago lives only a short time apparently does not feed. Viviparous females la ggs on mammals.

Larvae obligatory par sites develop in the kin, nasal sinuses or intestine Larvae hard t d sti gu sh fo classifi ti Thei bodies have 12 ann lar segments the first ge erally l ttle separated or act ally combined. More or less cylindric. N rrower i front tha in th rear are *Hypoderma* and *Gastrophilus* enlarged in front are *Dermatobia* and *Cephenomyia* The body is formed of well-separated annular segments, generally with lateral pad and warty formations. Ante nae short, of wart shape and have 1 or chitinous rings suggesting ocelli Posterio stigmata are important fo classification. In *Gastrophilus* they are placed in a cavity in the rear ring and have 3 curved, concentric slits. In *Dermatobia* they are enclosed in a cavity formed by the next to the last ring and re m ked sl ghtly differe tly

Oestrinae clude dermatologically interesting species as follow :

Gastrophilus haem rrhoidalis causes creeping eruption in Europe nd North America.
G intestinalis the larv of which li e in the stomach of the horse, may cause creeping eruption, especially in hostlers.
Rhinoestrus purpu es has caused oculomyiasis
Hypoderma bo is common throughout Europe and in parts of Africa, lays eggs especially on the hairs of cattle, without biting them The larv e produce tumors with small orifices, especially on young animals These larv frequently occasion creeping eruption in man
H lineata is common in North America, causing great economic loss by damaging hides t has been found in man in Europe
Oestrus ovis the sheep bot, or gad fly causes ophthalmomyiasis.

CUTEREBRINAE.—The interesting species is *Dermatobia hominis* a botfly which causes furuncular myiasis. The female lays eggs on insects, where they hatch; and the larvae leave their insect host for a warm blooded one where individually they pierce the hide and finish their evolution within the skin near the site of entry They frequently attack the ox, dog and man. The eggs are conveyed commonly by species of the mosquito, *Psorophora;* but other mosquitoes, bloodsucking muscoids several non-bloodsucking muscoids and the tick, *Amblyomma cajennense* may also serve In the skin the larva feeds, grows, and moults twice The mature third stage larva is from 18 to 24 mm. long and is flask shaped possessing well-developed oral hooks and dark brown anterior cuticle. The dark brown anterior spiracles each consist of rows of 6 small, dark brown processes located on the mesothorax. Near the anterior border of the second and third thoracic segments, and more conspicuously on the first 4 to 6 abdominal segments, are short, stout posteriorly-directed spines, or booklets which anchor the larva in the skin (Craig and Faust) Larval development requires about 50 to 75 days after which the larva works its way out of the skin falls on the ground and pupates in the soil.

Myiasis.—Larvae of brachyceran flies are able to parasitize man in various ways their parasitism is either necessitous or facultative Those of obligate parasitism provoke myiasis cutanea and some forms of myiasis of natural cavities larvae of facultative parasitism produce myiasis of sinuses, natural cavities and intestines.

CREEPING ERUPTIONS.—Three varieties of migratory animal infestations involve the skin: (1) those due to nematode parasitism (q v) (2) those due to acarine burrowers scabies and Tetranychus (q v) and (3) those due to larval flies, mainly oestrids of the genera *Hypoderma Gastrophilus* and *Dermatobia* Avoiding the ambiguity of creeping eruption, I prefer the names cutaneous helminthiasis for the nematode diseases, and cutaneous myiasis for dipteran infestations. See pp 581 583 584 617

CUTANEOUS MYIASIS is characterized by the development of dipterous larvae within the skin or subcutaneous tissues. The clinical aspects are varied

Cutaneous myiasis has received many names, some of which suggest particular parasitologic forms. Synonyms include dermamyiasis linearis migrans oestrosa and hypodermyiasis or ox-warble disease. Larbish or oerbiss, is a form of creeping eruption occurring in Senegal, probably due to the presence of dipterous larvae under the skin. Larva migrans is used usually in reference to creeping ancylostomiasis due to the dog hookworm (See p. 581)

CREEPING MYIASIS, first described by Lee (TransClinSocLond 8 44, 1874 18 74 1884) is a type of myiasis beginning with a small, painful, subcutaneous lesion which moves in a continuous fashion its course being marked by a red and ecchymotic line which disappears in a few days. The migration of the pain and of the red line is pathognomonic, the line is narrow somewhat elevated, tortuous, whitish or pinkish and threadlike and it marks the migrations of an immature larva within or just beneath the horny layer The tunnel made by the parasite is from 0 2 to 0 3 cm. in diameter and varies in length with the distance traveled by the animal. Ordinarily the larva moves at the rate of from 1 to 10 cm per day When the larva is ready to depart the tender spot remains stationary A little tumor develops there the summit perforates, and seropurulent liquid is discharged along with the larva itself.

The larvae of *Hypoderma bovis* (De Geer 1776) *H lineata* (de Villiers, and *H diana* (deer warble, Brauer 1858) are known to attack man. The larvae usually gain access by burrowing directly through the skin, to which, after diverse peregrinations, they return and give rise to subdermal and dermal lesions that lead to their discovery

The disease is common in the Shetland Isles and Norway and is caused in these regions by larvae of *Hypoderma bovis*. The same species has been found by Fülleborn in Africa and Brazil and it also occurs in France. A case due to *Gastrophilus intestinalis* was seen in Canada. In Russia and Siberia where this myiasis apparently is of frequent occurrence it is generally due to larvae of *Gastrophilus*. The empty eggs of *Gastrophilus haemorrhoidalis* have been found on the surface and hairs of the body

Young and Sudler (J 49: 1914, 1907) reported intranasal infection from the screw worm fly *Cochliomyia americana*. Singleton (J 61: 1782, 1913) reported a penile lesion due to *Dermatobia noxialis* the macaw worm, in a German laborer. Dyer (NOrMedJ 71: 105, 1918) described a case of fly-blown ulcers of an old man's leg from which King of the Bureau of Entomology identified the flies as *Lucilia caesar*, *L. pilatei* and *L. sericata*. In a case seen by Magath (AJS 2: 16 1930) *Dermatobia hominis* was the offender. Stewart (J 93: 709 1929) reported an extensive case due to *Phormia regina* (Meig) in which the scalp and ears were involved.

Gastrophilus larvae can be seen in their intraepidermal tunnels by applying a drop of oil to the skin through which the black transverse bands of spines on their segments are visible (Austmann J 87 1106 1926). They may then be removed by using a sharp needle. Injections of chloroform have been used with success.

SUBCUTANEOUS MYIASIS is characterized by ambulatory tumors the larvae eventually producing furuncular lesions from which they are discharged. Until that time they wander beneath the skin and give rise to fugacious, reddish, sometimes edematous tumors. The formation of these lesions is preceded locally by itching and shooting pains sometimes of considerable severity even causing the victim to cry out. Within several days the lesions disappear only to reappear at a more or less distant location. After persisting for 10 to 20 weeks, there occurs at the summit of the final tumor a reddish punctum which opens and permits one to see a pseudocore which is the whitish posterior extremity of the living larva. Cases of this sort are frequently seen by doctors and are also known to the rural people of Norway, Ireland, Brittany and Scotland. The larvae generally are of the species *Hypoderma bovis* or *Hypoderma lineatum*.

FURUNCULAR MYIASIS.—Brumpt limited this name to cases in which the cutaneous tumor is the primary and only manifestation occasioned by the larval parasites. This can be produced by larvae which have evolved at that location such as those of *Dermatobia* or by a larva which has migrated through the body without giving rise to other phenomena. In Europe this form of myiasis is generally caused by *Hypoderma diana* rarely by *Hypoderma bovis*. In America it is caused by *Hypoderma bovis* and exceptionally by larvae of *Dermatobia*. The latter do not migrate subcutaneously but they push into a hair follicle and form a purulent sac resembling a furuncle within which they evolve.

When the larva becomes adult it falls away spontaneously. The spot undergoes cicatrization, unless it is secondarily invaded by larvae of *Cochliomyia americanus* which may be numerous in the same region. The lesions are both sore and intensely pruritic. *Wohlfahrtia vigil* causes almost all cases of human myiasis affecting infants less than a year old, according to Vander sluis and Whittemore (MinnM 21 415 1938). The lesions were on the chest in their patient as is usually the case.

Cordylobia (cayor worms) may lodge in various parts of the body particularly the lower extremities. Without migrating the larva provokes a furuncular tumor of short duration which undergoes rapid evolution.

Gastrophilus larvae probably issue from eggs laid on the human skin or happening to be there, and they penetrate to the level of the depth of a hair follicle and continue their subcutaneous course provoking the red line characteristic of creeping eruption.

Hypoderma lineatum and *H. bovis* infestations result from ingestion of eggs or of young larvae which require some 6 months to reach the skin. Their presence is then revealed by the appearance of the tumor which has a minute opening through which the larva escapes. It is probable that man is capable of being infected by way of the digestive tract the hands, soiled with larvae or eggs by contact with animals conveying them to the mouth.

MYIASIS OF WOUNDS AND ULCERS.—The eggs of *Lucilia sericata*, *L. regina*, and *L. caesar* deposited in a wound will hatch in a few hours, and the larvae

will penetrate into the lesion and thrive there This may of course occur naturally as well as experimentally, either from accidental introduction of eggs or larvae into the wound or through the actual deposition of eggs or larvae by the flies. Purulent lesions, such as syphilitic sores and other stinking ulcers, attract them This form of myiasis is by far the most common in man and the animals, particularly in the tropics and among people who are careless with their injuries. In temperate regions, the fly is usually *Wohlfahrtia Sarcophaga* or *Calliphora* in hot regions, one finds *Cochliomyia Chrysomyia Sarcophaga Lucilia* and *Pycnosoma*

Fig. 357 —Furuncular myiasis due t *Dermatobia cyaniventris*. (Costa ADS 50 36, 1944.)

Surgical Myiasis.—As a therapeutic measure, larvae of certain flies have been put into ulcers, for they possess the ability to eat decadent and purulent parts of the wounds without attacking healthy tissues. Maggot therapy introduced by Baer (JB&JSurg 13 438 1931) has been used in America in many cases of osteomyelitis and other chronic affections. Technique must be meticulous, the flies being raised most carefully to avoid their infection with aerobic and anaerobic germs. Suitable larvae are placed in the wounds, and, when they have cleaned them satisfactorily they may be removed. Time expense and pain are disadvantages, while rapidity of débridement discovery of hidden sequestra and pockets of pus, stimulation of granulations, continuity of treatment and diminution of hospitalization and morbidity are the advantages, Maddock and Jensen (ASurg 37: 811 1938) decided after studying 99 cases of osteomyelitis treated with maggots.

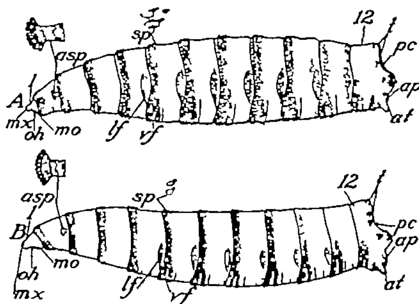

Fig. 862.—Lateral view of mature third instar larvae of (A) *Cochliomyia americana* and (B) *C. macellaria*. ×6. Abbreviations: ap, anal protuberance; asp, anterior spiracle; at, anal tubercle; lf, lateral fusiform area; mo, mouth; mx, maxillary lobe; oh, oral hook; pc, posterior cavity; sp, spiracles; t, tubercles; vf, ventral fusiform area; 1, first (or cephalic) segment; 12, twelfth segment. (Drs. F. W. Laake, H. C. Cushing and H. L. Parish, U. S. Dept. Agriculture Technical Bulletin 500, January 1936.)

Extracts of cultured larvae have been studied and seem to yield good results. It is believed that the active principle of the allantoin derived from the larvae is actually urea, and this clear crystalline substance may be used as the solute of wet applications. It is my opinion that any other bland isotonic nontoxic soluble crystal could be substituted with equal success when used for moist poultices.

MYIASIS OF SINUSES AND OTHER LOCATIONS.—Nasal myiasis is common. The oestrid affecting sheep is a viviparous insect which lays its larvae in the nasal fossae. When the young shepherds of Kabul are inattentive, the Oestridae lay eggs on their eyes, lips and even in their noses; and these provoke edema of the mouth and lips, erythema, conjunctivitis, and pain in the nasal fossae. The disease has been observed not only on the plateaus of Afghanistan but also in the central part of the Sahara where the flies abound from March to June and vastly discommode natives who inhabit regions at an elevation of 5,000 to 8,500 feet. Oestriasis as of sheep is frequent in man also in the Cape Verde archipelago, where it is seen in the nose pharynx and about the eyes.

Myiasis of wounds as well as of natural cavities may be caused by larvae of Diptera having facultative parasitism. The symptoms and severity vary with the localization or widespread distribution of the larvae.

Eggs of various flies may be laid in the nasal fossa. When the larvae develop, the patient first experiences severe discomfort and headache then pain which is practically intolerable. The bites of the larvae on the mucous membrane provoke sneezing and nosebleed. Inflammation affects the external parts of the nose within a few hours, and it swells. Larvae emigrate into the posterior nasopharyngeal cavity and the patient complains of pain in the throat. After devouring the mucous membrane of the nasal cavity the larvae continue their destructive work, invading the frontal sinus, and even necrotizing the palate, which may be perforated. Severe reflex difficulties ensue, with convulsions, vertigo, visual troubles, meningitic symptoms, sometimes aphonia and deafness. To appreciate the havoc, one needs only to see the volume and number of the larvae expelled, their mass representing a pint or quart of eaten substance. The disease has been observed in all countries. It is particularly common in the tropics

The auditory canal and middle ear may be involved. Otomyiasis in man is characterized by intolerable pain and the swelling of the ear suggests acute otitis. Larvae may perforate the tympanum or enter the mastoid cells, even getting into the venous sinuses and the meninges. Atrocious suffering is followed by death.

The eyes may be affected, but rarely as an isolated phenomenon. Larvae may enter the orbit by way of the sphenoid foramen and actually devour the bulb. Various larvae can cause acute and extremely painful conjunctivitis. Some Oestridae which ordinarily lay their eggs in the eyes of animals may deposit them in those of human beings.

The urinary passages and bladder may be involved, as the skin is, by wandering larvae which are eventually passed with the urine.

The affection produced by ingestion of larvae or by their development in the intestinal canal results generally from eating soiled food. Larvae in the stomach are likely to provoke nausea, dizziness, epigastric pain vomiting and diarrhea which rids one of the parasites; the cheese fly *Piophila casei*, is such a fly. When they reach the intestine they may produce symptoms as of severe helminthiasis, severe abdominal pain hemorrhage or typhoidlike accidents. When they remain for a long time which is rare, the symptoms simulate mucomembranous colitis (Bryant J 109: 578, 1937)

Treatment.—In myiasis of wounds, one flushes away the maggots and picks them out with forceps as well as may be. Stewart and Boyd (J 103 402 1934) found 15% chloroform in vegetable oil an efficient douche. Injections of chloroform and benzine are efficacious. *One may inject infusions of* basil or a weak phenol solution. In nasal myiasis, chloroform inhalations kill the larvae and enable them to be washed away with water (Dixon J 83 1332, 1924). Inhalation of the fresh plant *Ocimum basilicum* will promote the evacuation of larvae in nasal myiasis according to Mackie et al., quoted by Andrews (Diseases of the Skin, Saunders, 1954)

GNATS AND MOSQUITOES

NEMATOCERA.—These, the second division of Diptera, are insects which have long antennae of 6 to 15 segments. The body is slender and the wings long and narrow. The larvae generally live in water but some develop on land or in decomposing vegetation. The wing pattern is important in determining genera and even species. The families of parasitologic interest were classified by Brumpt as follows:

BIBIONIDAE	tibiae lack spurs		no discoidal wing cell	have ocelli
BLEPHAROCERIDAE	anterior tibiae spurred			
SIMULIIDAE	tibiae and metatarses large and flat		costal wing vein ends near the tip of the wing	lack ocelli
CHIRONOMIDAE	tibiae and metatarses slender subcylindric			
CECIDOMYIDAE		fewer than 6 final divisions of wing veins	costal wing vein goes across the wing	
PSYCHODIDAE	wings oval or lanceolate, hairy	more than 6 final divisions of wing veins		
CULICIDAE	wings rounded at summit, scaly			

BLEPHAROCERIDAE are little gnats which dance in the air particularly about water-wells. A few species of *Curupira* are bloodsuckers.

SIMULIIDAE are gnats of humpback appearance and generally dark hue. Their eyes are holoptic, joined in the midline, in males only. Antennae, cylindric and relatively short, are composed of 11 segments. The wing pattern is peculiar to the family. The buccal pieces are complete and powerful in the females. The mandibles and jaws are lanceolate. The epipharynx has hooks at its point for perforating the skin. Long and flexible maxillary palpes are formed of 4 segments. Salivary glands secrete substances variably toxic with different species. Development of larvae occurs only in well-aerated water. Eggs are laid on submerged aquatic plants. Hatching is comparable with that of mosquitoes, the larvae fixing themselves to plants or stones in the current of water by means of their posterior sucker. For certain species, it is known that the larvae moult 6 times. Their need for water and herbage is their vulnerable aspect from the point of view of control, best obtained by clearing and cleaning the streams.
